An image linked from an image server may be converted to a local image within the project either by using the Image - Unlink command or the Image - Download command. The Unlink command converts the existing linked image to a local image at whatever resolution is currently in use. The Download command may be used to automatically fetch all image files at any available resolution to create a local image at that resolution. Images linked from TerraServer may also be exported to image files. In that case, the exported image will be the same as that which would be obtained by unlinking the TerraServer image.

Note that exporting or unlinking an image linked from TerraServer will only use the data already downloaded from the server and will not attempt to download any more data. It will also only use the data for the most detailed image level. It is usually a good idea to use Image - Download to check how much data has already been downloaded for the most detailed image level prior to exporting or unlinking the image.

Another way to create a local image from a linked TerraServer image is to open the TerraServer image and then to use the keyboard F6 command or the Tools - Make Image command. The Make Image dialog allows us to create a local image in several different ways from the TerraServer image without unlinking the TerraServer
image. For example, we can use this command to create an image of the displayed window or of the entire linked TerraServer image at a desired number of pixels or scale.

If the connection is severed between a linked image in a project and the image server (such as, for example, if the project is moved to a different machine and a local URL must be changed to a global URL) the link to the image server may be re-established using the Image - Relink command.

To create a linked image from TerraServer:

1. Open a component window (such as a drawing or a map or other component) and pan it and zoom it so show the region you would like to have covered by TerraServer imagery.
2. Choose File - Link - Image
3. In the Link dialog’s Files of type box choose TerraServer ()
4. In the Link TerraServer Data dialog enter a URL to the TerraServer server in the Server box and press the Refresh button. The Server box will be pre-loaded with the URL of the default Microsoft TerraServer server, but it is possible that experts may wish to use different URLs.
5. If your connection to Internet goes through a proxy server, press the Proxy button and provide the required connection information for your proxy server.
6. Specify the maximum Scale of interest. Note that the Latitude and Longitude range boxes have been pre-loaded with latitudes and longitude values that precisely cover the extent of the view seen in whatever open component window has the focus. Press the Refresh button next to the Server box.
7. When the Refresh button is pressed, Manifold will communicate with the TerraServer server to find out what images are available for the region specified by the given latitudes and longitudes. This can take a very long time, possibly even a few minutes at a time, when TerraServer is busy. When the catalog of layers (the “Themes” in TerraServer jargon) has been fetched, all available images for the region of interest will be displayed as choices in the Themes box. For many parts of the US the choices are normally a DOQ, which is an overhead aerial image, or a DRG, which is an image created by scanning a paper USGS map. Some regions may have no images available. Choose a desired image in the Theme box.
8. Press OK. An image using a linked image icon will appear in the project pane using a name based on the theme, for example, “DOQ”. In a background process, Manifold will begin downloading the image into local cache so that it may be conveniently displayed.
9. Highlighting the image in the project pane will report it as a TerraServer image in the status bar together with the size of the image in pixels.

The new linked image can now be opened and used like other images except that until they are unlinked to create a local image, TerraServer images are read-only and cannot be re-projected. Until the image is completely fetched, when the image component is clicked open it will appear in an image window as a partially transparent gray rectangle covering the extents of the image. If the image is used as a layer in a map, it will appear in transparent color in those parts not yet fetched from TerraServer.

**Link TerraServer Data Dialog Controls**

- **Server** URL to be used to connect to the TerraServer server. The Server combo remembers recently used TerraServer servers, including those used in earlier sessions of Manifold.
  
  - **Refresh** - Update the Theme box with images available from the TerraServer server.

- **Theme** Images available for the specified region. Populated only after the Refresh button has been used to make contact with TerraServer.

- **Scale** Maximum resolution of the desired image expressed as the smallest discernable feature size. For example, 1 m images have pixels that are one meter in size.

- **Longitude** Longitudinal extent of the desired image. If a component window is open and has the focus these values will automatically be filled in to cover the view shown in the window.
Latitude

Latitudinal extent of the desired image. If a component window is open and has the focus these values will automatically be filled in to cover the view shown in the window.

Cache data between sessions

Controls whether the cache folder used to cache image tiles retains its content between different sessions of Manifold or not. By default, the option is turned on.

Proxy

Calls up the Tools - Options - Proxy server dialog that allows configuration of a proxy server connection, if a proxy server is used to connect to the Internet. Passwords supplied for proxy servers will be stored in encrypted form.

If no windows are open when the Link TerraServer Data dialog is opened, we will have to provide the latitude and longitude extents of the region for which we desire an image. If a window is open, then the latitude and longitude extents of that window will be automatically filled into the Latitude and Longitude boxes for the dialog. This is a great convenience but is subject to a few common-sense rules:

The open window must be a 2D graphical window, such as a drawing, theme, image, surface, labels component or map. The component must be correctly georegistered so that the window shows some real location on Earth. This is easy to verify: when moving the mouse cursor over the opened window the status bar will report the location of the mouse cursor. If the Tools - Options - Status Bar pane setting for Current location is selected and set to latitude / longitude the status bar will report the position of the mouse cursor in latitude and longitude coordinates.

If the latitude and longitude locations make sense (that is, if they are what we would expect them to be given the view shown in the window) then we know that the component in the window has, in fact, been correctly georegistered. If on the other hand the locations are obviously wrong (say, as if we are looking at an image showing an aerial photograph of Chicago and the locations are reported as some spot in the ocean off the coast of Africa) we know that the component is not correctly georegistered. This usually happens when a component from a non-geographically aware format has been incorrectly imported.

See the Projections and Imported Components topic for information about correctly importing components from formats that do not save georegistration information.

The Scale Parameter

The value of the scale parameter determines the size of pixels in the Manifold image that is created from TerraServer data served into the link. For example, a scale parameter of 1m will create an image where each pixel is one meter in size. Together with the bounding box of the image (that is the geographic extent of the image), the pixel size determines the dimensions of the image component in number of pixels vertically and horizontally. The dimensions and pixel size of the image are used when exporting the image and in other operations (such as Image - Download) done with the image.

The value of the scale parameter represents the maximum scale used by Manifold when downloading data from TerraServer. As we zoom in and out in the image, Manifold will switch display scales in order to download as little data as possible from TerraServer (fetching only enough data to fill the display window at the current zoom), except that it will never use a scale that is more detailed than the scale parameter specified when linking the image. Zooming in beyond that scale will result in pixels “expanding” into larger block shapes just as occurs when zooming far into an ordinary, local image.

Thus, the scale parameter allows us to limit the amount of data with which we work. This is an important consideration when working with TerraServer data, since requesting TerraServer coverage over a large geographic region can involve an immense amount of data at the highest resolution TerraServer can provide. By asking for a larger scale, we can still image a large geographic region at a convenient level of detail without waiting eons for the download of lots of fine detail that is not necessary.

Cache Data Option

The Cache data option is important because it keeps a copy of the linked image in local disk cache. If this option is on, the next time we open a project containing a linked image, Manifold will be able to use the copy of the image saved in the local disk cache and will not have to go through the process of downloading the image again.
The data cache will persist across sessions and projects so that once a tile is downloaded it will not have to be downloaded again.

The location of the cache folder is a TerraServer folder at whatever location is specified in the Data Cache item in Tools - Options - File Locations. The default value for the location is %MyDocuments%, so by default each user's files will be stored in the user's own cache folder.

When multiple users are working it might make sense to modify the default Data Cache setting for each user so the cache folder location is the same for all users and is on a shared resource available from all machines on the local network. For example, if there is a machine called Storage on our local network with a Cache folder on its C: drive, we might use a Data Cache setting of \Storage\Cache for all users. In that case, any tile files that are retrieved by one user will be available to all users so that tile files for a given view will never have to be fetched twice over the network. This assumes, of course, that the network is fast enough so that use of cache over the network will not be too slow.

It is also important when working with large TerraServer images that the location specified for the cache is on a disk drive with plenty of free space. Users sometimes will ask for download of TerraServer images without thinking about how large the resultant image may be and thus end up inadvertently requesting immensely large data sets.

The data cache folder may be moved to a different location so long as the path specified in the Data Cache option is adjusted to point to the new location.

Caution: Cache files persist forever and, in extreme cases, use up your free disk space unless they are manually deleted. See the recommended actions in the Managing Cache Files topic.

Notes

Not all imagery that can be fetched interactively from the TerraServer website is available for automatic download via the web service.

Even if we have a very fast Internet connection we must keep in mind that the connection to TerraServer may be much slower. Even though TerraServer uses very fast database technology, it is a free service that quite often is overloaded due to its great popularity. There may be times when images are very slow to load from TerraServer. To cancel a connection when using the Link TerraServer Data dialog, press the Escape key on the keyboard.

Using TerraServer Images in IMS Websites

When using TerraServer linked images within a Manifold Internet Map Server web page, keep in mind that linked images may take a long time to render as image tiles are fetched from the remote image server. For example, an IMS project that contains an image linked from TerraServer won't render that image on the website until the system fully downloads the entire required portion of the image from TerraServer.

The IMS page including the linked image can be no faster than the image server providing the image. If speed is of the essence, consider downloading the linked image into local storage, perhaps as a compressed image in ECW form.

The Manifold Image Server Interface (ISI)

Connection to TerraServer uses Image Server Interface (ISI) drivers built into Manifold to present TerraServer as a Manifold Image Server.

Manifold's Image Server Interface (ISI) is an open standard published by manifold.net to make it easy for third party developers to create drivers that connect image servers to Manifold System. Image servers that can work with Manifold System using an ISI driver are called Manifold Image Servers and can be automatically accessed as if they were a built-in part of Manifold System using the File - Link - Image dialog. See the Linked Images from Manifold Image Servers topic.

Selection in Images

Modifying Selections

See the introductory Selections topic for an introduction to selection in general and for a tutorial on basic selection methods that apply to all components.

This topic discusses a selection feature that is unique to images and surfaces. Certain selection functions make sense in images and surfaces but have no equivalent in other components. Such selection functions depend upon the component consisting of a continuous sea of pixels. In particular, when selecting pixels in images we often can refer to the selection as a region of particular shape. It is often highly desirable to be able to modify the shape of the region of selected pixels. We can do this with the Modify Selections commands or by Selection using Masks.

This topic uses images as examples. However, the techniques used apply to surfaces as well. Note that compressed images do not support selection.

Modify Selections

Selection modification commands are very useful when preparing images for use in vectorizing. In addition to general-purpose selection in images, they may be used to create "buffer zones" within images and other sorts of pseudo-analytical selections.

The Edit - Modify Selection menu provides four choices for modifying the shapes of regions of pixels that have been selected:

- **Border**: Take the current region of selection and convert it to region of selected pixels that are +/- the given width of pixels from the boundary of the current region.
- **Contract**: Shrink the region of selected pixels by the given number of pixels.
- **Expand**: Expand the region of selected pixels by the given number of pixels.
- **Smooth**: Create a smoother periphery of the selected region using the given parameters.

The Smooth function uses Threshold and Passes parameters. Each pixel on the edge of the selected region is evaluated by looking at its eight immediate neighbor pixels. If enough of the neighboring pixels are selected, then the central pixel will be selected. The threshold, a value from 1 to 4, states how many of the neighboring pixels must be selected before the central pixel is selected. The passes parameter states how many times this iterative process should be applied. The more it is applied, the smoother the periphery of the region of selected pixels will be.
Select touch was used in the image above to click on the sky. To eliminate the ragged edge of pixels at the periphery of the selection, we used Edit - Modify Selection - Smooth with the parameters shown below.

![Smooth dialog]

By increasing the number of passes we can make the periphery smoother as well as reduce the number of small "islands" of unselected pixels within the main body of the selection.

The selection modification commands are very useful when preparing images for use in vectorizing.

**Example: Using Modify Selection - Expand to create a Buffer Zone**

A "buffer zone" is simply a region that extends a certain distance beyond another region. For example, we might which to mark all pixels near the shoreline in an aerial photograph of waterfront development.

In this example we create a buffer zone of selected pixels that outline the upper part of the monument in our "bronze" sample image:

![Buffer Zone Image]

**Step 1: Select an upper region** - We do this by a combination of touch selection, Edit - Modify Selection - Smooth and then using select rectangle to subtract the lower region to leave a nice, smooth lower border. We use the Edit - Selections dialog to save this as a saved selection called "sky"
**Step 2: Select the inverse region** - Using Edit - Select Inverse to select the inverse region and then select rectangle with the mouse with Subtract from Selection mode to remove the bottom pixels. This leaves just the region in the upper part of the monument.

**Step 3: Expand the selected region** - Using Edit - Modify Selection - Expand we expand the region of selected pixels by 5 pixels.

This results in a region of selected pixels that extends outwards from the upper part of the monument.
Step 4: Use Intersect Selection Command from Selections Dialog - Within the View - Selections dialog we click on the sky saved selection. If the Preview button is checked, we will see a preview of the sky selection in blue. Note how it overlaps the expanded selection region created in the previous step.

Press the Intersect Selection command to intersect the sky selection with the expanded selected region. The selection now becomes the region of intersection, which is our desired buffer zone.

Using Modify Selection - Border

We can also create a buffer zone using Border selection modification. In this case, the "buffer zone" will extend both inward and outward from the edge of the previous selection region.

Suppose we start with a selection consisting of pixels in the upper part of the monument.
Using Edit - Modify Selections - Border with a setting of 5 pixels for the Width creates a zone of selected pixels extending both outward and inward from the previous periphery.

**Border Width**

The **Width** parameter is an approximate parameter in curved areas, since it is the number of pixel steps from the meandering line of pixels that is taken to be the center of the border region. The actual width of the border zone will be \([\text{width} \times 2 - 1]\) since the center line counts as one "width" amount.

Suppose we zoom into the image so we see the starting region of selected pixels at the head of the monument.
If we now run Border with a width of 1, a single line of pixels is selected at the periphery of the initial region. We can save this selection in the Selections dialog so that it may later be compared to other settings for width.

In the above illustration, instead of using a width of 1, we used a width of 3. We can see the previous setting of 1 in blue as a preview from the Selections dialog. Note how in vertical and horizontal areas where pixel stepping is clear we can see that the border region is five pixels wide because the "3" in the width parameter includes the center line pixel when counting out to either side. Thus, the border extends from the center pixel plus 2 pixels to either side.

**Touch Selection Tolerance Setting**

Touch selection will select all pixels whose color is within a given tolerance range of the pixel touched by the mouse. For RGB or RGBA images, tolerance is computed only on those channels that are made visible in the layers pane. For palette images, tolerance is computed based on the R, G and B values of the palette color as compared to other palette colors. Change the tolerance setting as desired in the Tool Properties pane to increase or restrict the range of pixel color values that are selected when using touch selection.
In the illustrations above we have increased tolerance from a low level to a much higher level and then clicked on the blue sky just above the head of the monument. As tolerance is increased a greater number of pixels are selected in colors that are more and more different from the blue hue of the touched pixel. At high tolerance settings pixels with colors very different from the touched pixel will be selected.

**Speed of Select Touch in Images**

By default, touch selection finds all pixels of similar color that are in a region connected to the touched pixel. Using `SHIFT`-touch selection finds all pixels of similar color whether or not they are in a contiguously connected region to the touched region. Determining whether or not pixels are within a contiguously connect region requires many spatial computations, so `SHIFT`-touch selection frequently will operate much faster than touch selection.
Selection using Masks

See the introductory Selections topic for an introduction to selection in general and for a tutorial on basic selection methods that apply to all components.

This topic discusses a selection feature that is unique to images and surfaces. Because images are made up of a continuous sea of pixels certain selection functions make sense in images but have no equivalent in drawings or tables. In particular, when selecting pixels in images we often can refer to the selection as a region of particular shape. It is often highly desirable to be able to modify the shape of the region of selected pixels. We can do this with the Modify Selections commands or through the use of Masks. Masks are used for purposes other than selection. See the Masks topic for other uses.

Masks

Masks are a way of using one image to make selections in another image. They are also a handy way of saving as many selections as we like for a particular image by saving the desired selection pattern to a file. A mask can be any grayscale image. There is nothing special about grayscale images used as masks. What makes a grayscale image a "mask" is simply how we use it.

We can create masks using any method used to create or edit grayscale images. Since masks are often used as a means of saving selections or other patterns from existing images Manifold provides an Edit - Save Mask/Channel command that makes it easy to create a mask using an existing image.

To Create a Selection Mask

1. Make a selection in the image.
2. Choose Edit - Save Mask/Channel.
3. In the Save Mask dialog, save the Selection to an image name.

This creates a new image that has white pixels in the region to be selected and black pixels elsewhere.

If we were to save the selection on the left as a mask the resultant mask image is shown on the right. Once saved, we can subsequently load the mask as a selection at any time we desire.
When we use \texttt{Edit - Load Mask/Channel} to make a selection in the image using a mask it is as if the mask were a cut-out in a sheet of cardboard through which we "spray" selection color onto the image, just like using a stencil.

\textbf{Masks are Images}

Masks are simply grayscale images like any other grayscale image. They may be opened, edited and otherwise changed as we desire. No selection will occur wherever there is a pure black (value 0) pixel. Pixels in any other color result in a selection being made at that spot. Masks used for selection are most often saved using just black and white colors so that the region to be selected is obvious.

We can create a new mask image at any time by simply inserting a new grayscale image into the project and then coloring it in black and white to show where the selection should occur. We can then use the "mask" image to make a selection. This allows us to specify regions that are to be selected using the full set of image editing tools within Manifold.

If we create the image at left above we can use it as a mask. Regions of white pixels will be selected. If we open the \texttt{bronze} sample image and use \texttt{Edit - Load Mask/Channel} to load the image as the Selection, we can select a region of pixels in the \texttt{bronze} image in the shape of the word "manifold."

We can create a selection mask by creating a grayscale image that has white pixels wherever we want a selection and black pixels where we do not want a selection. We can also create a selection mask by making a selection in an image and then using \texttt{Edit - Save Mask/Channel} to save it as a mask. We can combine the two methods, by first using \texttt{Edit - Save Mask/Channel} and then opening and editing the resultant mask.

\textbf{Matching Masks to Target Images}

Masks are usually the same size as the image on which they are to operate. If the mask is larger or smaller than the target image it will be used centered on the image and all pixels outside the mask will not be changed (that is, will not be selected).

Masks are often created to work with a particular image. For example, one might wish to create a selection mask that selected pixels only to one side of a riverbank in an aerial photograph. There are two frequently used methods to assure that the mask is the same size and otherwise matches positions in the target image:
• We can make a copy of the aerial photograph image and then edit that copy so that all the pixels not to be selected are black. We then convert the image copy to a grayscale image. If desired we can also use Threshold to force all non-black pixels into pure white.

• We can copy the aerial photo image and to position it as a partially transparent layer above the aerial photo image in a map. We can then “trace” the area desired using various editing tools to fill in the region not to be selected with black (or other convenient color) pixels. Using a map in this way makes it possible to create the selection mask by tracing over the target image as a guide where the guiding image will always be visible through the partially-transparent layer.

Invisible Pixels in Masks

Any invisible pixels in masks will not participate in whatever the mask is asked to do. If the mask is loaded as a selection, regions of invisible pixels will not be selected. If the mask is loaded as a channel, any parts of the mask containing invisible pixels will not alter the target image.

Additional Choices for Save Mask

When using **Edit - Save Mask/Channel** to save a mask, we have many choices in the dialog’s **Save** box in addition to saving the current selection as a mask. We can also save the mask using:

• The current selection.

• The region of invisible pixels.

• Any saved selection we have made for this image in the **Selections pane**.

• The R, G, or B channels in the image if it is an RGB image.

• The alpha channel in the image if it is an RGBA image.

See the Masks topic for a discussion on how the above options can be used to separate an image into different images for each channel.

Use with Surfaces

Masks can also be used with surfaces. Saving a mask from a surface results in an image that is georegistered to the surface and that retains any selection that was made in the surface. This is a handy way of saving complex selections as an alternative to using the **Selections pane**.

Editing Images

Editing Images

Editing images simply means changing the color/channel values of the pixels that make up the image and/or changing the size of the image. It's simple to say this, but there are numerous methods for doing so:

• Creating new images from drawings or other sources.

• Cutting, Copying and Pasting into the image.

• Drawing into the image “free hand” using image editing tools

• Using the Transform toolbar to change many pixels at once throughout the drawing.

• Using commands from the Image Menu such as resize to change the size or otherwise edit the image.

• Changing the image by projecting/georeferencing it.

• Altering images with scripts or other tools.

• Using Edit - Save/Load Mask/Channel to alter the image by channel (used to compose RGB images from multiple grayscale images).

• Edit the image using update queries that operate on the image's **virtual table** to directly change the colors of pixels or other characteristics. See the Virtual Tables for Images and Surfaces topic as well as the Queries and Images or Surfaces topic.

• Use commands
Not all editing effects will work with all types of images. Some effects will require RGB or RGBA images to function, since they require a continuous selection of many colors. Compressed images may not be edited.

**Resizing Images**

To resize an image by cutting away pixels or by adding pixels at the margin, use the Transform toolbar Crop, Crop Margin and Add Margin operators.

Changing the size of the image while retaining the visual appearance by inflating pixels or compressing them into fewer pixels requires resampling the image. Use the Image - Resize command to change the size of the image in such cases. This dialog allows a choice of methods to resample the image into a larger or smaller number of pixels.

**Cropping Images**

The Crop Margin on the transform toolbar for images crops the image down by the given number of pixels at the margin. The image is reduced in size and those pixels in the cropped margin are discarded.

The Crop command on the transform toolbar for images crops the image down to the minimum enclosing box for the selection. If there is no selection the Crop command has no effect.

The simplest way to crop images is to use **Select Box** to draw a rectangular selection box and to then launch crop. The image will be cropped to the size of the selection box. This is fast and works the same way that "crop" functions work in almost all graphics software.

In the image at left we’ve used **Select Box** to select the region enclosing Europe. We’ve used a **Border** selection style to show the selection. The image at right shows the result of the crop operation. The image has been reduced in size by the number of pixels cropped. It is shown on the checkerboard background within a larger image window.
Crop also works with irregularly shaped or discontinuous selections. Suppose we select pixels in South America as above.

Applying the crop operation using the Selection as the target will crop the image down to the size of the selection.

**Undo**

Image editing operations can be undone using Undo. The keyboard shortcut for Undo is **CTRL-Z**

**Zoom**

Images can be zoomed in and out. Use the View - Zoom to command to zoom to a specific level. The Native zoom choice in the Zoom To dialog will zoom the image so that one image pixel is exactly one screen pixel in size.
Selections and Editing

If a selection is made in an image any editing commands will be limited to the selected region only. This is a very important capability that is used to restrict the action of editing commands to desired parts of the image. It allows us to "paint" exactly up to a finite border without worrying that any paint will spill over into undesired portions of the image.

Suppose we use **Touch Select** to select all the pixels in our sample **bronze** image except those that make up the monument.

If we now switch the selection style to **Border** style so that the selection dots do not get in the way, we can draw a line using the **Insert Line** tool along the line indicated.

The line will be drawn only in those regions of selected pixels.
We can draw more lines in the image.

In all cases, only those pixels that are selected will respond to the drawing commands.

Here we will draw a circle using the Insert Circle tool.
Note that it paints over only those selected pixels.

All editing actions and not just drawing are limited to the selection. To create the above image we used Edit - Select Inverse to select just those pixels inside the monument and then we applied Threshold.

We can then follow up the Threshold command with a Gaussian Blur command, and then choose None for the selection style so that we can see the image without the red border defining the region of selected pixels. Note that the Gaussian Blur effect is sharp right up to the edge of the region of selected pixels.

See Also

Touch selection in images depends on the setting of Tolerance in the Tool Properties pane. A tolerance of 1 will select only those colors that are exactly the same as the color of the touched pixel. Increasing the tolerance value will allow colors that are less and less similar to the touched color to be considered the same.
Copy and Paste in Images
Copy and paste commands can transfer pixels between images. Pasted pixels will overwrite existing pixels in the same locations. When copying pixels from an image in one projection and pasting them into an image using a different projection, Manifold will automatically make any necessary coordinate system transformations.

Example

We select pixels from our bronze image and press CTRL-C to copy (or use Edit - Copy from the main menu).

We click on another image that is the same size as the bronze image and press CTRL-V to paste (or use Edit - Paste from the main menu).

The pasted pixels replace the original pixels. Because the destination image is the same size as the origin image the relative placement of the pixels is unchanged. The new pixels are selected.
We can deselect them to see the destination image as it now appears.

**Automatic Conversions**

When pasting from an image of one type (RGBa, RGB, palette or grayscale) to an image of another type, Manifold will automatically convert the pixels to the correct form for the destination image.

Suppose we have a palette image as seen above.

If we were to paste the same pixels copied in the previous example they would automatically be converted into the best match possible given the limited colors available in the palette image. Palette conversions when pasting will use default settings of the conversion algorithms.
If the pixels were pasted into a grayscale image they would be converted to grayscale. When pasted they would be selected.

Deselecting the pixels shows the grayscale conversion.

**Invisible Pixels are not Pasted**

Pasting invisible pixels has no effect upon pixels in the destination image.

Suppose we delete some pixels from the **bronze** sample image. Deleting pixels makes them invisible pixels.
We can then make a selection that includes both visible and invisible pixels. We can **Copy** the selection.

For this example we use a destination image in which pixels are colored in a black to white gradient created with the gradient tool.

When we **Paste** into this image the pixels will replace the original gradient pixels except in those spots where invisible pixels would be pasted.
Deselecting the pasted pixels shows that no changes were made to the original pixels in places occupied by invisible pixels.

**Pixel Locations**

Pixels will appear within the target image if their locations fall within the target image. When copying and pasting between two images of different size that are still in default, CAD-style coordinates, pixels will appear based on their X and Y distance from the lower left corner. To place pixels elsewhere, compose the images as layers in a map and then use **CTRL - grabber** to move the images as desired.

**Georegistration**

All pixels in Manifold images are georegistered to some point on Earth. If an image has not been imported from an image format that correctly captures projection location, it must be georegistered before it will make sense. Copying pixels from an incorrectly-georegistered image into a correctly-georegistered image will not move those pixels to the correct location. They will carry their already-defined (incorrect) location with them and thus will not appear within the destination image. See the Projections and Images topic.

**Copying Images and Pasting as Tables**

Images may be copied and pasted as tables. In that case, various attributes of the image will be available for pasting as **intrinsic fields** into the new table. See the Intrinsic Fields in Tables topic.
Masks

Masks are grayscale images that are used to control other images. Masks are used for two purposes:

- To make a selection in the shape shown by the mask.
- To alter the values in the R, G, B or Alpha channels of the target image using the values in the mask.

A mask can be any grayscale image. There is nothing special about grayscale images used as masks. What makes a grayscale image a "mask" is simply how we use it.

We can create masks using any method used to create or edit grayscale images. Since masks are often used as a means of saving selections or other patterns from existing images Manifold provides an Edit - Save Mask/Channel command that makes it easy to create a mask using an existing image.

Edit - Load Mask/Channel Options

Load Which part of the image is to be loaded. The selection, a channel, or invisible pixels.

From The source image to use for the mask. All grayscale images available will be listed together with their sizes.

Mode Specifies how to use the mask within the target image:
- Add - Add the intensity values of the mask pixels to the target.
- Invert - If the intensity of a mask pixel is greater than 128, invert the value of the target pixel.
- Maximum - Use the maximum of intensity of either the mask pixel or the target pixel.
- Minimum - Use the minimum of intensity of either the mask pixel or the target pixel.
- Replace - The default. Use the values of the mask pixels.
- Subtract - Subtract the intensity of the mask pixel from the target pixel.

Restrict to Selection If checked (the default), when a selection is present the mask will be applied only within the selected pixels.

Selection using Masks

Masks are a way of using one image to make selections in another image. They are also a handy way of saving as many selections as we like for a particular image by saving the desired selection pattern to a file.

To Create a Selection Mask

1. Make a selection in the image.
2. Choose Edit - Save Mask/Channel.
3. In the Save Mask dialog, save the Selection to an image name.

This creates a new image that has white pixels in the region to be selected and black pixels elsewhere.
If we were to save the selection on the left as a mask the resultant mask image is shown on the right. Once saved, we can subsequently load the mask as a selection at any time we desire.

When we use Edit - Load Mask/Channel to make a selection in the image using a mask it is as if the mask were a cut-out in a sheet of cardboard through which we "spray" selection color onto the image, just like using a stencil.

**Choices for Save Mask**

When using Edit - Save Mask/Channel to save a mask we have many choices in the dialog's Save box in addition to saving the current selection as a mask. We can also save the mask using:

- The current selection.
- The region of **invisible pixels**.
- Any saved selection we have made for this image in the Selections pane.
- The R, G, or B channels in the image if it is an RGB image.
- The alpha channel in the image if it is an RGBa image.

Masks created from any of the above can be used to subsequently control the selection; however, when saving the R, G, B or alpha channels the result is most normally used for as masks for channels or to separate the image into different grayscale images for each channel.

**Masks are Images**

Masks are simply grayscale images like any other grayscale image. They may be opened, edited and otherwise changed as we desire. When used as a selection mask, no selection will occur wherever there is a pure black (value 0) pixel. Pixels in any other color result in a selection being made at that spot. Masks that are used to make selections are usually "painted" in black and white colors even though the full range of grayscale colors may be used. This makes it easy to immediately see what is supposed to be selected and what is not.
Masks that are used to alter RGB or alpha channels are usually gray scale images of various kinds since a range of tones is sought for such purposes. The single value in each grayscale pixel in the range 0 to 255 is used for the value in the target channel.

We can create a new mask image at any time by simply inserting a new grayscale image into the project and then coloring it in black and white to show where the selection should occur. We can then use the “mask” image to make a selection or to control a channel. This allows us to specify regions that are to be selected using the full set of image editing tools within Manifold.

If we create the image at left above we can use it as a mask. Regions of white pixels will be selected. If we open the bronze sample image and use Edit - Load Mask/Channel to load the image as the Selection, we can select a region of pixels in the bronze image in the shape of the word “manifold.”

We can create a selection mask by creating a grayscale image that has white pixels wherever we want a selection and black pixels where we do not want a selection. We can also create a selection mask by making a selection in an image and then using Edit - Save Mask/Channel to save it as a mask. We can combine the two methods, by first using Edit - Save Mask/Channel and then opening and editing the resultant mask.

**Masks and Channels**

Before continuing with this topic, please read the Images and Channels topic and the RGBA Pixel Transparency topic if you have not yet done so.

In the example above, we used the Edit - Load Mask/Channel to load the Selection using a mask as a guide. We can also use the Load Mask command to load a channel using the contents of a mask as a guide. Using a mask we can load any of the following aspects of an image:

- The Selection.
- Make the pixels in a given region invisible pixels.
- The R, G, or B channels in the image if it is an RGB image.
- The alpha channel in the image if it is an RGBA image.
Suppose we saved the selection shown at the beginning of this topic as the above mask image, which we called mask1.

We can load it into the green channel for the bronze image with the Edit - Load Mask/Channel dialog by choosing Channel: green in the Load box.

This deletes all the previous values in the green channel of the bronze image and replaces it with the "all on" or "all off" values for green the mask specifies.

It is as though we spray-painted green color into the green channel using the mask as a stencil.
When combined with the unmodified red and blue channels in the **bronze** image the result is the above.

Again, it is as if we deleted all the green from the image and then sprayed pure green color into the image through the mask as a stencil. Note how the clouds are no longer white (because for the most part they no longer have any green color in them). Instead, the clouds are mostly magenta, which is the color that results from mixing bright red with bright blue.

Note that masks don't have to be used only with those images that were used to create them. We can load the sample mask above into the red channel of our sample castle image if we like.
We can use completely new masks that we create on our own with images. Here we have loaded the "manifold" mask shown earlier in this topic as the red channel in the sample bronze image. Note how the clouds now appear cyan, which is the color obtained with no red but very bright blue and bright green.

The illustrations above show simple, black and white masks. Grayscale images can also be used as masks to continuously vary the R, G, B or alpha channel in images.

**Using Masks to Specify Alpha Transparency**

Masks may be loaded into the alpha channel of images to control transparency.

Black regions in the mask mean zero transparency and white regions mean full transparency. Gray tones in between cause partial transparency.
Using the sample mask we created at the beginning of the topic results in the above pattern of transparency where the image is either fully transparent or not at all transparent.

If we take our sample mask, convert it to RGB, apply Gaussian Blur to blur it, and then convert it back to grayscale we can use it as a mask to create a transitional blend of transparency between fully transparent and fully opaque regions.

The image above shows what happens when we load the blurred mask into the alpha channel. Regions where the mask was completely black have no transparency and are fully opaque. Regions where the mask was completely white are completely opaque. The feathered edges in between where the mask has a blurred gradient of gray tones from black to white now have a blurred gradient of transparency from fully transparent to fully opaque.

One of the most frequent uses of Edit - Load Mask/Channel is to load a grayscale gradient to cause a continuously changing transparency gradient.
We can use the grayscale image of a gradient from black to white shown above as a mask for the alpha channel in our sample bronze image.

The result is a continuous variation of transparency from fully opaque (the white regions of the gradient) to full transparency (the black regions of the gradient).

**Using Masks to Specify Invisible Pixels**

We can use a mask to specify any regions of invisible pixels.
Suppose we would like the yellow star shown above to shine through our sample bronze image. To do this we will cut out a region of invisible pixels in the bronze image in the shape of the star.

We begin by creating a mask from the star image. To do this we first used Threshold to make the star entirely black and everything else white and then we used Invert to get the above image. This was converted into a grayscale image using Convert to.

We open the bronze image and then use Edit - Load Mask/Channel to load the invisible pixels using the star mask image created above.

The result is a bronze image with opaque pixels in black areas of the mask and invisible pixels in the white regions. The cutout region of invisible pixels is perfectly aligned with the edges of the yellow star because the yellow star was itself used to create the mask.
When we combine the two images in a map with the star image underneath the bronze image the yellow star shines through the bronze image.

**Applying Masks only to Selected Pixels**

If we check the **Restrict to Selection** box in the **Load Mask / Channel** dialog the mask will be applied only to selected pixels if a selection exists.

Let's use the image above as a sample image. We created this image using Image Editing Tools employing a variety of brushes, color and opacity settings. A region in the lower left corner has been selected.

The image above shows a simple mask created using a solid black image to which the Noise effect has been applied. This created an image with speckles of white on a black background.
If we load the Blue channel in the image with the mask using **Replace** mode (the default), the mask will be loaded only into those pixels that are selected if the **Restrict to Selection** box is checked.

This works no matter what pixels are selected. In the illustration above we have selected five circular regions of pixels.

If we load the Green channel with the mask with **Restrict to Selection** checked the mask will be applied only within the selected regions.

**Mode Choices**

The **Mode** option in the **Load Mask/Channel** dialog allows us to choose how we would like the mask to be used in the target image.

The default mode is **Replace**. Loading a mask with **Replace** mode means the values in the mask will replace the values for the channel loaded. Note for example in the illustration above how the yellow color in the central
circular region has turned red. That happened because the color yellow is a combination of red and green. When loading a mask into the Green channel that has white dots on a black background there is no green value in the black portions of the mask. Where the black portions of the mask replaced green channel pixels no green color is left and so only the red channel is left in what were originally yellow pixels.

Suppose we make a different selection in the original sample image.

If we load the mask into the Green channel using **Add** mode, note that the yellow pixels are unaffected where the mask is black. That is because black results in adding zero to the green channel intensity. Where the mask has white dots, the yellow is a brighter green-yellow because adding 255 to the green channel forces it to be full green. In the blue pixels of the target image the result is to create bright cyan (blue plus max green) in the spots where the mask has white pixels.

If we use **Subtract** mode, the values in the mask will be subtracted from the Green channel. There is no change in black parts of the mask since subtracting zero results in no change. In the yellow pixels of the target image, subtracting 255 in those spots where the mask is white results in total absence of Green and thus results in red pixels. Subtracting 255 from the Green channel in pure blue parts of the image has no effect since there is no Green there to begin with. Subtracting 255 from the green parts of the image results in black pixels.
A GIS Example Using Mode

The Mode option to combine a mask by adding it, subtracting it or otherwise combining it in a sophisticated way with an existing channel provides a powerful means to combine multi-spectral images into powerful and highly informative false color images. This example is copied from the Combining Channels into Images topic.

Using a straight, unprocessed combination of the Red, Green and Blue bands from the Landsat 7 Enhanced Thematic Mapper instrument (bands 3, 2 and 1) as the Red, Green and Blue channels in an image results in the muddy and uninformative image above.

We can enhance the image by using a Band 4 image as a mask and using Add mode to add its intensity values to the Green channel of the image. Band 4 is a reflective infrared band that is highly responsive to vegetation. By using it to "kick" the Green channel up we enhance the green element normally associated with vegetation.

We can further enhance the image by using a Band 7 image as a mask and Add mode to add it to the Red channel of the image. Band 7 is a lower mid-infrared band that is responsive to soil types. This lets us see not only vegetation but also soils.

See the Combining Channels into Images topic for additional examples of Landsat 7 image processing.

Matching Masks to Target Images

Masks are usually the same size as the image with which they are used. If the mask is larger or smaller than the target image it will be applied centered on the image and all pixels outside the mask will not be changed.

Masks are often created to work with a particular image. For example, one might wish to create a selection mask that selected pixels only to one side of a riverbank in an aerial photograph. There are three frequently used methods to assure that the mask is the same size and otherwise matches positions in the target image:
• We can make a copy of the aerial photograph image and then edit that copy so that all the pixels not to be selected are black. We then convert the image copy to a grayscale image. If desired we can also use Threshold to force all non-black pixels into pure white.

• We can copy the aerial photo image and to position it as a partially transparent layer above the aerial photo image in a map. We can then "trace" the area desired using various editing tools to fill in the region not to be selected with black pixels. Using a map in this way makes it possible to create the selection mask by tracing over the target image as a guide where the guiding image will always be visible through the partially-transparent layer.

• Use the Match command within a map to automatically "cookie-cut" one image with another and to adjust the pixel density and coordinate systems to match.

**Invisible Pixels in Masks**

Any invisible pixels in masks will not participate in whatever the mask is asked to do. If the mask is loaded as a selection, regions of invisible pixels will not be selected. If the mask is loaded as a channel, any parts of the mask containing invisible pixels will not alter the target image.

For example, when using the mask at left above to select pixels in the image at right above the region of invisible pixels will not result in a selection.

**Saving Channels as Separate Images**

At any time we can save the separate channels of an RGB or RGBA image as different grayscale images. To do so, we use the Edit - Save Mask/Channel command with the channel to be saved specified in the dialog's Save box.

See the Separating Images by Channels for a discussion on how Edit - Save Mask/Channel can be used to separate an image into different images for each channel.

**Nomenclature**

Transparency and opacity are two terms that mean the same concept viewed from different directions. When something is completely opaque it is not at all transparent. When something is perfectly transparent it may be said to have zero percent opacity.

Which word is used depends on the discussion. When imagining layers stacked up above each other like transparent sheets it is conceptually clearer to use the word transparency. When discussing a specific percentage of light transmission to be applied via a slider bar in a dialog most applications use the word opacity.

The convention in the graphics arts editing software industry is to adjust layer transparency with controls that set a number from 0% to 100% opacity, so that an image with 100% will be fully opaque and not allow any view of an image underneath it. Manifold follows this convention. This convention persists in the graphics arts industry even though the technical implementation of transparency effects is done using an alpha channel within RGBA images where the higher the value of the alpha channel (from 0 to 255) the higher the transparency.
One therefore encounters the slight conceptual dissonance of increasing opacity with higher numbers (up to 100%) in dialogs and other user interfaces while the internal data sets use numbers (alpha channel values) in which opacity decreases with higher numbers. Since we rarely set alpha values by hand this is not so bad. Alpha values are normally set using various tools, such as erasers, or masks. In the case of masks, the darker the mask region the lower the alpha value is and thus the higher the opacity. From a casual conceptual view this is very acceptable because it leads to an effect where black regions of masks cause full opacity and white regions of masks cause full transparency. Since we are used to thinking of "white space" as being transparent this works well as a natural mnemonic for the effects of masks.

Match
Painting within Channels

Editing effects within Manifold are applied only to those channels that are checked ON in the View - Panes - Layers pane. Painting commands will also be applied only to those channels that are checked ON. If you have not done so, please read the Images and Channels topic and the RGBA Pixel Transparency topic before proceeding.

Let's begin by filling an image with black color so items we draw will be clearly visible. If we draw a triangle using white color it will appear white with all three R, G, B channels ON. White paint is a color that has maximum values in Red, Green and Blue.

If we check OFF the Red and Blue channels and check ON the Green channel the triangle appears green because we only see the green values of the pixels.

Checking the Red channel ON and the other channels OFF shows only the red color values in the white triangle.
If we continue to use white as the color of our painting tool and add three dots with only the Red channel ON, they will appear in red color.

If we switch ON all three RGB channels we see the white triangle appears in white again but the dots drawn using white paint color are still red. Because the other two channels were OFF when the dots were drawn their pixels were created using only the Red channel values.

We can now click the Red channel OFF and the Blue and Green channels ON. The triangle appears cyan in color because cyan is the color obtained from an even mix of Blue and Green with no Red. Note that the three small dots are not visible because their pixels have no color values in the Blue or Green channels. If we draw a large dot using white paint it will be created in cyan color because the blue and green values from the white paint color will be written into the pixels using the active Blue and Green channels.
We now click OFF the Green channel so that only the Blue channel is ON and then we create a very large dot using white paint color. It appears blue because only the blue values from the white paint are written into the active Blue channel. The triangle appears blue and the other dot appears blue as well. We see only the blue part of the (blue + green) cyan color for the cyan dot. We do not see the three small dots because they do not have any blue values in their pixels.

If we click ON all three channels we can see the image as it has been created. All pixels were painted using white color. Only the white triangle was painted with all three channels ON so only it is white. The red dots were painted when only the Red channel was ON so they only have red color values. The large blue dot was painted when only the Blue channel was ON so the pixels in the large blue dot only have blue values. The pixels in the cyan dot were painted when both the Blue and the Green channels were ON so they have both blue and green values.

**Painting into the Alpha Channel**

When painting into an image's R, G and B channels the color values for each channel come from the separate R, G and B values of the paint color being used. When painting into the Alpha channel the value for each pixel comes from the **intensity** of the paint. Although any color paint may be used it is usually easiest to reckon the intensity by using different shades of gray. Because true gray colors have equal mixes of R, G and B color values the intensity of any shade of gray is simply the overall appearance of lightness or darkness of the gray color.

Let's take a moment to convert our RGB image into an RGBA image using the Image - Convert To command. We will now see an Alpha channel in the Layers pane in addition to the Red, Green and Blue channels. If we click the Alpha channel ON and all the other channels OFF we can paint into the Alpha channel without altering the other
channels. We can paint a series of dots into the Alpha channel using a lighter shade of gray color for each dot. The result is a series of dots that have increasing amounts of transparency (the lighter the gray color, the greater its intensity and thus the greater the transparency).

If we click ON all four channels we can see how the differing transparency levels affect the image. In particular, we can take a close look at the blue dot, the cyan dot and the uppermost red dot to see how parts of the dots are now semi-transparent as set by the alpha transparency.

If we layer the above image in a map above our sample bronze image we can see how the transparency applied by painting different shades of gray dots into the Alpha channel now allows more or less of the bronze image to be seen through the upper image. Note how the blue, cyan and uppermost red dots are partially transparent in regions where the gray dots were painted into the Alpha channel.

Separating Images by Channels

We can separate RGB images into three grayscale images that contain the color values for each R, G, and B channel by saving each channel as a mask. We can separate RGBa images into four grayscale images for each R, G, B, and alpha channel. To do so, we use the Edit - Save Mask/Channel dialog. See the Masks topic for detailed discussion on masks.

Separating an RGB Image into Separate, Per-Channel Grayscale Images

1. Open the RGB image to be separated.
2. Use Edit - Save Mask/Channel to save the red channel into a grayscale image.
3. Use Edit - Save Mask/Channel to save the green channel into a grayscale image.
4. Use Edit - Save Mask/Channel to save the blue channel into a grayscale image.

Example

We can use the Layers pane to see the separate R, G, and B channels in an image. We can save each of these channels using Edit - Save Mask/Channel to save the channel as a grayscale image.

The image on the left shows the red channel. The image on the right shows the grayscale image created as a mask from the red channel. Note that the sky is dark in the grayscale image because pixels in the blue sky have low values in their red channel.
We can create the image on the right from the red channel of the bronze image by choosing Channel: red in the Save: box of the Edit - Save Mask/Channel dialog.

Likewise, we can create a grayscale image for the green channel. Note that the bronze monument has bright tones in it because of the green color of the bronze monument.

Finally, we can create a grayscale image for the blue channel. Note how the sky is the lightest in this grayscale image because of the large amount of blue in it.

We can apply editing effects to the separate images and then recombine them back into an RGB image using the Edit - Load Mask/Channel dialog. See the Combining Channels into Images topic for an example.

Note that we do not need to split up an RGB image into separate grayscale images just to apply effects on a per-channel basis. Editing commands apply only to those channels that are visible. If we wish to apply commands to only one channel at a time we can uncheck the other two channels in the Layers pane and they will remain unaffected.
Combining Channels into Images

We can create RGB images by loading three different grayscale images into the R, G and B channels of the new RGB image using Edit - Load Mask/Channel. The most frequent application is creating a false color RGB image from multi-channel satellite sensor data. See also the Masks topic for more information on using images as masks.

Combining Per-Channel Grayscale Images into One RGB Image

1. Create an image of the desired size. This can be done by simply copying one of the channel images and renaming it.
2. Use Edit - Load Mask/Channel to load the red channel with the desired grayscale image.
3. Use Edit - Load Mask/Channel to load the green channel with the desired grayscale image.
4. Use Edit - Load Mask/Channel to load the blue channel with the desired grayscale image.

Example

The classic example of such work is creating false color RGB images using infrared bands from the Landsat satellite's thematic mapper sensor.

Using its Enhanced Thematic Mapper instrument the Landsat 7 satellite delivers images in seven standard Landsat bands plus a higher resolution panchromatic band from green color to near infrared. All the standard seven bands provide 30 meter resolution except the thermal infrared band, which delivers 150 meter resolution. The panchromatic band achieves 15 meter resolution.

</tbody>
</table>

We will take a sample Landsat 7 image from bands 4, 5 and 7, the most useful infrared bands.
Band 4 we will use as the green channel since it is most sensitive to the mass of vegetation at a particular location.

Band 5 we will use as the red channel since it is brighter and has better contrast than the band 7 image. This should provide a good distinction from the green channel.

Band 7 we will use as our blue channel. Since this is the darkest image, the resulting composite image should be mostly greens, reds and some yellows.

The resulting RGB image is a typical "false color" rendition of colors invisible to human eyes (from the infrared part of the spectrum in this case) translated into visible colors. We created this image by loading the above bands into the R, G and B channels using Edit - Load Mask/Channel. The image brings out areas of large plant biomass and also shows regions with contrasting water content of plants.
If desired, we can alter the various grayscale images before combining them into the false color image. This image takes band 7 and inverts it using an inversion center that's below the default so that the image does not become too bright.

If we load this new, inverted band 7 grayscale image into the blue channel we get an entirely different look to the image.

**Using the Mode Option**

The *Mode* option to combine a mask by adding it, subtracting it or otherwise combining it in a sophisticated way with an existing channel provides a powerful means to combine multi-spectral images into powerful and highly informative false color images.

Using a straight, unprocessed combination of the Red, Green and Blue bands from the Landsat 7 Enhanced Thematic Mapper instrument (bands 3, 2 and 1) as the Red, Green and Blue channels in an image results in the muddy and uninformative image above.
We can enhance the image by using a Band 4 image as a mask and using Add mode to add its intensity values to the Green channel of the image. Band 4 is a reflective infrared band that is highly responsive to vegetation. By using it to "kick" the Green channel up we enhance the green element normally associated with vegetation.

We can further enhance the image by using a Band 7 image as a mask and Add mode to add it to the Red channel of the image. Band 7 is a lower mid-infrared band that is responsive to soil types. This lets us see not only vegetation but also soils.

See the Import Landsat Files and Create Composite RGB Image example for a detailed example using Landsat bands. The example shows how to import typical Landsat data, how to create a composite RGB image and how to use image enhancement techniques to improve image readability. Finally, the example shows how to combine the 15 meter resolution panchromatic band with an RGB image created from 30 meter bands to improve overall resolution.
Composing Complex Images in Layers
Using layers in a map we can create complex images by building up images within layers.

This image is composed of eight layers, beginning with our sample bronze image.

We used the bronze image to make selections of the sky, clouds, the monument and the pedestal and to save them in the Selections pane. The illustration above shows the clouds selection, which was built up using Touch - Select and Add to Selection mode. These selections were saved as masks for future use. The selections were used to copy pixels out of the initial bronze image and to paste them as new images.

The first layer on top of the base image is an image created by taking an image with just the white clouds, colorizing them and then applying a Gaussian Blur to make a halo. This layer was moved up a few pixels relative to the rest of the image.
The clouds image by itself is transparent except for the clouds.

When it is placed in a layer over top of the halo, the clouds cover the halo except where it extends above them and in the gaps between clouds where the legs of the monument are located. These gaps will be covered by layers above.

The next layer is the drop shadow for the monument, which has been moved a few pixels to the right and down.
This provides a credible shadow effect when the monument itself is added in a layer above.

We now will add images in layers above for drop shadows for the text as well as the pixels for the text.

Like all the drop shadows, this shadow was created from the text image using Gaussian Blur.
The "Manifold" text line was created by making a screen shot of the Manifold text and pasting it into an image. We could then use **SHIFT - Select Touch** to select all the red pixels that made up the letters, choose **Edit - Select Inverse** to select all the pixels except the red letters and then choose **Edit - Delete** to make everything except the text invisible pixels.

One nuance of how we created the image is that the drop shadow for the monument covers the upper part of the pedestal, as can be seen in the illustration at left above. To remedy this, we selected the pedestal pixels, copied them and then pasted them as a new image layer at the top of the layer stack. As seen in the illustration at right above, this covers up the drop shadow that we do not want in front of the pedestal.

Images composed of many layers using a map are very easy to change. We created the above image by moving the Manifold text and drop shadow image layers below the monument and monument drop shadow layers in the map's layer stack. We then moved both the Manifold text image and the text drop shadow image up relative to the other images.

**Combining Tiled Images into One Image**

At times we may wish to mosaic or tile several different images into a single image. Perhaps, for example, we have several aerial photographs of a region that together could form a single image. There are two cases to consider. The first case is where we have georegistered images that can be seen in their correct geographic position within a map. The second case is non-georegistered images that when seen together as layers in a map will appear all on top of each other.

**Combining images into a single image (georegistered images)**
1. Assemble all the images in a map, each in its separate layer.
2. Make any adjustments in contrast, brightness or other visual characteristics to provide an even visual appearance between adjacent images.
3. Create a single image from the tiled map stack by using the Tools - Make Image command.

**Combining images into a single image (non-georegistered images)**

1. Assemble all the images in a map, each in its separate layer.
2. The images (see Repositioning Layers ) to their desired locations.
3. Make any adjustments in contrast, brightness or other visual characteristics to provide an even visual appearance between adjacent images.
4. Create a single image from the tiled map stack by using the Tools - Make Image command.

Manifold is different than programs like PhotoShop, where one has a Merge Layers command. The reason is that all images in Photoshop are the same pixel size so one can merge layers by simply overlapping pixels.

In Manifold, images can have all sorts of different pixel sizes. a 400 x 600 pixel image could be georegistered to cover the entire Earth or it could be a 1200 DPI image. For that matter, an 800 x 1000 pixel image could cover the same surface area as the 400 x 600 image. We could see these two images tiled next to each other in a map even though the one image has "smaller" pixels than the other one. To merge them into one image, we have to say what pixel size we want that final image to have. This is stated by implication when we specify the size of the combined image in the Save Image to dialog.

**Tech Tip**

Sometimes mosaic images overlap each other but do not match well at their edges due to photographic distortion or other effects. In such cases we can achieve a better visual blending of the images if we convert the "upper" image to an RGBA image and then use pixel transparency effects to "feather" the edge of the image from full opacity to full transparency. This can provide a blending effect that gives a better visual match to the adjacent image than a hard edge. See the RGBA Pixel Transparency and Create a Circular Feathered Image topics for relevant techniques.
Editing Palettes
Palettes may be edited interactively to edit images by altering the colors that are in the palette.

Double click on a palette component to open it in a palette window. Make any changes by selecting one or more color wells in the palette and then changing the color. Wells may be selected by clicking onto a color well for an individual color to select it, or by selecting more than one color well any standard Manifold selection method. Any changes made to a palette will immediately be applied to images that use that palette.

As is the case with other component windows in Manifold, when no mouse command mode is in force the mouse operates in "smart mode": clicking on a color well will select it. Double-clicking into a selected color well will change the color.

Example

Let's begin with our sample bronze image converted to a palette image with a limited number of colors.

We can open the palette in a palette window and click on one of the colors in the last row of color wells to select it. The palette color selected is the lightest color, which is used in the palette image for most of the pixels in the clouds behind the monument.

Double clicking into this color well allows us to change the color if desired, say, to bright green.

The result will immediately appear in the image. Note that all pixels using this palette color have changed to bright green.
We can change another color in the palette to bright yellow.

All pixels in the image using that color will be instantly displayed in bright yellow.

Image Editing Tools

Image Editing Tools

Image editing in Manifold uses several controls at once to achieve exactly the desired effect. To edit images we can choose:

- Image menu commands. These commands perform global changes on the image or the selected area, such as changing hue or contrast. See the Image Menu topic.
- Transform toolbar commands. These are simple commands or one-line versions of Image menu commands that change the entire image or just the selected area. See the Transform Toolbar - Images topic.
- Editing tools. These are found on the Tools toolbar for image and provide a variety of free hand and assisted editing capabilities.

Editing Tools

When we paint into an image, we choose a tool and then set any options for that tool.

- Tools are selected from editing toolbars.
- The specific action of tools is set in the Format Toolbar or in the Tool Properties pane.

The Tools Properties pane should be kept open when editing images so that parameters can be changed as desired.

To Edit an Image:

1. Choose a tool.
2. Adjust tool properties (such as color to be used) in the Tool Properties pane.
3. Use the tool in the image.

Tools Toolbar for Images
The Tools toolbar for images hosts the image editing tools. Image editing tools are for the most part analogous to drawing editing tools. There are a few modifications specific to the pixel nature of images.

- **Paint Areas** - A mode button: the selected tool will create filled regions of pixels.
- **Paint Lines** - A mode button: the selected tool will create lines.
- **Paint Points** - A mode button: the selected tool will create points where the mouse cursor changes direction on clicks.
- **Paint Area** - Paint pixels within the region clicked. Creates lines or points if shape modes so specify.
- **Paint Freeform** - Paint pixels within region about which the mouse is clicked and dragged.
- **Paint Line** - Paint a line defined by straight-line segments between clicks.
- **Paint Box** - Paint a rectangular box using a mouse click and a drag.
- **Paint Box on Center** - Paint a rectangular box centered on initial mouse click.
- **Paint Circle** - Paint a circle using a mouse click and a drag.
- **Paint Circle on Center** - Paint a circle centered on initial mouse click.
- **Paint Ellipse** - Paint an ellipse using a mouse click and a drag.
- **Paint Ellipse on Center** - Paint an ellipse centered on initial mouse click.
- **Brush** - Paint a dot with one click or a continuous line with a click and a drag. Paints unsmoothed freeforms even if smoothing is turned on. Very useful for single pixel editing (click on a pixel to color it) at high zooms.
- **Paint Bucket** - Click to fill a contiguous region of similarly colored pixels with foreground color. Fills to a given tolerance value of color. SHIFT click to pour into the given color in all regions of the image within the given tolerance, even if not contiguous. Use this as a "replace color" operation.
- **CTRL** click to replace colors within the threshold while retaining the same intensity.
- **ALT** click to paint color without regard to threshold. Used to fill the entire selection or the entire image (enabled if a snap mode is not set).
- **CTRL** and **SHIFT** or **CTRL** and **ALT** may be combined.
- **Gradient** - Click, drag and release to create a color gradient from foreground color to background color between the click point and ending at the release point.
- **Pick Color** - Click to pick the color at that location as the foreground color. Shift click to pick the color at that location as the background color.

**Regular and On-Center Commands**
Like selection tools, painting tools occur in both on-center and regular versions. We can see the difference between the regular tool and the on-center tool by painting a circle.

Using Paint Circle to click near the center of the monument above and then dragging to the spot shown will open a preview circle as shown. Releasing the mouse button paints within the indicated preview circle. With regular commands, the mouse shows the desired diameter of the circle. The Paint Circle command appears by default on the Tools toolbar for images.

We can use Paint Circle on Center to click at the same beginning location and then drag to the same ending location. Note that the preview circle is larger than the previous circle. With on-center versions of commands the initial click is the center of the circle and the mouse motion shows the desired radius of the circle. Use this command to draw circles centered on a given spot.

Frequently used controls

- **Tools**: Pick one of the editing tools from the tools toolbar. The choice of tool sets overall behavior, such as whether each click results in a point or whether we create a rectangle by dragging open a mouse box.

- **Brushes**: Manifold has many brush styles that may be selected in the format toolbar. Combinations of different brushes with different tools will result in different painting effects.

- **Color**: Most tools use only foreground color, as set in the format toolbar.

- **Size**: The Size parameter in the format toolbar specifies the size of points and the width of lines in pixels. It is applied to enlarge or decrease the size of brush used. Some brushes require a
Images

A technical parameter that defines the relative height of the density curve used for tools that paint pixels using a curve to define the amount of paint applied. Similar in visual effect to the "hardness" tool parameter in PhotoShop.

Tolerance Used with selection, paint bucket fills, etc. Specifies how close a color must be to the color specified before it is considered the same color. Increasing the tolerance value will allow colors that are less and less similar to the touched color to be considered the same.

Brushes

Brushes specify different patterns in which paint is applied. They have a distinct visual effect when painting points or lines. Areas are always filled with solid color when painting filled regions such as a rectangular box.

Varying tools, colors brushes and size can result in dramatically different visual appearance. The above illustration shows different brushes in different sizes applied with different colors. Reduced to 256 colors to fit into this Help documentation it is but a pale rendering of the original, vivid True Color image. Create your own to see what we mean.
When painting lines brushes will have the same effect as if they were dragged in the direction the line is painted. The illustration shows lines drawn using a fuzzy round brush in different colors and sizes.

**Size**

Changing the size parameter changes the size of points and the thickness of lines. It has no effect when creating filled regions of pixels using area commands.

The illustration above shows a brush used to make points with several different size settings, a box command using two different size settings for the line, and a single pixel sized curly line drawn freehand.

**Paint Mode**

Just like drawings, editing tools in images can automatically create their desired effects as combinations of points, lines or areas. In images, of course, these are not objects but just point-shaped, line-shaped or area-shaped regions of pixels. The main use of paint modes is to specify whether shapes such as boxes, circles or ellipses are created using outlines or as filled regions.

Graphics editors will often have separate commands for creating an outlined rectangle or a filled rectangle. Other graphics editors always create an outlined rectangle and expect that the user will use a paint bucket command to fill the rectangle if a filled rectangle is desired.

Manifold specifies how a rectangle should be created by whether the **Paint Lines** or **Paint Areas** button is pushed in. Pushing in the **Paint Areas** button creates a filled region of pixels with sharp edges like the box on the right in the illustration above. Pushing in the **Paint Lines** button only will create the region as an outline using whatever brush is specified in **Tool Properties** to create the line. A box created using a square brush illustrated at left in the illustration above.
Pushing in both the **Paint Areas** and the **Paint Lines** button will result in a filled region that is outlined by a line using the given brush style. The illustration above shows various combinations of the **Paint Areas**, **Paint Lines** and **Paint Points** shape modes using a fuzzy round brush set to a size of 20 pixels.

Tools will paint using whatever brush has been selected. The box at left in the illustration above was painted using a round brush for the line. The box at right was painted using a square brush for the line. Note that the square brush results in sharp corners when a **Size** greater than one is used and a round brush results in round corners.

Note that using a **size** larger than 1 pixel together with the **Line** button will result in a region that is larger that the centerline indicated by the mouse since lines are drawn on centerline. A line fatter that one pixel will extend out from the centerline drawn.

**Automatic Paint Modes**

By default, the **Tools - Options** parameter **Automatic Paint Modes** is checked ON. Automatic Paint Modes will automatically switch paint modes whenever a new image editing tool is chosen to provide the most likely paint mode for that tool. For example, when Automatic Paint Modes is ON, pressing **Paint Line** will automatically push in the **Paint Lines** mode button and push out the **Paint Areas** and **Paint Points** buttons. This default choice may be overridden by choosing whatever combination of paint modes is desired after choosing the tool.

For example, when Automatic Paint Modes is ON the **Paint Areas** and **Paint Box**, **Circle**, and **Ellipse** commands will paint areas of pixels only. To paint lines and points as well simply push IN the **Paint Lines** or **Paint Points** buttons after choosing these tools.

**Density**

Some brushes use a mathematical curve to define the amount of paint sprayed into various locations of the brush. The **Density** factory specifies the proportional difference between the maximum and minimum amount of ink sprayed into different parts of the brush as defined by the curve. In effect, it is either flattening or accentuating the curve.

The effect of increasing this factor is to give a greater appearance of paint density, hence the name of the parameter. The illustration above shows a typical curve-defined brush used to create a “point” with the density factor used for each example printed below in white. At low density the difference between the different regions of the brush are greatest and so it appears as a less dense brush. With high density there is less difference between paint applied throughout the brush and so the brush has a denser appearance.

**Opacity**
Opacity works with all brushes. By varying Opacity it is as if we have painted the brush on a layer above the image and then varied the transparency of the layer and then merged the two layers to achieve the final pixel color for each pixel.

The illustration above shows application of a brush where the Opacity of the top row is greatest (100) while the Opacity of the lowest row is only about 30. In all three rows the three yellow applications of the brush were made on top of the same cyan line. To allow comparison with Density, in each of the three rows the Density has been increased from left to right.

Note that Opacity is different than Density. The Opacity parameter applies evenly throughout the entire brush. By varying Opacity the entire brush effect is more or less transparent in an even way throughout the entire brush. Density changes the relationship within the brush.
Paint Bucket Tool

The Paint Bucket tool fills regions of similarly colored pixels with foreground color. There are four subtleties involved in using the Manifold paint bucket tool as compared to use of such tools in simpler graphics software:

- By default, the paint bucket tool pours color only into pixels contiguous with the point where the tool is clicked. Override this by using a **SHIFT** click.
- The paint bucket affects only selected pixels. If there is no selection, the paint bucket will operate on the entire image.
- The paint bucket pours color only into those pixels whose color values are within the **Tolerance** value set in the Tool Properties pane. Override the **Tolerance** consideration by using an **ALT** click.
- Use a **CTRL** click to paint color with the paint bucket while preserving the intensity levels of the previous colors. This is like a paint bucket "colorize" effect.

To use this tool we click on the Paint Bucket tool in the Tools toolbar for images. In the examples below we use a foreground color of purple. These examples will use the sample **bronze** image that has had the Threshold command applied to convert it to only black and white colors. This will show the effect of the paint bucket tool in a simplified image.

When the paint bucket is enabled Manifold changes the mouse cursor to a simple cross icon as shown above. We will click onto the black region at the rear of the monument.

The paint bucket pours purple foreground color into all black pixels that are contiguous with the pixel where the tool was clicked. Note that regions of black pixels in the image not contiguous with the click have not been colored.

**Using the SHIFT Key**
If we click at the same spot using a `SHIFT` click the paint bucket will pour purple color into all of the black pixels in the image no matter where they are located. This is a useful technique to replace one color with another throughout all pixels in the image.

**When a Selection is Present**

Suppose we select a rectangular region of pixels and `SHIFT` click with the paint bucket at the spot shown. The paint bucket tool will compute the pixels to be affected based on the color at the spot clicked but it will paint color only into those pixels that are within the selection.

If we switched foreground color to green and `SHIFT` clicked at the spot shown in the preceding illustration the paint bucket will paint green color into all of the black pixels within the selection.
**Tolerance Parameter**

The paint bucket tool measures the color value of the pixel at the point where it is clicked and then operates on pixels whose colors fall within the **Tolerance** parameter set in the Tool Properties pane. This is different than the default behavior of paint bucket tools within simpler graphics editors such as Microsoft Paint, where a paint bucket pours into all pixels of like color, or where the paint bucket pours into any selected region without regard to the color of pixels it is painting.

When painting into regions of pixels that are all the same color the use of the **Tolerance** parameter does not matter since in that case all of the pixels probably will fall within tolerance value being used. The **Tolerance** parameter most likely will make a difference when painting into regions of gradients or subtle transitions between colors.

Let’s look at an example using an image that contains a smooth gradient of color from blue to purple. Suppose we change foreground color to yellow and click the paint bucket tool at the spot indicated above. If we are familiar with the default behavior of paint bucket tools in simple graphics editors we might expect the yellow color to fill the entire selected region.

In Manifold, given typical default settings of **Tolerance** we might get the above effect. What happened?

If the **Tolerance** parameter in the Tool Properties pane is set to a low value, such as **10**, the paint bucket tool will paint only those pixels that are close in color to the one originally clicked. Blue colors close to that clicked were colored and blue colors transitioning to purple were also colored if they were not so purple that they fell outside the **Tolerance** range of **10**. Because the gradient in the example image was created using the Gradient tool, the transition in colors in the image occurs in a smooth diagonal gradation from upper left to lower right. The pixels affected by the paint bucket tool thus fall within an even, rhomboid region within the selection. The clearly defined edge of the region painted yellow by the paint bucket occurs because that is the edge at which pixels pass beyond the tolerance difference of **10**.
To color the entire selected region with the paint bucket we can simply increase the **Tolerance** parameter so that a wider range of pixels will be affected.

![Image showing the effect of increased Tolerance](image)

The result of clicking the paint bucket at the same spot with a **Tolerance** of 100 is that the yellow color is poured into the entire selected region. We can also get the same effect with an ALT click.

**The ALT Key**

Wishing to pour a paint bucket of color throughout a selected region is such a common operation that Manifold provides a faster way to do so than resetting the **Tolerance** parameter. Pressing the ALT key while clicking to pour the paint bucket will have the effect of pouring with maximum tolerance for that pour. The paint bucket will fill all selected regions regardless of their previous pixel colors. If there is no selection the entire image will be painted.

![Image showing the effect of ALT click](image)

Suppose we select a rectangular region of pixels in the sample bronze image and click with the paint bucket at the spot indicated, using a foreground color of yellow.
If the Tolerance parameter is at the usual setting of 16 or so, the paint bucket will fill pixels that are blue in color and close to the blue of the pixel that was clicked. Note that the paint bucket action is computed over the entire image but applied only within the selected region. Thus, the pixels on the other side of the box from the spot clicked are contiguous (considering the entire image) within the given tolerance to the spot clicked. Most of the blue sky would be painted were it not for the selection; however, the yellow color is painted only into the pixels that are within the selection.

Had we ALT clicked with the paint bucket at the spot indicated all pixels within the selected region would have been painted.

The CTRL Key

The CTRL key may be used when clicking with the paint bucket to preserve the intensity of colors while painting with the foreground color. The CTRL key may be used in combination with either the ALT key or the SHIFT key.

Suppose we select all pixels within the bronze monument and click at the indicated position with the paint bucket using yellow color.
A CTRL-ALT click will pour yellow color into the entire selection while preserving intensity levels from the colors previously in use. The effect is like doing a Colorize with the paint bucket.

Clicking at the same spot with just an ALT click will pour color into the entire selection without preserving intensity levels.

**Local Clicks Apply throughout the Image**

The paint bucket tool computes its action based on the spot that it is clicked regardless of whether this spot is inside or outside the selection. If a selection exists, the action of the paint bucket will be limited to the selected regions but it will also apply to all selected regions even if they are not connected with each other. This allows us to apply paint bucket action using the color of pixels at whatever location is easiest to click even if we intend the tool to apply only within the selection.

When used with the ALT key to paint throughout the selection, this means we can click very rapidly without having to worry about clicking within the selection.
If we **CTRL- ALT** click as shown above the paint bucket will pour color into all selected regions, preserving the intensity. Note that it does not matter whether or not we clicked inside or outside of any of the selected regions.

We would have had the same effect if we had **CTRL** clicked at that spot (or at any other spot) with very high **Tolerance** setting in the Tool Properties pane. Using the **ALT** key is a handy way of painting throughout all selected regions without having to be precise in our application of the paint bucket tool.

This effect of the Manifold paint bucket tool is different than what is encountered in some other graphics software, where a paint bucket tool applies to a region contiguous to where it is clicked. For example, clicking a paint bucket tool on the blue sky as shown above in some graphics editors would have resulted in a flood of yellow paint throughout all regions of the image **except** the selected areas. Clicking within any one of the selected regions would have painted only that region and not the other selected portions.

Manifold works differently because Manifold has a very strong set of selection tools that ordinary graphics editors do not have. Given Manifold's powerful selection methods the design philosophy of the system is that one makes a selection that is to be affected and then one applies tools to that selection. If we wanted to paint all the regions except those selected we would have taken a moment to use **Edit - Select Inverse** to invert the selection and then painted with the paint bucket. A strong array of tools for making selections, saving them and modifying them lets us choose exactly the region in which we wish our painting tools to apply.

**Notes**

Note that the use of **Tolerance** to guide the action of the paint bucket tool is not a negative thing: it is a powerful capability that allows the paint bucket tool to be used with fine control for replacing colors over a desired range of values. If we want the paint bucket to work without regard to **Tolerance** setting we simply **ALT** click.

When the paint bucket tool is in action, Manifold changes the mouse cursor to a simple cross icon. This is different than the cursor style used by some other software products for this type of tool. Other software programs will often use a small paint bucket icon for their mouse cursors. This has the advantage of showing what painting tool is in use, but such cursor shapes make it much more difficult to click with precision upon a desired spot. Manifold's cross cursor for the paint bucket tool makes it immediately clear where the tool is clicked.
Sometimes we would like to know in advance where the paint bucket will pour without having to Undo the operation. To see where the paint bucket will pour, use Select Touch to click on the spot where the pour will be made. Because Select Touch also selects pixels using the Tolerance set in the Tool Properties pane, it will select the same pixels that would be affected by a paint bucket pour. To avoid altering a pre-existing selection, save that selection first in the Selections pane so that it can be recalled after the Select Touch selection.

When using the paint bucket the CTRL key may be combined with either the ALT key or the SHIFT key. We can do a CTRL-ALT click or a CTRL-SHIFT click; however, the ALT and SHIFT key don’t make sense to use together since their combined action is equivalent to an ALT click.

**See Also**

See the example Painting into the Alpha Channel for an example of how the paint bucket tool may be used to paint into the alpha channel of an RGBA image. The paint bucket tool when used as the example shows is a very handy way of adjusting alpha transparency in partially transparent images.
Gradient Tool

The gradient tool paints all pixels with a color gradient from foreground color to background color. It will paint all pixels in the selection, or in the entire image if there is no selection.

Suppose we have an image that is all black color.

We will set foreground color to blue and background color to a gold-yellow color.

Click on the gradient tool in the Tools toolbar for images.

To paint a gradient into the image, we click where we want the gradient to begin and then drag and release where we want the gradient to end. In the example above we clicked in the upper left of the image and have dragged down and will release in the lower right.
There is no selection made in this image so the gradient tool will paint the entire image. All regions before the beginning click will be pure blue in color. All regions after the release click will be pure gold yellow. The regions in between will be painted in a continuous gradient of colors in a smooth mix from blue to gold. The regions “before” and “after” the initial click and final release are defined by lines perpendicular to the line of click and drag.

The result is that all pixels in the image are painted in either blue, gold or a mix of shades from blue to gold.

The gradient tool paints a gradient based on the initial click and the final release point. These do not have to be within the image. In the example above we clicked well outside the image and then dragged right and released outside the image as well.
The transition from blue to gold will be computed over the entire range of the click and drag but only that part of
the gradient that falls within the image will be painted into the image. Note that the image does not have any
pure blue or gold in it since the end points of the gradient click and drag were outside of the image.

We can force the gradient to transition from foreground to background color more rapidly by clicking and dragging
over a smaller distance. In the example above we have clicked and dragged upwards and slightly to the right
over a small distance.

The result is a rapid transition, so rapid that it appears mostly green with most of the image painted in either blue
or gold color.

When a Selection is Present
When a selection is present the gradient tool will work only within the selection. In the image above we have selected several round regions of pixels and one rectangular region.

We will switch to the **border** style of selection so we can see what happens inside the selection without the dense red dot selection pattern getting in the way.

We now click and drag with the gradient tool in the path indicated. Note that the points of click and release could be anywhere: there is no significance in the illustration above that the point of release happens to be within the selection in this particular example.
The result is that the gradient is computed as usual but it is painted only into those pixels that were selected.

We can disable use of selection color temporarily to see the result without selection borders. Using gradients within selections is a technique with an infinity of cool artistic possibilities.

We can take our sample bronze image and select all pixels outside the bronze monument. We use the dense dots selection style to make it clear which pixels are selected.
Once more we will switch to the border style of selection so that the red selection dots do not interfere with our view.

Let's change the foreground color to black and the background color to orange.

We now use the gradient tool from top to bottom as shown.

Viewing the result with selection color turned off, we can see that the gradient painted color from black to orange only into selected pixels. The effect is as if we see the bronze monument in front of a color gradient.

Notes

The examples above show the results of using the gradient tool when a selection is present. However, we would more frequently use such gradient effects within different images stacked in layers rather than within a selection in
only one image. This would allow us, for example, to independently manipulate the "cut out" of the bronze statue in one image/layer while we adjusted the gradient in a different image/layer.

This would come in handy if we would like to clean up the "halo" of lighter pixels in the bottom part of the bronze statue. These appear as a result of sloppy selection when we selected all of the pixels outside the monument. If the bronze monument were in a different image than the "background" gradient it would be much easier to clean up the lighter pixels.

See the example Painting into the Alpha Channel for an example of how gradients are used to paint into selections as well as how they can be used to paint into just one channel of an RGBA image. Gradients are a powerful way to specify alpha transparency so partially transparent images can appear to be "feathered" into a larger image composition.

### Transform Toolbar - Images

#### Target box  Operation box  Source / argument box

The Transform toolbar makes changes throughout the entire image. If a selection is present it will operate only on those pixels in the selection. If no selection is present it will apply to all pixels in the image.

The Transform toolbar consists of three boxes, from left to right: a **target box**, the **operation box**, and a **source / argument box**.

- **Target box**
  - Also known as the **scope box**. The pixels that will be affected, altered or which will control the operation. Choices in the target box will be [All Pixels], [Selection] or the names of any saved selections that have been saved in the Selections pane.

- **Operation box**
  - The function to be applied. The operation box is context sensitive and will show only those operations that make sense for images.

- **Source / argument box**
  - The value to be used. Depending on the operator, this may be another pixel set or a value entered by the user. Many operators, such as Desaturate do not require a source or argument. The source / argument box will not be enabled for such operators.

We use **dark blue**, **black**, and **violet** bold face fonts in this topic to distinguish the three boxes to make examples and explanation more clear. In real life Manifold uses the same black font color in all three Transform toolbar boxes.

#### Using the Transform toolbar

1. Click on the map layer or image that contains the target pixels.
2. Make a selection if the operation is to be applied just to the selection and choose [Selection] in the target box. Alternately, choose the name of a previously saved selection.
3. Choose the desired operator in the operation box.
4. Choose or specify a value in the source / argument box, if this operation requires it.
5. Press **Apply**.

#### Target box
The left-most box specifies the target pixels. These are the pixels that will be affected, altered or which will control the operation. The example above shows that there is no selection present, so the Transform toolbar will apply the Transform function to all of the pixels in the image. If we make a selection, the target box would include a [Selection] choice so that whatever operation we apply with the Transform toolbar will act only on those pixels that are part of the current selection. We could also choose the name of a saved selection.

Operation box

Choose a function from the long list of operators available in the operation box. The example shows Add Noise, which will add random noise pixels to the image. Note that many operators in the Transform toolbar's operation box are simplified versions of more flexible operators in the Image menu. The Transform Operators - Images topic lists operators available for use with images.

Source / argument box

Many operators do not require any sources or arguments. For these functions the source / argument box will be disabled.

Other functions will require specification of a source. This may an object set such as [All Pixels], [Selection] or the names of saved selections, all of which can be chosen from the combo box.

Some functions require an argument value that is entered by the user. To enter a value, click into the source / argument box, enter the value using the keyboard and then press Enter.

Examples

[All Pixels] Add Noise - Add random noise throughout the image.

[Selection] Add Noise - Add random noise only to those pixels in the selection.

[Selection] Brightness 64 - Reduce brightness to half the existing level (existing level is taken to be 128) for all pixels in the selection.

Sky Brightness 20 - Increase brightness for all pixels in the saved selection called Sky.

See Also

Transform Operators - Images
Many transform toolbar commands are versions of commands that also appear in the main Image menu. The hyperlinks below will jump to the Help topic for the corresponding command. Most commands are enabled for RGB or RGBA images. To use these commands with other types of images, first convert them to RGB or RGBA images.

- **Add Margin**
  Add to the rectangular size of the image by the given number of pixels at the margin.

- **Add Noise**
  Add color noise as set by the argument. A transform toolbar version of the Noise menu command.

- **Add Noise (Mono)**
  Add monochrome noise as set by the argument. A transform toolbar version of the Noise menu command with Monochromatic mode checked.

- **Auto Contrast**
  Automatically adjust contrast to balance contrast non-linearly throughout the entire image considering the overall intensity of each pixel.

- **Auto Level**
  Balance contrast throughout the entire image by balancing contrast within each channel individually.

- **Blur**
  Blur image by fixed amount. Blurs both features and colors. For a "blur" effect that does not mix colors, use the Median filters.

- **Blur (parameter)**
  Blur image by the number of pixels given in the argument. This blur is implemented as a matrix operator where the value of the argument is the weight of the center pixel with weights of all other pixels set to 1. Increasing the value therefore produces a lesser blur.

- **Brightness**
  Adjust brightness by the argument amount.

- **Contrast**
  Adjust contrast by the argument amount.

- **Crop**
  Crop image size to the selection.

- **Crop Margin**
  Crop the rectangular size of the image by the given number of pixels at the margin.

- **Desaturate**
  Reduce saturation to zero for all color values. Remains RGB.

- **Difference East**
  Detect and emphasize edge transitions to the East. See the Filters topic for general discussion of convolution matrix filters like this one.

- **Difference North**
  Detect and emphasize edge transitions to the North.

- **Difference North-East**
  Detect and emphasize edge transitions to the North-East.

- **Difference North-West**
  Detect and emphasize edge transitions to the North-West.

- **Difference South**
  Detect and emphasize edge transitions to the South.

- **Difference South-East**
  Detect and emphasize edge transitions to the South-East.

- **Difference South-West**
  Detect and emphasize edge transitions to the South-West.

- **Difference West**
  Detect and emphasize edge transitions to the West.

- **Diffuse**
  Migrate pixels by swapping them in a "random walk." Reapplying Diffuse several times will move pixels further and further away from their original positions.

- **Equalize**
  Equalize image to value given in the argument.
Flip Horizontally  Flip image left / right to mirror image. If a rectangular selection is present, the selection only can be flipped.

Flip Vertically  Flip image top / bottom to upside down image. If a rectangular selection is present, the selection only can be flipped.

Gamma  Alter gamma value by the argument.

Gaussian Blur  True Gaussian probability function blur by given amount. Slow to compute for very large images.

Grayscale  Cast all colors into gray tones by intensity. Remains RGB.

High Pass 1  Emphasize rapid transitions between pixels. Good edge detection with horizontal and vertical lines.

High Pass 2  Stronger emphasis on rapid transitions between pixels with strong edge detection on lines of all angles.

High Pass 3  Edge detection with crisp vertical and horizontals and fuzzy lines at other angles.

Invert  Invert pixel values so that 0 becomes 255 and 255 becomes 0. See the Invert topic for information on the Invert At transform.

Laplace 1  Good edge detection with emphasis on horizontal and vertical changes.

Laplace 2  Strongest changes at point of intersection of horizontal and vertical lines, resulting at a small X pixel pattern at the point of intersection; fuzzy detection of linear features at other angles.

Low Pass 1  Strong blur, with strong suppression of large pixel to pixel changes.

Low Pass 2  Blur, with medium suppression of large pixel to pixel changes.

Low Pass 3  Blur, with least suppression of large pixel to pixel changes. Removes graininess in some images.

Median Cross  Evens out color tending to preserve horizontal and vertical features. A "blur" that ignores perfectly horizontal and vertical linear features.

Median Square  Evens out color looking at a 3 x 3 matrix surrounding each pixel. A "blur" that preserves prevailing color.

Median Square 5  Strong evening out of color looking at a 5 x 5 matrix surrounding each pixel. Results in removal of isolated pixels of color differing greatly from surrounding pixels. A stronger "blur" effect that preserves prevailing color.

Motion Blur Diagonal 1  Blurs the image as if moved diagonally on the upper left / lower right axis by the specified number of pixels. See the Image - Motion Blur topic.

Motion Blur Diagonal 2  Blurs the image as if moved diagonally on the upper right / lower left axis by the specified number of pixels. See the Image - Motion Blur topic.

Motion Blur Horizontal  Blurs the image as if moved horizontally by the specified number of pixels. See the Image - Motion Blur topic.

Motion Blur Vertical  Blurs the image as if moved vertically by the specified number of pixels. See the Image - Motion Blur topic.

Posterize  Converts the image to a limited number of colors for a "poster" effect. Very low (2, 3 or 4) parameter values
Images gives the most obvious effect.

**Rotate** Rotate image given number of degrees. Negative degrees are taken as counter-clockwise rotation.

**Sharpen** Emphasize transitions to give images a sharper appearance.

**Sharpen (parameter)** A Sharpen with selectable value for degree of sharpness. This sharpen is implemented as a matrix operator where the value of the argument is the weight of the center pixel with weights of all other pixels set to 1. Increasing the given value therefore produces less sharpening.

**Sharpen More** Enhanced sharpness compared to standard Sharpen.

**Threshold** Converts an image into black and white based on whether each pixel is above or below the given value in intensity.

**Threshold Black** Like Threshold, but forces all pixels below the intensity given in the source / argument box into black while leaving all pixels above that value unchanged.

**Threshold White** Like Threshold, but forces all pixels above the given intensity into white while leaving all pixels below that value unchanged.

**Tile** Divides image into tiles of given X and Y extent and then averages pixel values within the tiles. This is used for aggregating and interpolating raster data images into larger tiles and for creating "pixelated" artistic effects.

**Tile Median** Equivalent to Tile command with Preserve Colors checkbox checked.

Many commands in the Transform toolbar are based on convolution matrix filters. See the Image - Filter topic for a detailed discussion of how matrices are used in filter effects and how to create new filter-based commands that may be added to the Transform toolbar.

**Image Menu Commands**

Many transform commands are one-line versions of commands available in the Image menu. The image menu appears when the focus is on an image window or an image layer is active in a map. Commands listed below will appear either under the main Image menu or under submenus such as Adjust or Effects. Commands are enabled for RGB or RGBA images. To use these commands with other types of images, first convert them to RGB or RGBA images.

**Open Palette** Enabled for palette images. Open the palette for this

**Dither** Uses a smaller number of colors in an image while preserving a perceptual effect through the use of dither patterns.

**Quantize** Convert image to the specified number of colors using enhanced or standard methods.

**Resize** Change the size of the image using desired interpolation method.

**Convert To** Convert images between grayscale, palette, RGB or RGBA images.

**Adjust Menu**

**Color Balance** Adjust RGB color values for Shadows, Midtones or Highlights

**Brightness / Contrast** Change brightness and contrast.
**Hue / Saturation**  
Alters hue, saturation and lightness.

**Invert**  
Invert pixel channel value. Creates a "photographic negative".

**Equalize**  
Alters individual pixel brightness so there is an equal number of pixels at all brightness levels.

**Gamma**  
Change mid-tone color brightness.

**Threshold**  
Forces grayscale pixels to white, black or unchanged based on a histogram.

**Threshold Color**  
Like **Threshold** but applies to each RGB channel individually.

**Posterize**  
Convert image to a limited number of colors for a "poster" effect.

---

**Effects Menu**

**Colorize**  
Adjust saturation and hue while keeping intensity the same, as if a color were applied to a grayscale version of the image.

**Gaussian Blur**  
Apply Gaussian bell curve blurring to create shadows, halos and transitions.

**Motion Blur**  
Streaked effect in the desired direction.

**Diffuse**  
Moves pixels by swapping them in a "random walk."

**Filter**  
Applies convolution filters, either custom filters or a choice from numerous presets.

**Fluoresce**  
Alter saturation and lightness in asymmetric ways to cause some colors to appear unusually bright.

**Noise**  
Add random monochromatic or color pixels.

**Relief**  
Add highlights and shadows to give a 3D effect to 2D images.

**Simplify**  
Aggregates pixels into larger clumps for a pointillist or mosaic tile effect. Can also remove small dots in cartographic work.

**Tile**  
Convert image into rectangular tiled regions of appropriate color.
**Transform - Add Margin / Crop Margin**

The **Add Margin** image transform toolbar operator adds the specified number of pixels to the top and sides of an image. By default, these are added as black pixels by default. The **Crop Margin** command

**Crop Margin** was used to trim 20 pixels from the margin of the center image to create the image on the left. To create the image on the right, we've added 10 pixels to the margin of the central image. By default, the **Add Margin** operator adds colors in whatever color is currently set as the foreground color in the format toolbar for images. Un-checking the **Fill new pixels with current color** box in Tools - Options will cause the margin to be added using invisible pixels regardless of the current foreground color.

Note: When used with surfaces, the **Add Margin** transform always adds invisible pixels.

**Use with Selections**

Selections do not affect the **Add Margin** or **Crop Margin** commands since these operate on the overall image rectangle.
Transform - Auto Contrast

The Auto Contrast transform operator automatically adjust the contrast throughout a given image or selection. If a selection is present, it works only on the selected pixels. If no selection is present it works on the entire image.

The Auto Contrast operator changes contrast throughout the image on a non-linear basis to achieve what the algorithm thinks is an optimum, even contrast. It works by reckoning the intensity of pixels considering all channels taken together. The results are similar to those produced by the Adobe PhotoShop Auto Contrast command.

The image on the right above has had Auto Contrast applied.

Note

Because Auto Contrast uses a non-linear algorithm that clips extreme bright and dark sample pixels, the effects it produces cannot be obtained by simply moving the Contrast slider in the Brightness / Contrast command.

See Also

See the Auto Level topic for a comparison of Auto Contrast and Auto Level effects. Auto Level adjust contrast within each channel individually.
Transform - Auto Level

The **Auto Level** transform operator is similar to Auto Contrast, except that whereas **Auto Contrast** sets contrast by reckoning pixel intensity considering all channels taken together, **Auto Level** sets levels within each channel separately.

**Auto Level** will often produce better contrast than either **Contrast** or **Auto Contrast**. However, because it adjusts intensities in each channel separately to produce the overall effect it can make minor color shifts. These minor color shifts will often enhance the sense of reality and vividness of an image.

**Example**

If take our standard **schloss** image above and apply **Auto Contrast** we get the image below.

If we start with the **schloss** image and apply **Auto Level** we get the image below. Compare the difference in appearance of trees in the image above with those in the image below. The **Auto Level** image provides slightly greener trees. There is also a greater sense of color differentiation in the yellow crenellations of the uppermost towers.
Compared to the original image the **Auto Level** image has slightly different color tones but in a productive way that yields a more vivid image. In other images, the color shift may be objectionable. For such images **Auto Contrast** may be a better choice.
Transform - Crop

The **Crop** image transform toolbar operator crops the image down to the minimum enclosing rectangle of the target box in the Transform toolbar. Normally, this is the **[Selection]** or the name of some saved selection. **Crop** has no effect if no selection is present.

The example above selects Tokyo airport and then crops down to the size of the selection.

**Crop** works fine even if the selected pixels are in many different discontinuous regions.
Classic mouse cursor "box" crops may be easily achieved using **select box** mouse selection. If desired, the selection style can be set to **border** to show the selection as a box.
**Transform - Desaturate**
Desaturates all colors in the image to produce an RGB image that uses shades of gray. Note that desaturation is not the same as conversion to a **Grayscale** image.

**Grayscale** and **Desaturate** will both produce monochrome grayscale images; however, the two have different effects as may be seen by applying them to the color wheel.

Applying **Grayscale** results in visual distinctions between the hues as color tones:

Applying **Desaturate** results in an even gray tone because the brightness level for all hues is the same:

When converting color images to photographs, **Grayscale** will usually produce a more natural appearance, while **Desaturate** will produce a more "posterized" look.

See also: Colors as Hue, Saturation and Brightness, Hue / Saturation
Transform - Diffuse

The **Diffuse** operator moves pixels by swapping them in a "random walk." Reapplying **Diffuse** several times will move pixels further and further away from their original positions. **Diffuse** is used to apply artistic effects.

The above images show a zoomed-in view with one application of **Diffuse** as well as a view after several applications of **Diffuse**. Note how pixels "drift" at random from their original positions with repeated applications of **Diffuse**.

When used with photographic images, **Diffuse** provides a pixelated, "dry brush" painterly effect. The illustration above shows the effect after using a level of 9, applied to the sample **bronze** image that was previously altered using the fluoresce command.
If a selection is present, the effect can be restricted to the selection as seen above.
Transform - Flip Horizontally / Flip Vertically

The Flip Horizontal and Flip Vertical commands flip an image right/left (mirror image) or vertically up/down. If a rectangular selection is present, it may be used in the scope box and the flip will be applied to the selection only.

For example, if we start with a selection in the example bronze image (shown using a border selection style) and apply Flip Horizontal to the selection it will flip the selected pixels horizontally.

Applying Flip Vertical will flip the pixels vertically.
Transform - Grayscale
Casts all colors into gray tones using computed intensities of colors to choose gray tones for pixels. Note that grayscale is not the same as conversion to a Grayscale image

Grayscale and Desaturate will both produce monochrome grayscale images; however, the two have different effects as may be seen by applying them to the color wheel.

Applying Grayscale results in visual distinctions between the hues as color tones:

Applying Desaturate results in an even gray tone because the brightness level for all hues is the same:

When converting color images to photographs, Grayscale will usually produce a more natural appearance, while Desaturate will produce a more "posterized" look.

See also: Colors as Hue, Saturation and Brightness, Hue / Saturation
Transform - High Pass
The High Pass filters in the Transform toolbar for images detect rapid changes in pixels using three different analytic matrices. These filters will emphasize linear features such as edges.

The examples below are based on an example image that is a screen shot of a drawing, converted to a raster image and shown above. The image therefore provides a nice mix of strong horizontal and vertical linear features made up of evenly aligned single pixels as well as pixels arranged in uneven linear patterns.

High Pass 1 - Good edge outlining with emphasis on horizontal and vertical changes.

High Pass 2 - Stronger emphasis on edge changes at all angles.

High Pass 3 - Strongest changes at point of intersection of horizontal and vertical lines, else relatively unchanged horizontal and verticals with fuzzing of linear features at other angles.

See the Image - Filter topic for a detailed discussion of how matrices are used in filter effects.
No Data
Transform - Median Cross / Median Square

The Median Cross, Median Square and Median Square5 filters in the Transform toolbar for images use a convolution matrix filter to even out colors and reduce smaller details while preserving prevailing color. These transforms are useful for processing images that will be used for classification and vectorization, to remove extraneous noise and detail while preserving broad regions of color.

- **Median Cross**: Evens out color tending to preserve horizontal and vertical features. A "blur" that ignores perfectly horizontal and vertical linear features.
- **Median Square**: Evens out color looking at a 3 x 3 matrix surrounding each pixel. A "blur" that preserves prevailing color.
- **Median Square5**: Strong evening out of color looking at a 5 x 5 matrix surrounding each pixel. Results in removal of isolated pixels of color differing greatly from surrounding pixels. A stronger "blur" effect that preserves prevailing color.

The effects may be seen by applying the transforms to an overhead image of Tokyo airport, seen below.

The **Median Cross** transform reduces speckles and averages out detail in large areas of color while preserving major lines such as the edges of the land areas against black water areas. Note that some fine details such as the very thin diagonal line extending into the water in the upper center of the image is preserved.

The **Median Square** transform seen below creates a greater averaging and greater suppression of speckles. The thin line extending into the water has been averaged away, but the small white dot indicating an island or large ship in the channel in the lower left corner is still present.
The **Median Square5** transform has the strongest averaging and nearly total suppression of speckles and individual dots.

Compare the above image to the image below created using Gaussian Blur with a setting of 5 pixels.

Note that the **Median Square5** transform preserves object outlines while **Gaussian Blur** simply blurs everything together within a range of 5 pixels.
**Transform - Rotate**

The **Rotate** transform rotates an image or surface the number of degrees specified in the source / argument box. Positive degree numbers cause a clockwise rotation and negative degree numbers cause a counter-clockwise rotation.

For example, rotating the above surface by **-45** degrees results in the surface below.

Rotation parameters may be decimal fractions, such as **45.55** for more precise rotations, if desired.
No Data
Maps

Map windows are the most frequently used windows in Manifold. A map is a projected view that contains layers. Each layer is a separate drawing, image, surface or labels component. Maps are the only view windows in Manifold with layers. They are used to see drawings, images, surfaces and labels components in combined, layered views.

Creating a New Map

We can create a new map using whatever source materials we like:

1. Create a new project using File - New. This opens a project view window.
2. Using File - Import, import any drawings or other components into the project the new map will use.
3. Create a new map in the project using File - Create - Map. We must specify the name of at least one drawing or image this map will use. In the Create Map dialog, check all the drawings or images from the project you would like to appear in this map.
4. Double-click on the new map in the project view window to open it in a map view.
5. Drag and drop any additional components from the project view window into the map view window. This adds them to the map.
6. If images (or any other components) are not already georeferenced, they must first be georegistered so that they appear in the proper geographic location at the correct size.
7. If desired, use Edit - Assign Projection to change the projection used by the map.

Maps are also used to edit drawings and images by using multiple layers for edits. PhotoShop-style editing of images using layers is accomplished in Manifold in a map view.

There can be more than one map window open and each map window is fully independent. Drawings and images can be used in multiple maps at the same time.

Maps can have multiple layers where each layer is a different drawing, image, surface or labels component. Tabs at the bottom of the map window allow moving layers back and forth in the layer stack. Double-clicking on a layer tab turns that layer on and off for visibility. Right-clicking on a layer tab pops open a menu of commands for that layer.

Editing an image or drawing in one map view will simultaneously change it in all other map or drawing or image windows in which it appears.

There is no structural limit on the number of maps or the components they show in Manifold. Since processing overhead increases as many maps are opened using many drawings and images, at some point a practical limit
will be reached based on your computer’s speed and your patience for slower operation. However, for ergonomic efficiency it makes sense to avoid a display cluttered with too many different maps showing many different views.

**Menus**

When we click into a map window, Manifold will automatically change menus and toolbars so they contain those menus and controls that work with maps. When we click on a layer in a map to make it active, the menus and toolbars will adjust to the configuration for that type of component.

Menu items that appear when a map window has the focus will apply only to the active layer. For example, **Edit - Select All**, **Select None** and **Select Inverse** apply to the active layer only, as does **Edit - Copy**. To apply selection commands to all visible layers, use the **ALT** key together with a mouse-based selection command such as **Select Box** or with a keyboard short cut such as **CTRL- C**. For example, and **ALT-Select Box** used with **Invert** selection mode will create an inverse selection over all visible layers. **ALT-CTRL-C** will copy all selected objects from all visible layers.

**Projections**

Map views use projections. At any point the map may be transformed to show its contents in a different projection.

When using a projection, map views do not change the native data within a drawing or image. Instead, the contents are reprojected “on the fly” if the projection shown in the map view is different than that specified within the drawing or image. If the same drawing is used in different maps, those different maps can use different projections and thus show that drawing simultaneously in different projections.

Since the mathematics of projection require a lot of computer processing, if using projections within maps that contain large drawings or images it makes sense to re-project the drawings and images used into the projection that will be used. If a drawing or image already uses the desired projection, there is no need for the map view window to reproject it on the fly. The result will be much faster interactive operation.

When a map is first inserted into a project, if it is created using only one component the projection of that drawing or image will be used for the map. If a map is created using multiple components at the same time, then Manifold will use the projection of the **largest** image or surface as the default projection. This is because images and surfaces are slower to re-project than drawings so the map will run faster if it takes the native projection of an image or surface and then re-projects any drawings to match.

At any time we can change the projection used by a map using the **Edit - Assign Projection** dialog.

**A shortcut:** If we would like the map to use a specific projection that's used by one of the components used as a layer in the map, we can easily specify the projection to be used by right-clicking on any layer and choosing the **Use Projection** choice from the context menu. The map will automatically switch to using the native projection used by that layer.

**Exporting Maps**

Manifold maps can contain many different types of components, such as drawings, images, labels and surfaces. Since most GIS formats can host only one such component type and do not support layers, the usual way of exporting a map to some different format is to export on its own each component that participates in the map. For example, various drawings and images in the map could each be individually exported on their own. An exception to this is the ability to export drawings in a map to either **DXF** or **KML** format.

Maps may be exported to **AutoCAD DXF** files, excluding any surface or image layers. See the Export Drawing - **DXF** topic.

Drawing layers in maps may also be exported to **Google Earth KML** or **KMZ** files. See the Export Drawing - **KML**, **KMZ** topic for details.
Layers
Maps show drawings, images, surfaces and labels components stacked in layers.

The "empty space" in drawings and labels components is transparent so objects in lower layers can be seen. Any layer may be made partially transparent so items underneath the "solid" parts of the layer may be seen as well.

Layer Tabs
Maps show layer tabs at the bottom of each map window. The layer tabs are automatically named the same as the drawing or image they contain. The leftmost tab is the top layer. Layer tabs may be used to manipulate the layers in a map.

Layer Tab Controls

- Click on a layer tab to make that layer the active layer.
- Double click on a layer tab to turn that layer on / off for display.
- Click and drag on a layer tab to move that layer to a different position in the layer stack.
- Right click on a layer tab to pop open a context menu of things we can do with layers.

The active layer tab is white. Inactive layer tabs will appear in the color defined in our Windows Desktop Display settings for “3D Objects.” Only one layer is active at a time. Selection commands and windows clipboard commands operate on the active layer only by default.

The Layers Pane

The Layers pane provides an alternate user interface for working with layers. The layer tabs at the bottom of each map are convenient when a small number of layers is used in a map. When a map has many layers the layer tabs are inconvenient to use because we must spend a lot of time scrolling left and right through the layer tabs to get to any particular tab.

The Layers pane provides a list of all layers in a map. It is normally left open and docked to the left or right side of the main Manifold window in a vertical orientation. It may therefore be used to keep dozens of layer names in view and to rapidly click on any one of them. For intensive image editing work involving many layers it provides faster control over layer characteristics (such as opacity) as well.

Layers Pane Controls

- Double-click on a layer to highlight it and to make it the active layer.
- Click on a layer and press the Switch to button in the layers pane toolbar to make it the active layer.
• Use the checkboxes to turn layers on and off for display.
• **Right click** on a layer for a context menu for that layer.
• Each layer may be set to a percent opacity to specify partial layer opacity.
• Move layers up and down in the layer stack with the **Move Up** and **Move Down** buttons.
• The **Border** and **Background** may be turned off and on using their checkboxes.

### The Border and Background Layers

The layers pane will always show two additional layers: the **Border** layer and the **Background** layer. These are system layers and are not real "layers" in that they do not correspond to any drawing or image in the project. Both may be switched ON or OFF via their checkboxes.

The **Border** layer shows a border about the maximum horizontal and vertical extent of the map. It is a useful way of checking if any objects are in the map but are not in view.

The **Background** shows what color to put underneath all other layers. By default white, it may be switched off to easily see if any white space in the map is part of the background or not. The background color for all components is set by default in the Tools - Options dialog. Each individual component can have its background color set to some color different than the default by opening the component in a window and choosing **View - Properties**. Changing the background color can dramatically change the appearance of a map.

The following three illustrations show the effects of changing only the background color from the default white, to black to green.
It is obviously important to consider background color when choosing formatting colors for objects in drawings. Note, for example, how the black color used for a railroad disappears when black is the background color. The map shown above was intended for use with a green background color, and not with white or black background. (The illustrations show a small region in Texas taken from a declassified US Military map provided by NIMA in VMAP Level 2 format.)

**Using Layers to Set the Map Projection**

When a map is first inserted into a project, if it is created using only one component the projection of that drawing or image will be used for the map. If a map is created using multiple drawings or images at the same time, then a random choice of one of the native projections of one of the constituent components will be used.

At any time we can change the projection used by a map using the Edit - Assign Projection dialog. If we would like the map to use a specific projection that's used by one of the components used as a layer in the map, we can easily specify the projection to be used by right clicking on any layer and choosing the **Use Projection** choice from the context menu. The map will automatically switch to using the native projection used by that layer.

**Layer opacity**

Layers may be given an opacity percentage that applies to the entire layer. As opacity ranges from zero percent to one hundred percent the layer will be either completely transparent or totally opaque.

If an image layer contains an RGBA image where individual pixels may have different degrees of transparency, the layer opacity will be evenly combined in a proportional way with all pixels.
Opacity Dialog

An alternative to setting layer opacity via the % edit box in the Layers pane is to use the opacity dialog that pops up from the context menu for map layer tabs. Right click onto a layer tab and choose Opacity to open the dialog:

The opacity dialog allows interactive setting of opacity by moving a slider bar. Check the Preview box to see the effect in real time. We can also click into the edit box and change the opacity value number.

Context Menu for Map Layer Tabs

Right click on a layer tab to see the context menu for that layer:

Visible    Show or hide this layer.
Add        Add a new blank drawing, image or labels component using the map's projection, or launch the Layers dialog to add components from the project pane. The component will be added as a layer just above the active layer tab.
Cut         Windows clipboard cut operation. Copy objects or pixels to the clipboard and delete them from the drawing.
Copy        Windows clipboard copy operation. Copy objects or pixels from this layer onto the clipboard.
Paste       Paste the contents of the Windows clipboard into this layer replacing any selected items.
Paste Append Paste the contents of the Windows clipboard into this layer.
Delete from Map Delete this layer from the map. The component will continue to exist in the project pane and in any other maps in which it participates.
Duplicate   Make a copy of this component in the project pane and insert it in the map.
Open        Open this component in its own window. If it is already open in its own window, activate that window.
Open in New Window Open this component in its own window. If it is already open in its own window, open it again in yet another window.
Rename      Change the name of this component
Order       Move layer to top, up, down or to bottom of layer stack.
Opacity     Set the opacity of this layer. See the Layer Opacity topic and the note below regarding the Opacity dialog.
Restrictions Specify if this layer allows clicking, editing or selecting using mouse commands. See the Layers pane topic for more information on layer restrictions.
Center      Center the active layer in the map window.

Example

Manifold System has such powerful image manipulation capabilities that it may also be used to create complex images by combining multiple images in layers as is done with professional quality graphics image editors such as Adobe PhotoShop.

For example, the marketing promotion "splash" screen used with 5.x and 6.x series Manifold System releases was created using over 40 layers of other images. Alpha pixel transparency and invisible pixels were used throughout the various layers so lower layers could combine to form the image. Looking at seventeen of the various layers we can see how the image was created:
The bottom three layers were screen shots from a Terrain window using different settings for sky and surfaces. The uppermost of these is the grid.

The next two layers are the floating city and its shadow, which are in separate layers so that the opacity and relative position of the shadow may be easily controlled. See the Gaussian Blur topic for details on creating drop shadows. The next twelve layers consist of text or logotype images together with various drop shadows.

The actual production "map" for the splash screen included over 40 layers. The extra layers contained variations of the logotype, different visual elements such as different sky cloud patterns and other variations. By checking the layers ON and OFF and moving the various layers about it was easy to try out many different variations to end up with exactly the effect desired.

Each image in the layer stack was heavily manipulated using various effects, resized, partially erased or made transparent to "feather" its features visually into features from other layers, and so on. For example, the city originated in a scanned photograph snapped from the bell tower in St. Mark's square in Venice. It was cut out of the photograph and then different parts of the image had hue, contrast and color balance adjusted in different ways. To bring out detail in the trees the green areas were re-built from several layers using different settings for brightness, contrast, saturation, colorization and color balance.

See the Composing Complex Images in Layers topic for an additional example of how to compose complex images using layers in Manifold.
Layers and Commands

Commands in the map window will automatically adapt to the type of layer that is active. The active layer is the layer whose tab was last clicked. Click on a layer tab to make it the active layer. The active layer’s tab will be shown in white. Toolbars will switch to supporting whatever type of component (image, drawing, labels or surface) is in that layer. Commands that are available in the component’s native window will be available for that component when it is the active layer in a map.

We can summarize the action of commands on layers in maps:

- The results of drawing transform operators always will be created in the active layer.
- Drawing transform operators use whatever layers or selections are specified in the scope box.
- Menu-based selection commands always work on the active layer.
- Mouse-based, visual selection tools work only on the active layer by default but can optionally apply to all layers.
- Windows Clipboard commands (including the Delete button) by default work only on objects in the active layer but optionally can apply to all layers.

ALT Key in Maps

Selection and Clipboard (Cut, Copy, etc) operations in maps work on the active layer by default. To extend the action of these operations to all visible layers, press the ALT key. For example, drawing a selection box in a map will only select objects in the active layer. Holding the ALT key while drawing a selection box will select objects from all visible layers. Pressing Delete deletes selected objects in the active layer only. Pressing ALT-Delete deletes selected objects in all visible layers. Think of ALT as a mnemonic for “All.”

Menu items that appear when a map window has the focus will apply only to the active layer. For example, Edit - Select All, Select None and Select Inverse apply to the active layer only, as does Edit - Copy. Menu commands cannot be extended to include all layers. The ALT key works only with mouse selection methods and keyboard commands. It does not modify menu commands (such as Edit - Copy) which always work on the active layer.

To apply selection commands to all visible layers, use the ALT key together with a mouse-based selection command such as Select Box or with a keyboard short cut such as CTRL-C. For example, an ALT-Select Box used with Invert selection mode will create an inverse selection over all visible layers. ALT-CTRL-C will copy all selected objects from all visible layers.

Example

We will import the bay_hydro, bay_land_areas and bay_roads drawings from the Examples directory on the Manifold CD.
We will rename the drawings to roads, hydro and land for brevity and then create a map with them as seen above. We will also open each drawing in its own drawing window. Note that the land layer is the active layer in the map. Our objective is to select all the points and to delete them.

Configure the selection toolbar as shown above. We choose Replace as the selection mode, and enable Select Points, disable selection of areas and lines, and choose Select Box. Note that the Select Labels and Select Pixels buttons are not enabled because there are no labels, image or surface components in the map.
While holding down the \textit{ALT} key, we click and drag in the map to open a selection box that encompasses all of the objects in the map. Because the \textit{Select Points} filter button is in, the \textit{Select Box} command will select all points within the box. The \textit{ALT} key extends the action of the command to all visible layers. If we had not used the \textit{ALT} key the command would have applied only within the active layer.
Points will be highlighted in red selection color. Note that the focus is on the map window as can be seen by the active color in the map window's title bar.

Even though there are selected objects visible in the map, if we choose Edit in the main menu with the focus on the map window, none of the Windows clipboard (Cut, Copy, etc.) commands are enabled. The reason is that there are no selected objects in the active layer.

We can click on the hydro layer to make it the active layer.
The **hydro** layer's tab changes to white to show it is the active layer.

If we now choose **Edit** in the main menu, we will see that the Windows clipboard commands are enabled. This is because there are selected objects (points) in the active layer.

If we choose **Edit** - **Delete** we delete the selected points in the active layer. Note that the **hydro** points disappear both from the **hydro** drawing window as well as from the map window.
To delete the points from the roads layer we click on the roads layer tab to make it the active layer and then we choose Edit - Delete.

Layer Restrictions

The Restrictions button in the layers pane displays and sets layer restrictions. Layer restrictions may also be set by right clicking on a layer tab in a map window and choosing Restrictions.

Each layer within a map may be specified to be clickable, editable, selectable or snapable (in any combination) with mouse commands. Each layer has four restriction options:

- Enable mouse clicks
- Enable mouse editing
- Enable mouse selection
- Enable mouse snaps

By default, all four options are enabled so objects in layers by default may be clicked, edited, selected or snapped.

The layers pane shows edit restrictions with a no marking each restriction. The "yes" implied by default is not shown for greater legibility. For example, in the above illustration the Cities layer is clickable and snappable but not editable or selectable. Double-click into any restriction setting in the layers pane to toggle it between no and the default yes setting.

If we were to right click on the Cities layer tab in the map and choose Restrictions the Layer Restrictions dialog would show restrictions status for that layer. In this dialog a check mark enables the function and no check mark removes the function. For example un-checking the Enable mouse edits box will prevent a CTRL-ALT click on an object in that layer from selecting it for editing.
Layer restrictions are used to show layers in maps while preventing some layers from participating in mouse commands. This makes it easier to edit desired layers in complex maps. Another use for layer restrictions is in Manifold IMS to restrict the action of hyperlinks or the Info tool to a limited set of layers.

Layer restrictions operate only with mouse commands. Keyboard and menu commands are not limited by layer restrictions, and smart mouse selection does not observe layer restrictions. For example, if a layer has had the Enable mouse selection checkbox un-checked none of the mouse selection commands will select objects in that layer. However, using CTRL-A or Edit - Select All will select all objects in that layer, the query toolbar will select objects in that layer and queries will select objects in that layer.

**Copying Restrictions to All Layers**

A CTRL-double click (that is, double-clicking while holding down the CTRL key) onto a restriction for one layer in the layers pane will copy that restriction to all layers. For example, suppose we have many layers in a project but we only want one layer, called Roads, to be editable. We can set the Editable restriction in the Roads layer to no and then CTRL-double click to set the Editable restriction to no for all layers. We can then click off the Editable restriction in the Roads layer so that it is the one layer that is editable while all the others are not editable.

**Notes**

We should keep in mind the interplay between user interface dynamics, layer structure and layer restrictions. When computing the effects of clicks and layer restrictions, Manifold first determines the clicked object and then checks if the click should be processed or not.

Let's consider an example case of a map with three layers. The upper layer has a single point formatted as a green circle, the middle layer has an area and the lower layer has a point formatted as a green square.

![Map View Example](image)

Seen in the map view, we see the round point above the area, shown with a hatching area style with transparent color in background, so that anything below the area shows through the "mesh." The square point is below the area.
If we could see the layers in the map in three dimensions, they would be stacked as above. Suppose the points are in layers with no restrictions, but the area is in a layer that is restricted and does not allow clicks.

In that case we could click on the round point but we could not click on the square point. Because the (restricted) area is above the square point, if we tried to click on the square point we could not do so because any clicks in that vicinity would be judged as clicks on the area that covers the square point.

Suppose the square point was in a layer above the area. Even in this case it would be difficult to click on the square point because anytime we click near the square point but not right on the center of the square point Manifold will judge the click to be onto the area. Since the area is within a restricted layer the click would not be processed.

Note that the size of the icon used for a point style does not determine the clickable region around that point. One must click on the center of the point to select it.

Layer Opacity

Each layer in a map can have the opacity of that layer individually set from zero opacity to 100 percent opaque. Layers that are partially transparent will allow objects, labels and pixels from layers underneath them to be partially visible. Opacity is controlled by settings in the layers pane. Transparency may also be set via the Opacity dialog in the context menu for layer tabs in maps.

To change the opacity of a layer in a map, open the map and then open the layers pane. Press in the View Opacity button in the layers pane. This adds an Opacity column to the layers pane.

Double-click into the Opacity setting for any layer to change it. 100% opacity (default) means the contents of the layer are opaque. 0% opacity means the contents of the layer will be invisible because they are completely transparent. When entering opacity numbers, there is no need to enter the % percent character: simply enter a number from 0 to 100 and press ENTER.

An alternative to setting layer opacity via the % edit box in the Layers pane is to use the opacity dialog that pops up from the context menu for map layer tabs. Right click onto a layer tab and choose Opacity to open the dialog:

The opacity dialog allows interactive setting of opacity by moving a slider bar. Check the Preview box to see the effect in real time. We can also click into the edit box and change the opacity value number.

Layer opacity will be combined with whatever opacity is already defined within the component. For example, RGBA images will have per-pixel transparency enabled. Using layer opacity with such an image layer will apply the layer opacity throughout the entire RGBA image in addition to any per-pixel transparency.

Note that changing the transparency of a map’s layer in the layers pane does not make any changes to the component involved. It only changes how that component is displayed in the layer stack. So, for example, if we have an RGBA image participating in a map when we change the layer opacity there is no change to the alpha channel values for each pixel.

Examples

Suppose we have a drawing of US counties (at left, below) and a drawing of congressional districts (at right):
Both drawings consist of areas. We would like to show them together in a map so that we see how congressional districts are shaped compared to counties. Without layer opacity it would be difficult to portray the overlap cleanly since whichever drawing was placed in an upper layer would hide the lower drawing.

Our solution is to use layer opacity. We will place the congressional districts drawing in an upper layer and then change its opacity until we get the desired effect showing both layers at the same time.

90% opacity: This provides slight visibility of the underlying counties drawing layer and would be a good choice if the main interest is the congressional district outlines.

75% opacity: Allows more of the counties drawing to show through the upper layer. Note that combining the colors of the lower and upper layers will tone down the rather garish initial colors of the upper layer. In effect, we are adding gray color to the upper areas which has the effect of reducing saturation of the combined image.
50% opacity: A good choice if the main focus is on county boundaries but where congressional district shapes should be easily available.

25% opacity: This decreases opacity of the upper layer so much that it is barely visible. This is a good way of applying subtle color to a map intended mainly to show counties that may also need to have other information, such as labels or point locations, included as well. The relatively faint outlines of congressional boundaries provide guidance for those interested in districts without being so visually obvious that they clutter the map.

Layer opacity is a great tool for utilizing images within maps.

A classic problem with georegistered images displayed in the same map as drawings is that the visual context of the image may interfere with the clear visual perception of objects in drawings.
Decreasing layer opacity makes the image fainter so that drawing objects can better stand out. A similar effect could be achieved by altering the brightness and contrast and saturation of the image but that would require an alteration in the image.

Changing layer opacity allows us to increase or decrease opacity of the layer without any change in the image component. This allows us to interactively seek the exact visual effect desired by increasing and decreasing the opacity for the layer. We will often use layer opacity in this way to "fade out" a background map when we would like to provide a subtle backdrop while retaining visual attention to map elements in the foreground.

Making images partially transparent allows objects in drawings underneath those images to be visible. In the above screen shot, we see two green circular areas appear through the image from a layer below.

The layers pane for the above map sets the opacity of the SanFrancImage layer at 50% so that the circular areas in the Antennas drawing can be seen.

Note that layer opacity is applied in addition to any transparency effects inherent in the image itself.
For example, suppose we change the **SanFranImage** image into an RGBA image and then "feather" the transparency so that all but the central portion of the image is transparent. We can use the image in a map with drawings. This example shows the same drawing layers with a new image layer. (The **Antennas** drawing is clicked off in this illustration).

If we apply transparency to the image layer and turn on display of the **Antennas** drawing we can get an effect that combines the pixel transparency in the RGBA image with the overall layer opacity given in the map's layers pane.

Layer opacity works with any layer that may be displayed in a map. Labels layers, for example, may also be made partially transparent in maps as shown above.

**Graphics Arts**

Combination of layer opacity with RGBA pixel transparency provides a wide range of artistic effects.
We can copy our standard bronze example image, convert it to an RGBA image and then create a feathered circular region while leaving the rest of the image transparent.

We can then layer this in a map with a copy of the bronze image that has opacity set low to provide a fainter image.

The result is a combined effect that highlights only part of the bronze image. The effect is more dramatic when seen in a True Color 24-million color image as is normally seen in monitors. The images in this Help file have been artificially reduced to only 256 colors to fit within the constraints of the Microsoft Help system.

Note that this same effect could have been achieved by feathering the image in the upper layer alone. In this case, instead of having just an opaque circular region feathering to the larger part of the image with complete transparency, the circular region could have been feathered out to a larger region of partial opacity. The advantage of creating the combined image in two layers is that the bottom layer can easily be altered in opacity to allow an interactive approach to setting the opacity desired. One simply increases or decreases the opacity of the bottom layer until one sees the effect desired.
Combined Layer Opacity

Layer opacity in Manifold works just as transparency does when stacking layers of transparent plastic film. The results are visually combined and not simply arithmetically additive.

Suppose we have a map with three drawing layers, each of which contains a blue square. The screen shot above shows the map. Two of the layers have layer opacity set to 50% and in these two layers the blue squares have been positioned to overlap each other. The third layer has 100% percent opacity.

Note that the square in the layer with 100% opacity appears completely opaque. The checkerboard background is not visible through it at all. The squares in the partially opaque layers have been rendered partially transparent so that the checkerboard background may be seen through them. Where the squares overlap the background is less visible because it is seen through two layers of partially transparent “material.”

If we turn on the default, white background in the layers pane we can see how the objects appear against a white background. This illustrates an effect that is occasionally confusing to beginners: the color of the region where both squares overlap is lighter (because of opacity) than the completely opaque square. The logical error made by beginners is to think that if one square has 50% opacity and the other square has 50% opacity then a sight line through both squares should be 100% opaque.

In reality, opacity is more a percentage multiplication effect than addition. When see through one square that is 50% transparent the sight line results in combined color that is 50% from the square and 50% from the background. If we now place another 50% filter of the same color into that sight line the result is color that is 75% the color of the squares and 25% the color of the background. Thus, an overlap of two filters each of which is 50% opaque has the same effect as one filter with 75% opacity and is not the same as 100% opacity.

Layer opacity is a Map Property

Layer opacity is a property of a map layer and not of the drawing or other component that is shown in that layer. The same drawing, for example, can appear in a layer in more than one map and in each map the layer containing the drawing can have a different opacity setting. The opacity used within each map is specified within that map’s layer only.

Changing the opacity of a layer does not make any change to the component shown in that layer. Layer opacity simply changes how the map shows the component in that layer.

Nomenclature

Transparency and opacity are two terms that mean the same concept viewed from different directions. When something is completely opaque it is not at all transparent. When something is perfectly transparent it may be said to have zero percent opacity.
Which word is used depends on the discussion. When imagining layers stacked up above each other like transparent sheets it is conceptually clearer to use the word transparency. When discussing a specific percentage of light transmission to be applied via a slider bar in a dialog most applications use the word opacity.

The convention in the graphics arts editing software industry is to adjust layer opacity with controls that set a number from 0% to 100% opacity, so that an image with 100% will be fully opaque and not allow any view of an image underneath it. Manifold follows this convention. This convention persists in the graphics arts industry even though the technical implementation of transparency effects is done using an alpha channel within RGBa images where the higher the value of the alpha channel (from 0 to 255) the higher the transparency.

One therefore encounters the slight conceptual dissonance of increasing opacity with higher numbers (up to 100%) in dialogs and other user interfaces while the internal data sets use numbers (alpha channel values) in which opacity decreases with higher numbers. Since we rarely set alpha values by hand this is not so bad. Alpha values are normally set using various tools, such as erasers, or masks. In the case of masks, the darker the mask region the lower the alpha value is and thus the higher the opacity. From a casual conceptual view this is very acceptable because it leads to an effect where black regions of masks cause full opacity and white regions of masks cause full transparency. Since we are used to thinking of "white space" as being transparent this works well as a natural mnemonic for the effects of masks.

**Printing and Opacity**

Manifold will correctly print maps (as well as layouts that include maps) with correct opacity for the layers used. However, if the Print using GDI+ option is turned off then only surfaces and images will be printed with correct opacity. Turning off the Print using GDI+ option forces Manifold to use ordinary GDI, which cannot print opacity in drawings.

Although .pdf and .ps formats are often thought of as "universal" formats that can capture exact renderings of data for use in other programs, they do have numerous limitations. For example, neither .pdf nor .ps can render opacity. If a layout includes a map that shows a drawing below an image that has 50% opacity in the map, the .pdf created by exporting the layout to a .pdf file will show the image with 100% opacity. .emf exports do support opacity for images and surfaces but not for drawings.

Although .pdf and .ps formats are often thought of as "universal" formats that can capture exact renderings of data for use in other programs, they do have numerous limitations. For example, neither .ps nor older versions of .pdf can render opacity. If a layout includes a map that shows a drawing below an image that has 50% opacity in the map, the .ps created by exporting the layout to a .ps file will show the image with 100% opacity. Exports using .emf support opacity for images and surfaces but not for drawings.

**Notes**

How are the feathered circles created in the RGBa images shown above? See the Create a Circular Feathered Image example.

Readers outside the US may be surprised to see that congressional districts are not always aligned to boundaries of cities or counties. In fact, they appear to have bizarre, arbitrary shapes in some cases. In the US the political party in power can use its majority vote to draw the boundaries of districts assigned to each congressional representative. This power to draw district boundaries is used to maintain political control by drawing districts based on known demographics of supporters and opponents.

The technical challenge is to draw district boundaries that unite one's supporters and fragment the opposition in a way that prevents opposition voters from ever making up a majority of any district. The practice is known as "gerrymandering" after Massachusetts Governor Eldbridge Gerry (1744-1814) whose second term as Governor featured a bizarre rearrangement of voting districts.
Repositioning Layers

We will often want to move layers up, down, left or right to reposition them relative to each other within a map. Moving a layer within Manifold means repositioning the component that makes up that layer. If the component shows a drawing or image at some geographic location, moving the layer means moving all the objects or pixels in the layer to a different geographic location. This changes the georegistration of the component.

In ordinary graphics editors (like PhotoShop) that work with layers, moving layers is a simple matter of using a move tool to move the layer as desired. Because Manifold always works within a geographic context (even for "non-geographic" images or CAD drawings), moving layers about within Manifold involves some nuances that may require additional thought. There are two approaches to moving a layer within Manifold:

- Repositioning the component using Georegistration or the Register dialog. These dialogs may be used at any time to reposition one component relative to another. Although normally used within geographic maps of various kinds, the georegistration dialog may also be used to align images or CAD drawings in non-geographic work.
- Interactive repositioning using mouse and keyboard moves. These methods may be used when the layer to be repositioned has the same native projection as the projection in use in the map. Since all non-geographic image and CAD work is done in Manifold using an Orthographic projection by default, such methods are available for casual repositioning when using Manifold as a CAD system or as an image editor.

Georegistration and the register dialog are covered in their own topics. This topic discusses interactive methods for repositioning layers.

Requirements for Interactive Repositioning

To move a layer using interactive methods the layer must have the same native projection as is used for the map. The projection in use for a map may be seen in the status bar. The projection used by a particular layer may be seen by right clicking on the layer's tab and choosing Properties from the context menu. To re-project the map window so it uses the native projection of a layer, right click on that layer tab and choose Use Projection from the context menu.

This requirement is automatically met when using Manifold as a CAD editor or as a graphics arts editor. That is because blank images and drawings are created by default in Orthographic projection unless some specific geographic context is specified for them. Images and drawings imported from non-geographic formats (such as those used for graphics arts or photographic work with images or CAD formats such as .dxf) will likewise be imported using Orthographic projection.

The requirement is also met in much geographic work that combines both images and drawings. Images are usually overhead aerial or satellite photos that are best saved in Orthographic projection. It's a good idea to re-project all drawings, images and the maps that show them into the same Orthographic projection centered on the same central latitude and longitude point. This will assure fastest possible performance and will allow use of interactive repositioning methods.

Interactive Repositioning Methods

If the mouse is not occupied in a command mode, we may interactively reposition layers in maps using the following CTRL-Grabber and keyboard commands.

- **CTRL-grabber**: Pressing the CTRL key while clicking and dragging with the Grabber tool will reposition the layer. Using the Grabber tool without CTRL will pan the viewport of the window. Using CTRL grabber will move the actual layer.
- **CTRL <arrow>**: Pressing the CTRL key while pressing one of the keyboard arrow keys will move the layer in that direction.
- **SHIFT - CTRL <arrow>**: Pressing both the SHIFT key and the CTRL key while pressing one of the keyboard arrow keys will move the layer in that direction in greater jumps.
To use these commands, the layer being repositioned must use the same projection as the map. Use the Project to Map choice in the layer tab's context menu to re-project the layer's component to match the projection currently used in the map. This is a permanent alteration in the data.

Example

The illustration shows a map that includes a partially transparent drawing layer above an image layer. The image layer is the SanFran image that has been georegistered to a position close to, but not quite exactly, the desired position. Both the drawing and the SanFran image are in Orthographic projection, as is the map.

We can see that the SanFran image should be moved to the right.

We accomplish this by pressing **SHIFT-CTRL right arrow** a few times and then pressing **SHIFT right arrow** to make the match as exact as possible.

[The illustration shows the city of San Francisco as seen from Landsat 7. The prominent dark rectangular region is Golden Gate Park. The dark region under the triangular point at the top of the San Francisco peninsula is the Presidio, with the point itself being the launching spot of the famous Golden Gate bridge. The bridge itself is just barely discernable between the point and the opposite shoreline.]

Manual Georegistration
Merging Layers

Layers can be merged in two ways:

- Copy objects or pixels from one component and paste them into another.
- Create a merged image by using the Tools - Make Image command.

To merge Drawing A into Drawing B:

1. Open Drawing A.
2. Select all objects in Drawing A with Edit - Select All or with CTRL-A.
3. Copy all objects in Drawing A with Edit - Copy or with CTRL-C.
4. Open Drawing B.
5. Paste into Drawing B with Edit - Paste or with CTRL-V. If the data field structure for Drawing A is different than Drawing B, the Paste Objects dialog will be raised to allow us to specify how fields should be pasted.

Do not select any objects in Drawing B before pasting. If any objects are selected in Drawing B just before the paste command, they will be deleted and will be replaced with the objects being pasted.

Copy and paste of pixels also works between images.

To merge multiple image layers into one image:

1. Create a map showing the desired images in the desired layer stack order.
2. Choose Tools - Make Image to create an image component at screen resolution. For greater resolution, first create a print layout of the map, open the layout and use Tools - Make Image to create an image (when used with layouts this command allows choice of resolutions).

A new image will be created in the project that is a combination of the images seen in the map. This image can then be dragged and dropped into a map and used as a layer.

Comments

Why doesn't Manifold simply merge images as does the PhotoShop Merge Layers command? Why require the intermediate Make Image dialog? PhotoShop has a much simpler model of images where pixels are always the same size. Manifold images can be georegistered so that a pixel can represent a very small area on Earth or many square kilometers. The merge process must necessarily resample pixels to interpolate size up or down to merge two images of different size.

Drawings also potentially involve a bit more complexity because two different drawings can have entirely different field structures in their tables.
Maps

Zoom Ranges

The zoom range is a property of projected drawings and other components that appear in maps. Zoom ranges specify the zoom levels at which a component is displayed in a map, including the ability to "pin" the rendering of items to a given zoom level. For zoom levels outside the specified zoom range the component will automatically be hidden from view. The zoom range mechanism therefore makes it possible to create maps where dense components are not seen when the view is zoomed far out and where the component is displayed when zooming far enough into the map.

- Zoom ranges only affect the display of components within maps.
- Zoom ranges only work for projected components. They don't work for Latitude/Longitude unprojected components.

Zoom ranges are set within the native type of component window, but they become operational only when the component is displayed in a map window. Zoom ranges may be set by right-clicking on the layer’s tab in a map window or by opening the layer in its own component window and then choosing View - Properties - Zooms.

To set zoom range, open the component in a window (for example, open a drawing in a drawing window) and choose View - Properties and then click on the [...] button to the right of the Zooms caption to open the Zooms dialog.

The Zooms dialog offers these controls:

- **Minimum zoom**: If blank, show component at any zoom level. If a value is entered, show component at any zoom level above this value and hide it otherwise.
- **Maximum zoom**: If blank, show component at any zoom level. If a value is entered, show component at any zoom level below this value and hide it otherwise.
- **Render zoom**: If blank, redraw points and labels at the same screen size regardless of zoom level. If a value is entered, render points and labels at their specified point sizes only at that zoom level and render points and labels at a larger size when zooming in beyond the specified render zoom level, and render them at a smaller size when zooming out from the specified render zoom level.
- **Current Zoom**: The current zoom of the component when the View - Properties - Zooms dialog was launched. This provides a reference value from which we may get our bearings when deciding what values for zoom ranges or Render zoom we wish to use.
By default the Minimum Zoom and Maximum Zoom ranges are empty, which means the component will be visible in maps at any zoom level. We can choose preset zoom values in factors of ten from 1:1 to 1:1000000000 in the list boxes or we can enter a custom value. The Current zoom number shows the current zoom in the opened drawing window. It will vary as we zoom in or out of the window. It has no effect in setting zoom ranges except to provide a guide that may be used to estimate which zoom values to enter in the Minimum Zoom or Maximum Zoom boxes based on the current appearance of the component window.

![Component window with zoom settings](image)

If we set the Minimum Zoom range value set to 1:10000000 the component will not be visible at all zoom levels up to 1:10000000 after which it will be displayed in maps. If we zoom in to some zoom level below 1:10000000, say, to 1:100000, the component will not be displayed. As we zoom farther out to a zoom level above 1:10000000 the zoom level will appear.

![Component window with custom zoom range](image)

If we like, we can enter a custom zoom range. For example, we can enter 30000000 in the Maximum Zoom box.

This setting of zoom ranges means that the component will be hidden in maps at zoom levels less than 1:10000000 as we zoom farther out and the zoom level goes above 1:10000000 the component will appear. If we continue zooming farther out beyond a zoom level of 1:30000000 the component will disappear. At all zooms between 1:10000000 and 1:30000000 the component will appear.

**Very Important:** Although the zoom range is set when the component window is open, it has an effect only when the component is displayed within maps. Also, zoom ranges can only be set on projected components. They cannot be set for components in Latitude / Longitude coordinates.

See the Turning Layers Off/On by Zoom topic for an example.

**Render Zoom**
The default operation of Manifold within component and map windows is to provide a "dimensionless" rendering of point, line and area styles so that no matter what zoom is selected the styles will appear using the size specified in the format toolbar. For example, if a given point style is specified to be 6 printer's points in size, it will always be shown onscreen exactly 6 points in size. If we zoom in or out the point style will always be shown 6 points in size.

Manifold provides this behavior because vector components such as drawings can be zoomed in or out as much as we like. Normally when, say, many points are clustered together we would like them to continue to be the same size as we zoom further in so that many tightly bunched points can be resolved into visibly separate points.

In the default operation of Manifold, if we wish to have a "paper space" relationship between zooming in and out and the size of symbols such as points, we can use a print layout to create a composition based upon the fixed size of a sheet of paper. When we zoom in and out of a layout, the points and other vector symbols we see will get larger and smaller just as if we were looking at a printed sheet of paper more closely with a magnifying lens or from farther away.

In specialized applications we may want to force component windows to have the same behavior as a print layout display, where the size of labels, points and other symbols will change if we zoom in or out. We can force such behavior by specifying a Render zoom value. The Render zoom value specifies the scale at which styles will be drawn exactly at the size specified in the format toolbar. Zooming farther in, for lower zoom values, will cause the styles to be drawn proportionately larger in size. Zooming farther out, for higher zoom values, will cause the styles to be drawn proportionately smaller in size.

Inexperienced users are often confused between the free-scale world of vector component windows and map windows and the fixed-scale world of a print layout. The normal way of creating displays in which labels and symbols get larger and smaller as we zoom in or out is to use a print layout. Do not use the Render zoom parameter as a sloppy way to get a print layout effect within, say, a drawing or a map window just because the use of print layouts or scaling within print layouts is not understood. Better to study the documentation for print layouts and get those concepts clear so that the right tool may be used.

Keep in mind that one of the significant benefits of component windows like drawings and maps is exactly that they do not mimic the behavior of paper maps. For most purposes the default behavior of component windows provides benefits that would be obscured if symbols and labels were to get larger and smaller as we zoomed in. It is natural for beginners to want to approach GIS using the mental paradigms of paper maps, but it would be a mistake if such an approach denied users the signal benefits of a computerized workspace.

On the other hand, there are times when using a Render zoom value is the right choice. For example, suppose we want to publish a map component to the web using the Internet Map Server and to keep things conceptually simple for some users we want the resultant images to behave like a print layout when they are viewed. In that case, we can use Render zoom to make the image appear like a paper space image so that as visitors zoom farther into the image labels and point styles will appear larger.

**Example**

Consider a map of congressional districts in the US that includes as a layer a drawing containing points for major cities in the US.

We open the map and zoom in to whatever zoom we think will be our "standard" zoom, a typical view.
We then invoke View - Properties - Zooms and note the Current zoom value. It is approximately one to twenty six million.

We can enter 26000000 into the Render zoom box to make this the standard render zoom value.

If we now zoom farther into the drawing the point styles will increase in size. If we zoom twice as far into the drawing the points will be twice as large.
The farther we zoom into the drawing, the larger the point sizes will be, just as if we were viewing a printed sheet of paper through a magnifying lens.

Note that the display computed at the Render zoom value will be the same display, except for increase or decrease in size of symbols and labels, at higher or lower zooms. For example, zooming farther into the map does not allow any overlapping points to be resolved into separate points. This effect can be seen with labels.

Suppose we have a labels layer for the names of major cities in our map and we also set the Render zoom value for that labels layer to 1:26000000 just like the city points layer. Shown above is the map is zoomed to the same starting view, an approximately 1:26000000 zoom. The labels are displayed based upon computations for clipping overlapping labels at that zoom level.

As we zoom farther into the map, the labels simply get larger. No labels are added or deleted.
Just as the case with point styles, the farther we zoom into the map the proportionately larger the labels will become.

Comments

Why are zoom ranges not used in Latitude / Longitude maps? The reason is that such maps use geographic degrees as their unit of measure. Unlike meters or other linear measures used in projected coordinate systems, the size of a degree is different depending on its location on Earth. Degrees near the Equator are sixty nautical miles "wide" (their extent in longitude) but degrees very near the North Pole are only a few meters wide.

Because the size of a degree varies, any scale factor expressed in degrees also varies. If zoom ranges were allowed to apply in maps using Latitude / Longitude, one could have components appear and disappear in maps not as a result of zooming in or out but simply as a result of moving Northward or Southward along a particular meridian of longitude.

**Match**

The *Match* command appears in the context menu for image and surface layer tabs in maps. The *Match* command matches the image or surface in the active layer to another image or surface within the map. *Match* can be used either with surfaces or images. Any image can be matched to another image or surface. Surfaces can also be matched to another image or surface. To simplify nomenclature, this topic describes its use with images. Usage with surfaces and/or images is exactly the same.

*Match* is used to harmonize two images so that they have the same pixel density, the same height and width and use the same coordinate systems. Using one image as a guide, *Match* will resample, crop or pad with invisible pixels the image being matched so that it is the same size and resolution as the other. All necessary coordinate conversions and maintenance of georegistration will be done automatically. Matching images allows them to be used as masks for each other and to be used together for other purposes.

**To match an image or surface to another**

1. Create a map that includes both components. Verify that they overlap.
2. Right click on the layer tab for the image or surface that is to be altered, and choose *Match* from the context menu.
3. In the *Match* dialog choose the image or surface that is to be matched.
4. Press **OK**.

Because *Match* makes the altered image or surface exactly the same size as the component being matched, after the match process finishes you will only see the uppermost component. Unless the upper component is in a partially transparent layer, the lower image or surface will not be seen because it is exactly the same size and beneath the upper image or surface.

*Match* should be used only with images or surfaces that have some overlap when seen together in a map. See the **Troubleshooting** section below.

**Example**

Suppose we have two images in a map.

One image is a small RGB image called *SanFran* showing part of the San Francisco bay area. This small image was created by georegistering the example *SanFran* image and then cropping it to a small region. This image is in Orthographic projection.
The other image was created by importing the `san_francisco-e.dem` digital elevation module data set from USGS as a surface. The surface was then copied and pasted as an image called `Shading`. Because the original DEM data was in Latitude / Longitude projection the resulting image is also in this projection.

Both images are georegistered, so when we place them together in a map they appear in correct alignment. The illustration shows `SanFran` in a layer above `Shading`. The `SanFran` layer has an opacity of 70% so some of the `Shading` layer shows through from beneath to provide a greater sense of relief. Even though the native projections of both images are different, the map shows them together using the map’s own projection.

We would like to be able to use the pixel data from the `Shading` surface as a mask to alter the values in the `SanFran` pixels. To do this, we need to cut the `Shading` image to exactly the same size as the `SanFran` image. Because the `Shading` image is not in Orthographic projection like the `SanFran` image, it must also be reprojected to match the same coordinate system used by `SanFran`. This will involve interpolation of pixels. Finally, the
image must be re-sampled to be cast into exactly the same number of vertical and horizontal pixels as used by 
SanFran. The Match command performs all of these steps automatically in a single command.

Match operates on the image or surface in the active layer. To match Shading to SanFran, we right click on the 
Shading layer to make it active and choose Match from the context menu. This opens the Match dialog.

The Match dialog lists all of the other images and surfaces in the map. In this example, we only have one other 
image, SanFran. We click that image and choose OK.

The result of the Match is that the Shading image is re-projected into Orthographic projection using the same 
parameters as the SanFran image, georegistered to it, and interpolated and cropped so it is exactly the same 
size, position and pixel density as the SanFran image. Seen in the map window, the Shading image is cropped 
exactly to the size of the other image so it lies completely underneath the SanFran image.

If we open each image in its own window and view the two image windows side by side, we could see how the 
Shading image was cropped.
Padding with Invisible Pixels

In the above example, Match matched the size of the Shading image to SanFran and resampled the Shading image so there is a 1:1 correspondence between pixels in the matched image and those in SanFran. Because the Shading image covered a wider geographic area than SanFran the Shading image had to be cropped.

If the Shading image did not cover all of the region covered by SanFran, invisible pixels would have been added to make up the rectangle covered by SanFran.

Suppose we had used a SanFran image that covered a larger geographic region.
When seen in a map with 50% opacity in the upper SanFran layer, we can see how there is an overlap between the two images and there is also a large region that is covered by SanFran that is not covered by Shading.

We can operate Match as before by right clicking on the Shading layer, choosing Match and then choosing SanFran. The result will be that the Shading image is cropped to the region covered by SanFran. However, in this case it is also extended with invisible pixels.
If we click open the Shading image in its own image window and turn on the Border for that window in the Layers pane we can see that the image extends to the East and North of the gray shading region that was part of the original Shading image.

Matching with Overlaps

Suppose we just want the region of intersection between the SanFran image and the Shading image? There are several possible ways to accomplish this. Using Match we could proceed as follows:

We select the invisible pixels in the Shading image. This can be done using Shift-Touch Select or using the invisible pixels selection in the Selections pane.
Next, we use **Edit - Select Inverse** (or the keyboard shortcut **CTRL-I**) to invert the selection and use **Crop** to crop the **Shading** image to the region shown. This is the region of intersection between **SanFran** and the original **Shading**. There is no change in the visual appearance of **Shading** because we have simply cropped out invisible pixels.

Finally, back in the map window we need to crop **SanFran** to the new **Shading**. To do this we can use **Match** once more. To use **Match**, we right click on the **SanFran** tab in the map and choose **Match**. This time we match **SanFran** to the **Shading** image.

![Map image]

Seen in the map window together, the **SanFran** image with an opacity of 50% in a layer above the **Shading** image, both images are now the same visible size with the same number of pixels.

**Use as Masks**

Once it is matched to **SanFran**, we can use the **Shading** image as a mask to adjust the pixel values directly in the **SanFran** image. It's possible to show **SanFran** in a partially-transparent layer above the **Shading** image map, so the shading shows through as seen above, but this effect cannot be controlled as easily in brightness and saturation and other characteristics as adjusting the pixel values directly in **SanFran** with information from **Shading**.

For this example, we will make a copy of **Shading** that is called **Shading 2**. Because **Shading** is matched to **SanFran** each copy of **Shading** will also be matched to **SanFran**. We use **Brightness / Contrast** to lower the brightness of **Shading 2** so it appears in very dark shades of gray.
Next we click on SanFran and choose Edit - Load Mask / Channel. We load Shading 2 into the blue channel of SanFran using Add mode. This adds the values in Shading 2 to each pixel in the blue channel. We repeat this procedure to load Shading 2 into the red and green channels of SanFran using Add as well. The reason we lowered the brightness of the Shading 2 image before using it as a mask is that we knew by adding it to each of the red, green and blue channels we would increase the overall brightness of the SanFran image.

After some tinkering with Brightness / Contrast with the SanFran image we achieve the image on the left. Note how the relief has been enhanced as compared to the original SanFran image seen on the right. The image on the left has much better mountain relief in the upper left of the image as well as in the lower left and in the mountains along the East Bay in the upper right.

The images used in this example are low resolution, small images. The surface used does not have as striking relief as, say, the Montara Mountain example seen in the Surfaces topics. When surfaces are combined in channels with satellite images in high resolution using dramatic relief the results can be truly breathtaking.

Tech Tips

Why did we make a copy of Shading and use that as the mask? This was done simply so that we would have a copy to work with to alter as we desired, secure in the knowledge that we had the original matched image to use should we like to begin again.

We could have processed the Shading 2 image in many different ways before using it as a mask. For example, we could have used Threshold to force pixel values to black or white for a starker effect. For that matter, we could have used Threshold on the original san_francisco-e surface to render invisible all pixels at sea level. That would have emphasized shading and elevation patterns on land only.

Although this topic uses the example of combining a shading image with a photographic satellite image, we will also use Match to prepare many different other types of images for various channel combinations. For example, we may have one image showing temperatures as seen by a satellite and another derived from a surface showing aspect that we wish to combine. Or, perhaps we have one image that has “large” pixels because it was created
using a satellite instrument with 90-meter resolution that we would like to combine in channels with an image from a different band satellite instrument that sees the Earth in 15-meter resolution. **Match** is a handy tool to help match such images so they can be used together.

**Troubleshooting**

**Images or Surfaces must overlap** - **Match** should be used only with images or surfaces that overlap each other when seen together in a map. It doesn't make sense to use it otherwise. Suppose we had two images in a map that did not overlap and we asked Manifold to **Match** image A to image B. Since no part of image A covers the same region as image B, Manifold will merrily extend image A with enough invisible pixels until image A does cover the same region as B. Manifold would then crop the image to leave only those pixels in locations under image B. In essence, it would result in the creation of an image consisting of invisible pixels only. Such situations can be easily avoided: If the two images don't overlap when displayed together in a map, don't use **Match**.

**Match is not a georegistration tool** - Use Georegistration with control points to georegister one image or surface to another. If the two images or surfaces do not overlap with correct geographic georegistration, **Match** cannot force them to overlap by moving them nor does it perform georegistration.

**Match does not move images** - Use georegistration or the techniques in **Repositioning Layers** to move images into alignment. In the overlap example above, note that those parts of the SanFran and Shading images that do overlap are already in exact geographic alignment.

Think of **Match** as a cropping and re-sampling tool to achieve pixel and size alignment between images that are already georegistered. If large images are being used together in a map it is a good idea for simple system efficiency that the projections used by images and surface be the same, and that this same projection is also the one used by the map. Although **Match** will perform any coordinate transformations necessary to also match coordinate systems (projections) the function will work faster if projection conversion is not also required.

**Performance Note**

**Match** provides comprehensive progress bars so it is possible to see how long a particular match will take and to cancel the match if it is taking too long. Because **Match** performs so many functions in a combined way, large images can take a long time to match depending on the speed of the machine.
Transfer Selection

The Transfer Selection command allows transfer of a selection from one component in a map to another. It is most frequently used to select pixels in an image that are within a selection made in a drawing or vice versa. The Transfer Selection command appears in the context menu when right clicking on a layer tab or in the main menu for that component in the main menu bar. It may be used to transfer selections between drawings, images, surfaces and labels in any combination.

To transfer a selection from layer A to layer B:

1. Create a map that shows layer A and layer B together.
2. Right-click on the layer B tab and choose Transfer Selection.
3. In the Transfer Selection dialog, ensure that the checkbox for layer A is checked and the boxes for other layers (if any) are not checked.
4. Press OK.

The Transfer Selection command will transfer the selection from all checked layers to the target layer specified in the dialog’s Modify box. For example, if an area is selected in a drawing layer and the selection is transferred to an image in the map all pixels in the image that fall within the selected area will also be selected.

When used to transfer selections to objects, the Transfer Selection command will select any object that touches (that is, when any part of the object falls within) an existing selection. Pixels are selected if the center of the pixel falls within a selected object.

Controls

Modify  Transfer the selection to this component. Will be loaded by default with the name of the component whose layer was right-clicked to call up the context menu.

Select All  Use all layers in the map.

Select None  Do not use any layers in the map.

Select Inverse  Check those layers not currently checked and un-check those currently checked.

Using  Transfer the selection in the checked layers to the layer in the Modify box.

Example

This example transfers a selection from objects in a drawing to pixels in an image.
We have a map that contains an image called **Australia Image** and a drawing called **Australia and Oceania** that shows boundaries.

We add a drawing called **Circles** in which we create some circular areas. The areas are shown in blue in the illustration above using a 50% Layer Opacity value.

We select one of the circular areas using touch selection. We would like to transfer this selection to the image so that all pixels that lie within this selected circular area are selected in the image.
We right-click on the **Australia Image** layer tab and choose **Transfer Selection**. In the **Transfer Selection** dialog we check the **Circles** box since we only wish to transfer the selection from that layer and not from the other drawing. Press **OK**.

If we turn off the **Circles** layer in the map we can see that the pixels in the **Australia Image** layer that lay within the selected circle are now selected.

**Example**

The previous example transferred a selection from objects in a drawing to pixels in an image. This example shows the opposite situation, where a selection in pixels is transferred to objects in a drawing.

Suppose we select the pixels of the darker region in the image as seen above. The selection was made quickly using touch selection and **Add to Selection** mode. Note that not all pixels in the region of interest have been selected. For our purposes it will not matter that all pixels in the region of interest have not been selected.
We now wish to select those objects in the Circles drawing layer that touch any of the selected pixels. To do so, we right click on the Circles layer tab and choose Transfer Selection. Note that it does not matter that all of the pixels in the region of interest have not been selected since the size of the circles is such that some selected pixels will be in each of the circles.

In the Transfer Selection dialog we check the Australia Image box to transfer the selection from that layer to the Circles layer.

The result is that all four circular areas that touch any of the selected pixels are selected.

Notes

To transfer selections between components the components must appear together in the same map. If the components are not correctly georegistered and so do not appear correctly aligned in the map then the selection transfer process cannot function.
The examples show transfers between area objects in drawings and pixels in images. Other objects, such as lines and points, can also be used. For example, a frequently used technique to extract information from raster images or surfaces into vector form is to create a fine grid of points in a drawing, select certain pixels in an image and then transfer the selection to the grid of points. The drawing's table can then be opened and a value assigned within some field for all of the selected points.

**Tracing**

Tracing is the process of creating drawings from images. By using the pixels of an image as a guide we can trace over the image and create points, lines and areas in a drawing. The tracing process is like laying a sheet of tracing paper onto a photograph and then drawing lines with a pen to outline what is seen in the photo. The photo image is thus converted into a line drawing. Tracing is also called *vectorization* in older GIS systems.

To trace an image we use a map where the drawing layer in which objects are created appears about the image layer. We can then see both the drawing as well as the image being traced. There are two main methods of tracing within Manifold:

- **Freehand Tracing** At any time we can draw points, lines and areas freehand using the pixels within an image as a guide.

- **Tracing Tools** Tracing tools use pixels in the image layer as a guide to create objects in the drawing layer semi-automatically. For example, the *Trace Point* command will create a point at the center of a pixel cloud.

When tracing an image we will usually use a combination of the above methods. When working with compressed images we can use freehand tracing only, since compressed images do not allow any manipulation as is necessary with tracing tools.

**Example**
Suppose we would like to create a drawing by tracing over a satellite image of San Francisco Bay.

If we insert a new drawing into the project and then insert a map that has the drawing in a layer above the image we can use the Tools toolbar to draw points, lines and areas into the drawing using the image as a guide. The illustration above shows we have added six points and have drawn a magenta line.

If we turn off the image layer in the map we can see just the drawing that has been created.

**Typical Workflow for Tracing**

Most tracing of images in GIS is a five step process:
Acquiring the image.

Georegistering the image.

Preparing the image for better tracing.

Tracing the image.

Editing the resultant drawing.

Acquisition of the image is a key step that often drives what happens in the rest of the process. Scanned images of paper maps are often used in tracing projects. Modern scanners have a bewildering array of options that can result in very different image characteristics for the scanned image. For example, some scanner settings will result in Moiré patterns when printed images are scanned at certain scanner resolution settings. We must learn to operate our scanner software well so that the images we use do not introduce any unnecessary difficulties.

Georegistering the image places it in correct relationship to the location of the drawing and the projections that are being used. This is accomplished via control points referenced to known locations.

Preparing the image involves using Manifold image commands to reduce clutter in the image and to clean up parts of the image that will interfere with tracing. We will often make several copies of the image (we do this after georegistering so all the copies are correctly georegistered as well) so that each copy can be differently processed. Preparation might involve relatively simple procedures such as using Threshold to pick out different colors and make all the rest of the image black or white. We might reduce the number of colors or otherwise simplify the image. We might even apply more involved procedures such as manually editing out text or other items that would interfere with automatic tracing tools. When certain very important parts of the image such as a particular region need to be traced we may take the time to select the region, smooth the selection and then adjust the color within the region to a single color so that it can be automatically traced.

Tracing the image is usually straightforward but time consuming. There is a basic trade-off between quality of tracing and the speed with which tracing is accomplished. Using automated tools is faster but results in lower quality tracing. The highest quality tracing is usually accomplished with the simplest methods: trace points at key intersections and then use those points to create lines and areas in the drawing. Areas are often best created by first tracing lines and then using those lines to build areas within the drawing.

Editing the resultant drawing is an inevitable step in any tracing project. It is often much faster to assume from the very beginning that a substantial amount of editing will be done in the drawing. One can then focus on tracing only those parts of the image necessary to build up the drawing as desired. We will often edit the drawing in one window while leaving the map with both the drawing and the image open in another window. We can then easily switch between editing just in the drawing or tracing and editing with the image as a guide.

Freehand Tracing vs. Automatic Tracing

In this documentation, we refer to manual tracing where the operator draws points, lines and areas as freehand tracing. The Freehand tracing topic provides tips for such work.

Tracing where Manifold creates points, lines and areas is called automatic tracing. The Tracing Tools topic discusses tools available for our use in automatic tracing. Surprisingly, it is often faster and more effective to limit the amount of automatic tracing we would like Manifold to perform.

That humans see what appear to be distinct objects in raster images is a trick of human cognition: there are no objects in images, only patterns of colored pixels within a continuous sea of pixels. Humans learn at a very early age to automatically recognize certain patterns of pixels as distinct things. We can do so even give a lot of extraneous pixel junk and other clutter that our brains automatically filter out.

It is the most natural thing in the world for a human to trace a straight line over a fuzzy, pixelated representation of a line; however, programming this simple human action so that computers can trace a straight line through the same fuzzy pixel cloud has proven remarkably difficult. There are no automatic tracing programs that produce entirely satisfactory results in all cases. At best, certain subtasks can be reliably performed if a human operator participates in the process by giving hints to the computer. We give hints to Manifold on what we way by setting the parameters in the Tool Properties pane for tracing commands.

Part of the difficulty in programming the process is the nature of human choice. All images contain ambiguities. We may think in some cases that it is "obvious" how to trace a particular image but this is usually because we unconsciously assume that "of course" certain choices will be made in a given way. When we trace the image manually we make those choices the way we want to make them without thinking twice.
One key aspect of choice is that images are intrinsically imprecise. At the pixel level images are full of ambiguities and imprecision. A very important part of tracing is making a continuous set of small decisions as to where different features are located and where they start and stop. At times this can be quite arbitrary and is simply a matter of "eyeball" judgement. We know how we like to make those judgements but our computer does not.

Everyone would love a tracing program that could take any image and automatically convert it into a vector drawing, pausing only to read our minds to know what it is we would like to do in the case of any ambiguity. So far there is no such program that comes remotely close to this objective. Most "fully automated" tracing programs are instead used to create an intermediate drawing that is then used as the raw material for manual corrections. Basically, the final drawing is created by manually editing the output of a "fully automated" program.

The Manifold viewpoint is that it is faster to use a semi-automated process right from the start. For these reasons the Manifold tracing tools assume that an alert operator usually will participate in the tracing process. The operator makes the big choices by pointing and clicking and by setting parameters while the computer does the drudge work of averaging pixel clouds to find good centerlines for lines and central locations for points.

See the Freehand tracing topic for manual tracing and the Tracing Tools topic for use of automatic tracing tools.

Historical Note on Digitizing Tablets

At times users may be curious why Manifold does not support digitizing tablets as a means of converting paper maps or other paper documents into vector data. The reason is that using scanners is much lower cost, much more efficient and much higher accuracy.

Digitizing tablets were flat panels to which a paper map or other document could be attached. A user could move a sensing stylus or puck to different locations on the paper and press a button to note that location (sensing electronics built into the tablet could determine the location of the stylus or puck at the moment the button was pushed). The tablet could then output the various locations so collected, which the associated tablet software could assemble into points or lines as desired. Some tablets provided more sophisticated functions, whereby the tablet could be used as a sort of mechanical user interface (UI) system together with a computer monitor, allowing the user to click the puck on sections of the tablet marked with a command menu.

Digitizing tablets made sense in an era when computers were weak and had very limited capabilities. Before mice and windowing graphical user interfaces (GUIs) became ubiquitous it made sense to cobble up a mechanical interface that allowed point-and-click interfaces no matter how primitive. Digitizing tablets also had the benefit of producing a relatively small stream of data, only the locations clicked, which could fit within the memory and data processing limitations of computers in that era.

In modern times, of course, the Windows metaphor is universal with every computer equipped with a mouse. Scanners have become so inexpensive that less than $50 buys a scanner that can scan at over 1400 DPI in full color. Once an image of a paper map has been scanned into a computer at high resolution, we can then use the full power of the computer to digitize that image as we would like.

An important benefit of using scanned images is accuracy. Humans cannot position a digitizing stylus or puck on paper with accuracy greater than about 10 DPI. However, once an image has been scanned at very high DPI we can then use the power of the computer to zoom into that image and click onto individual pixels if so desired. That gives humans the power to click with accuracy of thousands of DPI, if desired.

Working with scanned images also allows the computer to assist us with tracing tools such as semi-automated tracing, georegistration of image layers, overlays of other layers at the same time and similar assistance.
unavailable with a digitizing tablet. For example, a user wishing to create a new vector drawing of some region for which only paper maps are available might scan in a paper map, georegister that image using control points and then also link in an overhead satellite photo from an image server, displaying the scanned paper map image with partial opacity in a map over the satellite image.

Tracing can then proceed as a freehand tracing interpolation guided by the user's eye between what the paper map shows (which might be inaccurate due to printing or other errors) and what the satellite photo shows. The result can thus be better than using either a scanned paper map or a satellite image alone.
Freehand Tracing

It's easy to create new drawings in Manifold by tracing over images. Although we may choose to new drawings from images using the help of Manifold's tracing tools at times we will simply wish to trace over an image free hand. Freehand tracing works with all image types.

Suppose we have a georegistered image displayed in a map. To trace over it we begin by inserting a blank drawing into the map in a layer above the image. We then use the image as a guide while drawing points, lines or areas over the image.

See the Adding Shapes and the Adding Points, Lines and Areas topics for information on how to draw shapes.

Example

We have created a new map called trace example that was created use the globe sample image. We then created a new blank drawing layer called trace.

From the Tools toolbar we choose Insert Area with the Create Areas option on and the Create Lines and Create Points options off.

In the illustration above, we began by clicking approximately on the Suez Canal and now have clicked our way about halfway around Africa. When drawing areas, there is always a "rubber band" line closing the area from the location of the first click to the location of the current cursor position.
When we click all the way around Africa to the Suez Canal, we right click to finish the command and create the area.

**Notes:**

The created area does not line up very well with the image because we were too far zoomed out for good accuracy when we created the area (we zoomed out to keep the overall image size small enough to fit into this Help documentation). For better detail, we should zoom in further. When inserting a shape, the map view will automatically scroll when the cursor gets near the window border.

The color of the preview line shown in the shapes toolbar can be adjusted in Tools - Options. If we were tracing over a uniformly dark image, the black line shown in the first illustration above would not be visible. We could change this color to bright red or some other color visible on a dark background.

Sensible use of Snap and other guide options will allow us to align our mouse clicks to the underlying image with great accuracy. This example is designed to show the concept of tracing over an image in a simple way.
Tracing Tools

If we do not wish to use freehand tracing, Manifold provides tools to make tracing easier by creating points, lines and areas for us in a semi-automatic way. The tracing tools are found in the **Tracing toolbar**. The Tracing toolbar works within maps to create objects in drawings by using pixels in an image layer to guide the creation of objects in a drawing layer. This function is called **vectorizing** in older GIS packages.

Tracing tools work with all image types except compressed images - to trace compressed images, use freehand tracing.

### Trace Auto

Autoselect between creating areas or points depending on Tool Properties when clicking on a region of pixels of a similar color within the given tolerance.

### Trace Area

Create an area when clicked on a region of pixels of a similar color within the given tolerance. A **Shift click** will create areas within all such regions that qualify as areas throughout the image. Potentially slow in large images or complex shapes.

### Trace Line

Create line when clicked on a region of pixels of a similar color within the given tolerance. A **Shift click** will create lines within all such regions that qualify as lines throughout the image. Potentially slow in large images or complex shapes.

### Trace Point

Create a point when clicked on a region of pixels of a similar color within the given tolerance. A **Shift click** will create points within all such regions that qualify as points throughout the image.

(CTRL click) 

CTRL clicking with a trace tool tells the tool to build objects only in regions where pixels are the same color as the tracing color well. If the tracing tool is clicked on pixels of any other color no tracing will occur.

(SHIFT click) 

SHIFT clicking is an "open" command. It tells the trace tool to build objects in all regions throughout the image where pixels are colored like the place clicked. Caution: in a large image this can take a very long while.

### Pick Color

(Not on the tracing toolbar) This tool is on the editing toolbars for both drawings and images. It is listed here because it is frequently used with the tracing tools. Sample the color in the clicked pixel and use it as the foreground color. A **Shift click** chooses the background color.

Tracing toolbar buttons are enabled when a drawing layer in a map is clicked. Tracing commands require both an image and a drawing layer in the map. The pixels in any visible images layers are used as a guide to create objects in the active drawing layer. Normally we will use several different drawing layers and switch between them so different objects may be created in different drawing layers.

**Tool Properties Controls when Tracing**

All images consist of a sea of pixels. The only thing that differentiates one pixel from another is its color. Tracing tools all work by examine the colors of pixels at the place they are clicked and will continue to search from that initial click point to see how far the clicked color (within the tolerance specified in **Tool Properties**) extends into surrounding pixels. Tracing tools use the parameters specified within Tool Properties to decide how they should deal with the pixels they find that are contiguous with the pixel clicked.

**Snap Tolerance**

When a snap mode is on, the distance in pixels or physical units within which the cursor must be to a given
snap item (such as a line when snapping to lines) before the cursor snaps to that item.

**Value Tolerance**
Color tolerance to use to reckon that pixels are the same color as the pixel originally clicked.

**Point size**
A distance parameter given in native drawing measurement units that is used to distinguish a point from an area. Pixel regions smaller than this distance will be created as points, while those larger than this distance will be created as areas.

**Match neighbors**
When automatically creating areas, fill in the area to align exactly to the edge of any neighboring areas that already exist.

**Trim size**
A distance parameter given in native drawing measurement units that is used to trim unwanted side lines when automatically creating areas.

**Pick Color**

The color picker sets foreground color by sampling a color in an image. Clicking into the foreground color well and drilling down into the color dialogs will show the RGB value of the color chosen with the color picker tool.

Color picker action:

- Clicking anywhere in an image with **Pick Color** chooses the color of the clicked pixel for the foreground color.
- **Shift** clicking anywhere in an image with **Pick Color** chooses the color of the clicked pixel for the background color.
- When the Layers pane is used to turn channels off **Pick Color** will only pick those color values represented by the channels that are visible.
- When only the Alpha channel is turned on in the Layers pane, clicking **Pick Color** into the image will pick a grayscale color value representing the value of the Alpha Channel.
- Clicking **Pick Color** on invisible pixels results in no change.
- When used in a map **Pick Color** chooses color from the highest visible image in the map layer stack.

**Restricting Tool Action by Color**

Tracing tools can be set to use the color shown. Tracing tools normally create objects based on whatever color exists at the point they are clicked. If desired, we can force the tool to use only the specified color by **CTRL clicking** with the tool. This is useful when clicking onto small portions of the image. Set the desired color and then **CTRL click** with a tracing tool to be sure we are clicking only on that color. **CTRL clicking** on other colors will have no effect.

**Tracing Many Objects at Once**

Normally, **tracing** tools will trace just the region of pixels on which the tracing tool is clicked. **SHIFT clicking** on a spot in an image with a tracing tool will cause all regions of pixels of the color clicked to be traced. In Manifold, a **SHIFT** is usually an "open" command. For example, in **Select Touch** a click will select all contiguous pixels like the one touched while a **SHIFT click** with **Select Touch** will select all pixels like the one touched throughout the entire image even if they are not contiguous.

The **SHIFT click** tracing command applies only to that tool used. Using it with **Trace Line** will trace only lines within all pixel regions like the one touched. **Trace Auto** will automatically trace areas, lines and points throughout the image when used with **SHIFT click**.

**Point size and Trim Size**
The **Trace Auto** tool needs to know if it has been clicked on a region of pixels that qualifies as a point or an area. It does this using the **Point size** parameter in the **Tool Properties** pane.

For example, in the illustration above we would want the **Trace Auto** tool to trace the larger purple rectangles as areas and not as points. To make this determination, the tool sees how far the clicked pixel color extends into neighboring pixels and compares it to the **Point size** parameter. If the clicked color extends in all directions no more than the point size parameter, the trace tool knows it has been clicked on a point. If the clicked color extends further than the point width parameter, the trace tool knows it has been clicked on an area.

When autotracing lines the **Trim size** parameter helps the system avoid following a pixel fog into unreasonably complicated lines. If lines are growing undesired side branches, the **Trim size** parameter may be modified.

Note that the **Point size** and **Trim size** parameters are given in the native measurement units of the target drawing. Fractional values are allowed. For projected drawings, the native measurement unit is normally meters or feet. By definition, this means that for sensible use of the **Trace Auto** tracing tool the image and drawing should be in a projection, most likely a meter-based projection.

**Example**

Suppose we wish to trace over some elements of a scanned paper map.

We begin by choosing the **Trace Area** tool and clicking onto the large purple rectangle.

The point where the **Trace Area** tool cursor is first clicked choose the color used to find the area. In this case the tool finds all contiguous purple pixels from the central point. If the **tolerance** factor was set very high the tool would use the lighter purple pixels as well.
The area is created in the region of purple pixels.

We can click on other of the purple rectangles with the Trace Area tool to trace them into areas as well.

If we Shift click on one of the purple rectangles, the Trace Area tool will create areas for all such regions of clicked color.

To create a line we choose the Trace Line tool and then click on the brown contour line just below the two large rectangles we traced into areas.

When we click onto a brown pixel in the line the tracing engine follows contiguous brown pixels up and down to see where the line object should be created.
We show the approximate region where the line is created in magenta pixels, with the line object that was created drawn in black.

On zooming out we can see the line has been created. It is shown as a thick magenta line so it is more easily visible. Note that the new line has been created from the point where the brown pixels ended at the "200" number in the lower left up to the point where the brown pixels ended at the "P" in the "Alpine" letters. While text within the image may be very helpful to readers when it gets in the way of tracing lines it is simply clutter.

We can create points with the tracing tools as well.

To create a point, we choose the Trace Point tool and then click on regions of pixels that we want interpreted as points. In the above case, we can click on the two black dots near the line that was just traced.

The trace tool will follow the black color of the point from the place clicked as shown in the illustration above, which is zoomed far into the image. If our Point Size tool property setting is wider than the geographic distance covered by the pixels that make up the dots they will be interpreted as points and will have a point object created at the center of each.
Because points are often represented by small regions of pixels it is often most convenient to zoom into the point before clicking on it. This avoids accidentally creating a point if we click on some pixel junk near the region on which we intended to click.

**Tracing with Multiple Images Visible**

We may wish to trace using maps where several images are visible at the same time. The tracing tools auto-select which image is used for tracing by choosing the highest visible image at the location where the tool is clicked. That image is then used to guide tracing. This is similar to the action of the **Pick Color** tool, which picks color from the highest visible image in the map layer stack.

The illustration above shows the scanned paper map image used as an example earlier in this topic. Above it in the map layer stack is a drawing and then above the drawing is an RGBA image that contains several semi-transparent rectangles with invisible pixels between the rectangles.

The illustration above depicts the two image layers as we looked at them in a perspective view. The drawing layer (not shown) is between them. The rectangles in the upper image have been made semi-transparent so we can see what happens underneath them.

If we use the **Trace Area** and **Trace Line** tools and click on the points indicated we will be clicking onto the scanned paper map image. In those locations the uppermost image has no visible pixels. Thus, the first visible image layer under the point being clicked is the scanned paper map image's layer.
The result is that the tracing tools create objects in the drawing layer by following pixels in the scanned paper map image. The tracing process follows the pixels in the scanned paper map layer even when those pixels lead "underneath" visible pixels in overlying layers. Note how the traced line object goes underneath the overlying semi-transparent rectangle, for example.

If we would like pixels from several images to guide the action of tracing tools we should first merge those image layers into one image layer (by showing the layers to be combined in one map and then using Tools - Make Image to create a single image) and then use that one image layer to guide tracing.

**Example**

In this example we show how to use tracing tools with surfaces to create areas from a surface. This is an atypical usage of tracing tools that uses an image as an intermediary step.

Let's begin with the Montara Mountain example surface from the Manifold CD. Our objective is to create areas in a drawing that exactly overlay a region of interest in the surface. This is a common task when creating drawings from surfaces, for example, to create vector maps of islands or other features in regions where we have terrain elevation data but no other detail.

We copy the surface and work with the copy of the surface so that any changes made are not permanent.
We begin by selecting the region of interest. We can use whatever selection tools we like, for example, touch selection using add and subtract selection modes.

We press **Edit - Delete** to delete the selected pixels.
We use Tools - Make Image to make an image of the surface, we create a map based on that image and then we open the map.

We zoom into the image to a region that shows the "deleted" part of the surface. Note that when seen in the surface the deleted region shows the default checkerboard background. In the image, which is a literal snapshot of the screen, this part of the image is not transparent pixels but rather consists of light gray and white pixels that render the checkerboard background as it was seen.

We select the region of darker gray boxes by using **SHIFT - Select Touch**.
Next, with selection mode set to **Add to Selection** we select the region of white boxes by again using **SHIFT - Select Touch**.

Finally we select the grid between the boxes with one more **SHIFT - Select Touch** click.
With three quick clicks we have selected the entire region of pixels in the image that represent the region selected and then deleted in the surface.

To make this region stand out we launch the **Image - Adjust - Hue / Saturation** command and adjust **Lightness** all the way to -100. Press **OK**.
This makes all pixels in that region black. This is a color that does not otherwise occur in the image so it is a useful way to mark the desired region with easily discernable pixels.

We add a new drawing to the map and with the drawing being the active layer click on Trace Area and then we click on one of the black pixel regions.
This creates an area in the drawing that overlays the region of black pixels. We click the Trace Area tool cursor into the other black region.

This creates another area overlaying the other region of black pixels.
If we turn off from display the image layer we can see that we have created a drawing with two area objects that precisely overlay the region of pixels that were selected in the original surface.
Labels

Text labels are added to maps with Labels components. To add labels to a map we create a labels component and add it as a layer to the map. We can add the text for labels manually in a labels component, or we can have Manifold automatically create labels by deriving them from objects in a drawing. When labels are automatically created from objects in a drawing, Manifold will use the locations of the objects to place labels and can automatically create the text for those labels by using data from the drawing's table.

A labels component contains information showing where all labels should be placed, the text they contain and how that text should be displayed, including the geometric shape of the label as well as formatting information such as style, font and colors to use.

Labels components may be opened in their own windows or used as layers in a map together with other components such as drawings and images. Except for the labels they contain, labels components are completely transparent and may be stacked as layers in maps to create whatever effect is desired.

For example, the map shown above consists of a drawing layer with two labels layers above it.

The drawing layer shows the shoreline of Europe.
One of the labels layers, called **Land**, is used to host labels indicating regions on land. Labels in this layer are formatted in the style seen above for **Italy** and **Sicily**. Text in this layer is boldfaced using *Times Roman* font in black foreground color.

Although normally layers labels are displayed within map windows, we can also open a labels component in a labels window as seen in the illustration above. Because the labels component is completely transparent except for the text labels it contains, we can see the default checkerboard background in this window. To show a solid background instead of the checkerboard pattern, open the Layers pane and click the **Background** layer on. If the labels component shows a solid background and we prefer the transparent checkerboard pattern, we can click the **Background** layer off in the layers pane.

A second labels layer, called **Sea**, is used to host labels indicating sea areas. Text in this layer is formatted using the *MS Sans Serif* font, boldfaced, in blue foreground color.

The composite effect seen in the map is like stacking two transparent sheets of labels layers above the drawing layer.
We can use many different labels layers to create labels in the map in whatever formatting is desired. The
different layers may be clicked on and off, and can be controlled on a layer-by-layer basis.

Important Options for Labels Components

Manifold may be used in very many different types of applications, so Manifold provides many options for creating
and working with labels. There are capabilities for working with labels manually, for having the system create
labels automatically for us and for a combination of both manual and automatic labels. There are three main
option choices when working with labels:

- **Bound** or **Unbound** labels - Unbound labels are manually created in a free-form way. Bound labels
  are “bound” to a drawing because they are created automatically or semi-automatically from that
drawing. Bound labels may be converted to unbound labels with the Labels - Unlink command at
  any time, but unbound labels cannot be converted to bound labels.

- **Synchronized** or not synchronized - Bound labels can be **synchronized** so they automatically pop
  into existence or are deleted as objects in their parent drawing are created or deleted. Unbound
  labels have no connection to any drawing so this option does not apply to unbound labels.

- **Per-Label Format**, On or Off - By default, the Format toolbar controls the appearance of all labels in
  a labels layer. Turning on per-label formatting makes it possible to independently set the format of
  individual labels. This is very convenient for some purposes but requires extra thought or better
  user organizational skills in some circumstances. Per-label formatting may be turned on or off at
  any time for any labels component using the Labels - Per-Label Format setting.

The choices we make within the above options allow us to specify how labels components behave in our
application, ranging from an exclusively manual, label-by-label control over the placement and appearance of
labels (using unbound labels with per-label formatting turned on), to fully automated creation and placement of
labels (using synchronized bound labels with per-label formatting turned off) or any combination of manual and
semi-automatic functionality in between.

Bound and Unbound Labels Components

Labels components may be **bound** or **unbound**. Unbound labels are manually created, and bound labels may
be automatically created.

- An **unbound** labels component is like a notepad where we can manually add whatever labels we want
  at whatever position we want. Unbound labels components may also be referred to as standalone
  labels components.

- A **bound** labels component is automatically derived from a parent drawing using the positions of
  objects in the parent drawing to specify the positions of corresponding labels. A bound labels
  component is by default synchronized with its parent drawing. By default, there will be a label for every
  object in the drawing and each label will be located exactly at the same position as its parent object.
  Labels bound to lines will by default be aligned to follow those lines, even if the lines are curved lines

Although any labels component may be opened in its own window as well as being used as a layer within a map,
unbound labels components are almost always used only within a map.

AGUASCALIENTES

Because labels components are completely transparent except for the labels they contain, as seen above it is
difficult to maintain visual orientation when an unbound labels component is opened in its own window unless
some other objects can be seen. Unless other layers in a map provide a visual context for position and zoom level it is difficult to work with an unbound labels component on its own.

When a bound labels component is opened in its own window the objects in the parent drawing from which the labels are created will be shown in the background in light gray color as seen in the illustration above. This provides visual context for the labels and makes it easy to work with an unbound labels component either in its own labels component window or as a layer within a map.

A bound labels component may be converted to an unbound labels component by right clicking on the labels component in the project pane and choosing Unlink. The synchronization of a bound labels component to its parent drawing may be turned on or off. The position of label and its metric, that is, the geometric shape that defines that label (normally the location of a point or of a linear shape followed by the label) may be edited.

The Create Labels Dialog

New labels components are created with the Create Labels dialog.

There are three main ways of launching the Create Labels dialog:

- In the main menu, use the File - Create - Labels command. This creates a new labels layer in the project pane.
- Right click in the project pane, either on a drawing component or on an empty portion of the project pane and choose Create - Labels in the pop up context menu. This creates a new labels layer in the project pane.
When a map window is open, right click onto the layers tabs and choose Add - New Labels. This creates a new labels layer in the project pane and after the labels component is created it will be automatically added to the map as a layer.

The Create Labels dialog uses the following controls:

- **Name**: Name to use for the new labels component.
- **Parent**: Contains a list of all drawings in the project as well as a [None] option. Choose the name of a drawing as a Parent when creating a bound labels component. Choose [None] to create an unbound labels component.
- **Columns**: Shows the column names and database type of each column in the parent drawing's table. Enabled when a drawing is chosen as a Parent.
- **Text**: Text to use for the label. May contain a combination of user supplied text as well as the names of columns in [ ] brackets. Column names in brackets will be substituted with the value of that column for the object to which the label is bound. Enabled when a drawing is chosen as a Parent.
- **Automatically label new drawing objects**: If checked, automatically create new labels when new objects are added to the parent drawing. Enabled when a drawing is chosen as a Parent. Checked by default. Labels components with this option checked are said to be synchronized with their parent drawing. See the Synchronized Labels topic.
- **Use per-label format**: If checked, each label will be individually formatted. If not checked, labels will be formatted in accordance with the format toolbar for the labels component until they are selected to be individually formatted. Not checked by default. See the Formatting Individual Labels topic.

To create a labels component we can right click into the project pane and choose Create - Labels. This launches the Create Labels dialog.
If we right-clicked onto a blank portion of the project pane the Create Labels dialog will be launched with no Parent drawing specified by default and those portions of the dialog that would normally work with fields available in a parent drawing will not be enabled. Use this path, or choose [None] in the Parent box to create an unbound labels component.

On the other hand, if we wish to create a bound labels component we can right click onto a drawing in the project pane and then choose Create - Labels in the pop up context menu. In this case the Create Labels dialog will launch with the name of the drawing we right-clicked already loaded into the Parent box.

To Create an Unbound Labels Component

1. Open the map window in which the labels component will be used.
2. Launch the Create Labels dialog, most conveniently by right clicking on a layer tab and choosing Add - New Labels.
3. In the Create Labels dialog, verify [None] is the choice in the Parent box and press OK.
4. Drag and drop the new labels component from the project pane into the map window. This adds the labels component to the map window as a layer. This step is not necessary if we created the labels layer by right clicking on a map layer tab and choosing Add - New Labels, as this method will automatically add the new labels component to the map after it is created.
5. Click on the labels layer tab to make it the active layer.
6. Click the Insert Label button.
7. Click in the map window wherever a label is to be added. In the Insert Label dialog, enter whatever text is desired.
8. Unclick the Insert Label button when finished adding labels.
9. Change the settings in the Format toolbar to change the appearance of the text.

The new unbound labels component will appear in the project pane at its own level and not indented underneath another component.
By opening the map window first and then using File - Create - Labels when the open map window is the active window, we automatically create the new labels component with a native projection that matches the map. Since labels components are almost always used only within map windows it makes sense to create them using a native projection that matches the projection in use in the map window.

To Create a Bound Labels Component

1. Using either File - Create or by right clicking in the project pane and choosing Create - Labels, launch the Create Labels dialog.
2. Choose the name of the parent drawing from the list in the Parent box.
3. Specify the text desired for the label in the Text pane, using fields from the Columns pane above if desired. Press OK.
4. Open the map, and drag and drop the new labels component from the project pane into the map.
5. Click on the labels component's layer tab in the map to make it the active layer and use the Format toolbar to change the appearance of the labels as desired.

The new bound labels component will appear in the project pane indented underneath its parent component.

When creating a bound labels component the labels component will be created using the projection parameters for the parent drawing.

Labels Menu Commands

The Labels menu will appear in the main menu when a labels component is the active component.

- **Add** Appears when a labels layer in a map has the focus. Allows creating and adding a New Drawing, New Image or New Labels component to the map, as well as calling the Add Layers dialog to add or remove layers from existing components in the project pane.
- **Open Drawing** Open the parent drawing for this labels component. Enabled for bound labels only.
- **Open Table** Open the table for the parent drawing of this labels component. Enabled for bound labels only.
- **Text** Open the Text dialog to allow altering label text. Enabled for bound labels only.
- **Per-Label Format** Shows current state of and also toggles per-label formatting on and off for this labels component. See the Formatting Individual Labels topic.
- **Synchronized** Shows current state of and also toggles whether or not this labels component automatically creates a label for each new drawing object. Enabled for bound labels only. See the Synchronized Labels topic.
- **Unlink** Convert a bound labels component into an unbound labels component. Enabled for bound labels only.
Changing Label Text

To change the text of an unbound label, right click on the label and choose Edit from the context menu. In the Edit Label dialog change the text to whatever is desired.

To change the text used in bound labels, in the main menu choose Labels - Text. The Text dialog that is launched reproduces the column pane and the text pane from the Create - Labels dialog so that the text used for bound labels may be changed.

Creating Labels from Fields

Bound labels allow us to create automatically many labels at once by using text fields in tables associated with drawings. We do this by using the Edit - Create - Labels dialog to create a bound labels component that is derived from a particular drawing. See the Creating Labels from Fields topic.

Pasting Objects as Labels

If we copy objects from a drawing and paste them as labels, Manifold opens the Paste Labels dialog to allow us to specify how we want those labels to be created using the following controls:

- **Columns**: Shows the column names and database type of each column in the parent drawing's table.
- **Text**: Text to use for the label. May contain a combination of user supplied text as well as the names of columns in [ ] brackets. Column names in brackets will be substituted with the value of that column for the object to which the label is bound.
- **Link labels to drawing objects**: If checked, create a bound labels component. The default is not checked so that an unbound labels component is created.
- **Automatically label new drawing objects**: If checked, automatically create new labels when new objects are added to the parent drawing. Enabled only if the Link labels to drawing objects option is checked. Labels components with this option checked are said to be synchronized with their parent drawing. See the Synchronized Labels topic.
- **Use per-label format**: If checked, each label will be individually formatted. If not checked, labels will be formatted in accordance with the format toolbar for the labels component until they are selected to be individually formatted. Not checked by default. See the Formatting Individual Labels topic.

The dialog allows us to use content from database fields even if the Link labels to drawing objects option is not checked. If it is not checked, the database field values will be substituted into the label text on a one-time basis to create unbound labels with that text. If it is checked, the database field values will be dynamically applied on a continuing basis to create bound labels using that text.

By default, the Automatically label new drawing objects option is off so that unsynchronized labels are created. This makes it possible to paste a subset of a drawing to create labels only for the pasted objects.

When pasting drawing objects to create labels, the labels component is created using the same projection as the originating drawing.

Labels and Projections

Labels components have projections just like drawings and other components.
• A **bound** labels component always takes its projection from its parent drawing. A bound labels component cannot be re-projected into a projection different from its parent drawing. If the parent drawing is re-projected to a new projection, any labels components bound to that drawing will be re-projected as well into that new projection.

• An **unbound** labels component has its projection defined based upon the circumstances of its creation. If some other component is open and has the focus the unbound labels component will be created using whatever projection that active component uses. If no other component has the focus, then the labels component will be created using the default Orthographic projection. Unbound labels components may be re-projected into whatever new projection is desired.

The above system is very similar to that used for assigning projections when new drawings or other components are created, with the exception that the projection of a bound labels component is always synchronized to the projection of its parent drawing.

**Controlling Zoom Range for Labels**

We can turn labels components on and off for display in maps the same way that drawing layers are turned on and off for display: use Zoom Ranges to set the zoom range over which the labels component should be displayed. Zoom ranges work only with projected labels components and do not work for layers components using a latitude / longitude, unprojected coordinate system.

This capability will often be used when creating labels components that contain lots of labels. The zoom range can be set so labels are visible only when zoomed far enough into the map so that the visible labels can be distinguished from each other. For example, when viewing a map of an entire country a labels layer that shows labels for smaller towns may have zoom ranges specified so that those labels are not displayed when the view is zoomed out so the entire country is seen. The zoom ranges would be arranged so that as we zoom farther into the map so that only more local regions are in view then labels for smaller towns will be displayed. See the Turning Layers Off/On by Zoom example topic.

Note that at some zooms labels may disappear even if a zoom range has not been specified. Labels bound to line objects, for example, will only appear if the line is large enough for the label to fit at the current zoom. As we zoom farther out and lines get smaller, labels bound to those lines will eventually not be able to fit into the smaller space the line occupies on screen.

**Antialiasing**

By default, text labels in Manifold are not antialiased. Checking on the **Antialias text** option in the user interface section of Tools - Options will cause text in labels to be antialiased.

When the **Antialias lines** option is checked (it is on by default) lines, the borders of areas and the borders of text boxes used with labels will be antialiased.

**Creating Line Labels**

In addition to the default **Insert Label** command button shown above, Manifold provides commands to create labels that are aligned to lines.

- **Insert Line Label**  
  Add a text label aligned to the guideline composed of straight line segments that is drawn with the insert tool.

- **Insert Freeform Line Label**  
  Add a text label aligned to the freeform, curved guideline that is drawn with the insert tool.

These tools create labels in the shape of a guideline, either a guideline consisting of straight line segments or a more curved, freeform guideline. The line label tools are much less frequently used than the default **Insert Label** command because the labels they create tend to be useful only at the zoom level at which they were created.

Line labels are aligned to a guideline, which is an invisible line to which the label is aligned. If the label is selected for editing by CTRL-Alt clicking on the label, the guideline will become visible.
Line labels can only use a plain text style or a halo or shadow style. Line labels using other styles will be rendered as plain text. Line labels can only contain one line of text. If more than one line of text is entered when creating a line label the lines will be concatenated together into a single line of text.

**Example**

To use the **Insert Line Label** command, open an unbound labels component and click on the **Insert Line Label** tool.

Click where the guideline is to begin, and then click at the next coordinate of the guideline.

Continue clicking at each coordinate defining each guideline segment.

Click the coordinate for the end of the line and then right click to end construction of the guideline.

The **Insert Label** dialog will pop up. Enter the text desired for the label and press **OK**.

The new line label will appear.
If we unclick the **Insert Line Label** button (so the mouse is not engaged with that command), we can **CTRL-Alt** click the newly-created label to select it for editing. That will cause the guideline to appear with edit boxes at the coordinates defining the guideline. We can adjust the shape of the guideline (and thus, the label) by clicking and dragging edit handles. We can move the entire guideline by **SHIFT**-dragging an edit handle.

Note that the label does not occupy the entire guideline. At the zoom in use the default text size is not large enough to fill the entire guideline.

If we use the format toolbar to increase the size of the font, we can see that the label expands to use more of the guideline.

The size of the label text on the screen will be fixed at the given point size of the font. If we zoom in or out the label text will stay the same size. However, the guideline will appear to be larger or smaller as we zoom in or out because the guideline has a true geographic dimension.

For example, suppose we zoom into the view so that the guideline appears larger. The label text stays the same size and will fill less of the guideline. Because label text is centered on the middle of the guideline, the label text will be aligned to only that much of the guideline that extends from the center to the distance required for the text.
We can zoom even farther in to see this effect.

If we understand how line labels work and we have a label selected for editing so the guideline appears, it is clear how the label automatically aligns to that part of the guideline it occupies at any given zoom level. However, if the label is not selected for editing (the default), it can be disconcerting to see the label change shape as it adapts to an invisible guideline.

For example, if we zoom out the label changes shape...

...and then changes shape yet again as we zoom farther out.

Because of the above behavior, line labels are best used at a given zoom. They are normally used to annotate geographic features where a particular zoom will be used for a final view. For example, we might want to create a curved label that follows the arc of a coastline. The label will have a correct appearance at the zoom level in which it was drawn, but zooming in or out will alter the appearance. That doesn't matter if we are composing a map to be seen at a particular zoom.

**Using the Layers Pane with Labels**

The Layers pane helps control the appearance of labels within label windows. The layers pane includes checkboxes for two system "layers" - a background color layer and a border layer that shows an enclosing box about the height and width of the label.

By default, labels are shown against a white background (or whatever color has been set to be the default background color). Un-checking the **Background** box will use a checkerboard background pattern. Manifold uses to provide a backdrop for any transparent regions. Checking the **Border** box in the layers pane will draw a one-pixel border around the height and width of the label. This is a good way to see the actual extent of a label that contains regions of invisible pixels.

Note that only maps can have true "layers" in Manifold in the sense that they can layer more than one component within the same map window. The border and background "layers" in the Layers pane for labels are not true layers even though they appear in the Layers pane in the same manner as do layers in maps. These are simply system controls that take advantage of the Layers pane as a conceptually convenient user interface.
Layouts and the Layers Pane

If a labels component has any Layouts created they will appear as "layers" in the layers pane for that labels component. Checking the box for one of these print layout layers will cause a layout rectangle to appear in the labels window that shows the region covered by the layout.

Right clicking onto the hatched border of one of the layout rectangles in the labels window will cause a context menu to appear with controls based on that layout rectangle. For example, we can Zoom to a given layout rectangle, Print it or change its Properties. If a layout is empty (for example, if the layout scope is set to selection and no labels are selected in the parent labels component) zooming to the layout will do nothing.

Use Tools - Options - Colors - Layout Rectangle to change the color in which layout rectangles are shown. The default color is black.

Advice for New Users

Users new to GIS who are familiar with graphics arts editing packages such as Adobe Illustrator are sometimes baffled by the focus of Manifold on automated facilities for the construction of labels. There are several reasons why GIS has evolved a more automated focus on label creation and manipulation than have graphics arts packages:

- GIS is used for much more than static cartography, so it must have capabilities to support those other uses.
- GIS displays are normally automatically-created, dynamic displays while graphics arts packages are used to create static, predictable compositions.
- GIS tends to work with immensely larger data sets than do graphics arts packages.

Graphics arts professionals new to GIS often do not realize that the usage of GIS packages to create static cartography, that is, to create fixed maps for publication, is but one small part of how GIS packages are used, however important that task may be. If your job has been creating maps with a graphics arts package such as Adobe Illustrator, it is only natural that your first exposure to GIS would arise from such tasks and that your first interest would be in how to use a GIS package to accomplish similar cartographic objectives.

However, one reason graphics arts professionals are drawn to GIS is that GIS provides many capabilities, principally those revolving around the tying of database information to geography and geometry, not found in graphics arts packages. The main value of GIS in most applications is the use of visual representations of data, such as maps, to get a handle on complex data relationships that would be very difficult to see by scanning through rows and columns of letters and numbers.

Labels play an important role in many such uses, but just as numbers must be automatically computed in spreadsheets for the spreadsheet to work, in GIS applications using visual displays to explore data, labels must pop into existence as needed in the form needed to support such data management.

In these and many other uses of GIS the visual display of data in GIS packages is highly dynamic while the purpose of a graphics arts package like Illustrator is to create a single, static composition.

Automatic creation and control of label characteristics is very important because many times the projects we create in Manifold will be seen through views that are automatically created and that cannot be predicted in advance. For example, if we create a map with many layers in Manifold and that map is displayed to people through a Manifold Internet Map Server web site, each view seen in that web site will be automatically created depending on how that particular user zooms or pans into the map. In such views labels had better be automatically created, sized and placed so that each view that is created is reasonably attractive and useful for its intended purpose.

Even in the simple case of ordinary interactive usage of Manifold, when someone pops a map open on their desktop and then zooms in or out or pans the map to different locations the views will constantly change in terms of zoom level or location. Any labels that are in play must automatically be adapted to the new view for the labels to play their intended role. They must be created or hidden, moved to slightly different locations, change their shape to adapt to a different shape of a line at different zoom level and so on.

That's a situation very different from Illustrator or, say, PhotoShop, where we might spend a lot of time getting some graphic image exactly right. But every professional graphics designer who has spent hours of effort on an
Manifold® System Release 8.00 User Manual

Illustration for a journal article or for an advertisement has done so based on a specific, static understanding of the composition. If the map changed to show different material the composition would also have to change.

Finally, the amounts of data encountered in GIS are vastly greater than are used with graphics arts packages. Much GIS data is automatically harvested by satellites and then converted into huge raster and vector data sets, possibly with connections to hundreds of fields of information for each object in the map. A data set representing a world map might contain hundreds of gigabytes of information and even a simple local map might include many thousands of objects and tens of megabytes of data. A GIS working with such data must have the ability to manage large amounts of data to reduce it down to what is of interest.

Labels created from such data are best created automatically, since few people are interested in manually sifting through tens of thousands of objects to decide which should be labeled by hand. In fact, automation of such tasks is exactly why a graphics arts professional might be forced to undergo the supremely unpleasant task of learning a new and unfamiliar software package.

It is true of course that none of the above points prevent a GIS package from acquiring the facilities for manual graphics arts editing that we take for granted in a package like Illustrator. However, the above factors place the priority of what features are implemented by the GIS vendor more on automated label facilities to support the distinct usages of a GIS package. As time goes on and Manifold continues to evolve, more and more features similar to those in graphics arts packages will be available in addition to those distinctly GIS features already implemented.

Users who have strong feelings about desired labels features should visit the Support page on the manifold.net web site and read the link on that page that gives advice on making suggestions and user advocacy and then send in a suggestion for what is desired.

**Tech Tips**

Labels components may be copied and pasted as a drawing. The result will be a drawing of points where each point has a "Text" field in the drawing's table that contains the contents of the label text. Copy labels and Paste As a drawing is used in two situations:

- When importing some formats, such as .e00, the result of the import may be a labels component where we would also like to have a drawing showing a point at each label location.
- Labels components may be exported to AutoCAD DXF format. See the Export Drawing - DXF topic.
- Copying a labels component and pasting as a drawing is a quick way to move the labels text into a drawing of points that have one text field. Exporting such a drawing might be a useful way of exporting the labels component to a different format. The labels text can be a composite text made up of several different fields, so this is a quick way to capture that text into a single field.
- For convenience, right clicking on a drawing in the project pane and choosing Create - Labels will launch the Create Labels dialog with that drawing already highlighted in the dialog's Parent pane under the presumption that we would like to create labels for that drawing. To not pre-select a drawing in this way simply right click into the blank region of the project pane when choosing Create - Labels from the context menu, or click anywhere in the blank region of the Create Labels dialog so that no drawing is chosen.
- By default, Manifold will autoclip labels (not show some labels) to prevent the display from being too crowded with labels. If you add labels and they disappear or some other labels disappear, they are being autoclipped by the overlap resolution algorithm. To turn off autoclipping open the labels component in its own window, choose View - Display Options and un-check the Resolve overlaps box.
- When using a mouse equipped with a scroll wheel, the scroll wheel zooms in and out of a labels component. Holding the CTRL key down while scrolling will force the zoom to operate near the center of the window.
- Manifold provides one-step Undo when deleting or duplicating a label or when editing a label metric.

Creating Labels from Fields

Labels that are created from fields are always bound labels in Manifold. Bound labels are automatically created from objects in a drawing, including possibly fields taken from the drawing's table, so they are "bound" to that drawing and its objects.

Bound labels may also be synchronized with the drawing as well. If the labels component is synchronized with the drawing, then adding new objects to the drawing will create new labels for those objects and deleting objects from the drawing will delete their associated labels. See the Synchronized Labels topic for more details.

Whether or not bound labels are synchronized, if their text is taken from fields then they will automatically be updated with any changes in the drawing's data fields. For example, changing the formatting of the table's columns, such as changing a numeric field to show two digits after a decimal point, will automatically change the format of that numeric field as it appears in a bound label as well.

Creating a labels component that prints text based on data fields is the same as creating any bound labels component. We simply use the names of fields within square [ ] brackets in the Text pane of the Create Labels dialog.

There are several main ways to create a bound labels component:

- In the project pane or from the File menu choose Create - Labels and then choose a Parent drawing from which labels will be created using fields from that drawing's table.
- Copy either an entire drawing or some or all objects from a drawing and then Paste As a labels component. This will raise the Paste Labels dialog to create a labels component that is bound to the originating drawing.
- Right click in the project pane, either on a drawing component or on an empty portion of the project pane and choose Create - Labels in the pop up context menu. Choose a Parent drawing in the resulting dialog. This creates a new labels layer in the project pane.
- When a map window is open, right click onto the layers tabs and choose Add - New Labels. Choose a Parent drawing in the resulting dialog. This creates a new labels layer in the project pane and after the labels component is created it will be automatically added to the map as a layer.

Whichever path is used to raise the Create Labels dialog, we can illustrate the process using the File - Create - Labels command as follows:

To create labels using fields in drawings:

1. Choose File - Create - Labels
2. In the Create Labels dialog, click on one of the drawings listed in the Parent combo list.
3. This enables a list of fields in that drawing in the Columns pane. Double click on a field and it will appear in the Text pane.
4. Edit the Text pane as desired.
5. Press OK

Double-clicking a field name to place it within the editing pane is a useful shortcut but is not necessary. If desired, we can enter field names such as [Place_name] manually. Double clicking is recommended to avoid typographical errors in the names of fields.

When a labels component containing bound labels is opened in a labels window the parent drawing will be displayed in gray default color as a background to provide a visual context for the position of the labels.

Example

We will use the Mexico example drawing to create labels.

![Mexico Drawing](image1.png)
![Mexico Table](image2.png)
We begin by importing the drawing into the project. We then right click onto the **Mexico Drawing** component in the project pane and choose **Create - Labels** to launch the **Create Labels** dialog.

The dialog shows **Mexico Drawing** loaded into the **Parent** combo box since we right clicked onto that drawing. If we had right clicked onto an empty portion of the project pane or if we had launched the **Create - Labels** dialog by choosing from the **File** main menu then the **Parent** box would have been loaded with **[None]** and we would have had to choose **Mexico Drawing** from the list made available in the **Parent** combo box.

If we had other drawings in our project these would be available in the **Parent** list as well. When we choose a drawing in the **Parent** box the columns for that drawing will appear in the **Columns** pane.

In the **Columns** pane we scroll down to **Place_name** and double click it. Double clicking a field name in the **Columns** pane will load it into the text in the **Text** pane. We could also simply enter the field name in brackets in the **Text** pane; however, double clicking the name from the **Columns** pane is often faster and less subject to typographical error.
We can now click into the *Text* pane and add any desired literal text. In this example, we have added "*My name is*” to the text for the label. When the label is constructed the field names in brackets will be replaced by the value in that column for that label's parent object. All text not in brackets is taken as literal text and will be displayed exactly as entered.

We can now click into the *Text* pane and add any desired literal text. In this example, we have added "*My name is*” to the text for the label. When the label is constructed the field names in brackets will be replaced by the value in that column for that label's parent object. All text not in brackets is taken as literal text and will be displayed exactly as entered.

**Note that intrinsic fields will also be listed in the **Columns** pane. If desired, we could scroll down to and double click on the **Latitude (I)** and **Longitude (I)** fields to add these in brackets to the **Text** pane. Intrinsic fields are computed by the system for each object. The **Latitude (I)** and **Longitude (I)** intrinsic fields report the centroid position of an object in the map. See the Intrinsic Fields in Tables topic for more information on intrinsic fields. When we are done adding text in the **Text** pane we press **OK**.
A new labels component appears in the project. Since it is created using fields from Mexico Drawing it appears in the project hierarchy under its parent component.

We can create a map that shows Mexico Drawing and the Labels label component together as layers with the labels layer above the drawing layer. Note how values have been substituted for [Place_name], [Latitude (I)] and [Longitude (I)]. The label is positioned at the centroid of the area. Each area in the drawing has a label.

Changing Formatting of Numbers in Labels

Suppose we would like to create labels with fewer digits after the decimal point in the latitude and longitude values? The formats of numbers in labels are taken from the format used for the columns in the table that provide those numbers. To change the appearance of numbers in labels that are taken from columns, change the formatting of those columns in the table. See the Formatting Columns topic.

For example, to change the appearance of the latitude and longitude intrinsic values, open the table and display the intrinsic columns. Next, change their formatting by right clicking on their column heads and choosing Format. Changing the format of the column will also change the format of any label that uses numbers from that column.

Changing Text used in Bound labels

If we would like to change the text or fields used in bound labels like the example above, open the labels component in its own window and choose Labels - Text to launch the Text dialog.

Creating Labels for Some, but not All, Objects

At times we may wish to create labels for some, but not all, objects in a drawing. We have several methods available:

- Select those objects (such as areas in a drawing) for which labels are to be created. Copy the objects and paste them as a drawing, and then create labels for that drawing.
- Un-check the Automatically label new drawing objects option in the Create Labels dialog, so that the resultant labels component is not synchronized. Alternately, after the component is created un-check Labels - Synchronized from the main menu so that it is not synchronized. We can then select and delete all labels we don’t want. If only a few out of many labels are desired, it will be faster to select those labels we do want, choose Edit - Select Inverse to invert the selection and then delete. See the Synchronized Labels topic for more info.
- Create a field that can be used for thematic formatting so labels that are not to be displayed can be thematically formatted using invisible color and desired labels can be formatted using a visible color. This technique allows only some of the labels to be made visible.
- Create unbound labels manually. The disadvantage of this method is that label text cannot be taken automatically from fields as is the case with bound labels. See the Adding Text Labels topic.
- Create bound labels and then use the Unlink command to convert the bound labels component into a standalone, unbound labels component. The labels may then be repositioned or individually deleted or altered.
- Use linked drawings to create a drawing from a query where the results of the query are the drawing objects we want to have labeled. Create a synchronized, bound labels components using that dynamic drawing as the parent and then use that labels component. This can be faster than the thematic formatting approach because the labels component only contains those labels desired.

Example

In this example we create labels for some provinces in Mexico, using thematic formatting to show only some labels but not others.
Consider a map with one layer, the example drawing of Mexican provinces. We add a labels layer by right clicking on the **Mexico Drawing** layer tab and choosing **Add - New Labels**.

In the **Create Labels** dialog we choose the **Mexico Drawing** component as the parent and double click the **Place_name** column to add it to the label text. Press **OK**.
This creates a new labels component, called **Labels**, and also adds it as a layer to the map. Note that labels are created for all provinces. The default auto-clipping will hide some labels that would otherwise overlap other labels. Overlap resolution may be adjusted using the **View - Display Options** dialog for the labels component.

At this point, the smart thing would be to simply un-check **Labels - Synchronized** to make this an unsynchronized labels component. We could then simply select and delete unwanted labels.

However, since this is an example for Help that is intended to illustrate various ways of working with fields in tables in connection with labels, we will use a trickier approach, that of thematic formatting. This technique does not make much sense in ordinary interactive usage, but it is often used in IMS applications where we may want labels to appear or disappear based upon the contents of data fields.

We will create a new data column and the use that to guide whether or not a label is visible.

In the project pane we double click on the table for the drawing to open the table.

We right click on any of the table’s column headings and choose **Add - Column** to add a column to the table.
In the Add Column dialog we create a new Boolean field called Label. A Boolean field can have only two values, which depending on the formatting for the column in use, can be represented as 1 or 0 (default formatting), True or False, Yes or No, On or Off and so on. Boolean fields are handy when a value may be either on or off.

There is no special meaning to our choice of the name Label for the new column. It is only a mnemonic to remind us that this field's values will be used to turn labels on or off for display.

<table>
<thead>
<tr>
<th>STVE</th>
<th>Place_name</th>
<th>Label</th>

<td>Baja California</td>
<td>0</td>
</tr>
</tbody>
</table>

The new field is created with default 0 values. Our task now is to fill the Label cell with a 1 for those provinces for which we wish to have labels displayed.

This is easily done by clicking on the drawing layer in the map to make it the active layer and then selecting those provinces for which we want labels. We use touch selection in Add to Selection mode to click each province to be selected.
If we switch back to the drawing's table, we see that those records corresponding to selected provinces are also selected. We double click into the **Label** cell for any of the selected records...

...enter a 1 and then...

...when we press **Enter** the new value of 1 will be propagated into the **Label** value for all of the selected records. Manifold uses auto-scoping for selection editing in tables, so that a change made to any selected record is a change made to all selected records. This is a very convenient way of modifying many records at once.

We have now marked all selected provinces with a value of 1 in their **Label** column. We can use this column to thematically format the labels component so that labels with a 1 in their object's **Label** column are visible and those with a 0 in their **Label** column are invisible.
Click on the labels layer in the map to make it the active layer and then in the pull-down menu for the **Foreground Color** well in the formatting toolbar choose **Theme**.

This launches the thematic formatting dialog. We choose **Label** as the field to control the formatting. We double-click into the **Values** color well for the 0 value and choose invisible color. We will continue to use the default black color for the 1 value. Press **OK**.

**Note:** the thematic formatting dialog shows both 0 and 1 values in the **Values** pane for our editing pleasure because there are already some 0 values and also some 1 values in the table. If we did not previously change some of the values to 1 in the table the formatting dialog would only show 0 value in the **Values** pane.
In the map window we can see that now only labels for selected states will be visible, because other labels are rendered in invisible color and cannot be seen. Not all labels are seen because some (such as the label for Durango province to the East of Sinaloa) will be suppressed by the auto-clipping algorithms designed to prevent overlapping label text.

We can clean up the display by deselecting the selected provinces in the drawing. We can also change the formatting of labels in the labels layer to turn on **Bold** face so the labels stand out better.

The example above works well to display labels for only a subset of objects in a drawing. However, it has the performance impact of computing labels for all of the objects in a drawing and then reckoning which of those labels should be displayed with invisible color (so they cannot be seen) and which should be displayed for visible color. If we have 100,000 objects and only wish to show labels for five of those objects the above technique is somewhat wasteful because it requires the computation of 100,000 labels even though only five of the labels will be seen.
A more efficient technique would be to create a drawing consisting only of the five objects for which labels should be displayed and then create a labels component bound to that drawing. In that case, only five labels would be in play in the labels component. We could create such a drawing dynamically by using a query to create a linked drawing based upon the other drawing and then create a labels component that is bound to the linked drawing.

**Showing Multiple Labels per Object**

Sometimes we would like to show more than one label for objects. For example, we might have a drawing showing cities as points with population and name fields. We would like to show a label for population and a label for the name for each point.

![Text: Name, Population]

One way to accomplish this is to create a single label that uses the contents from both the name and population field as seen above.

Another way to show two labels for each point we create two labels components. We copy the cities drawing and paste it once as a labels component using the name field. We then paste it a second time as a labels component using the population field. Use a different alignment for the two labels components so that the two labels do not appear on top of each other. We then use both labels components in a map with the drawing. When using this method it may be important to turn off the **Resolve overlaps between labels** option in the **View - Display Options** dialog for labels so the different label layers do not clip each other.

**Labels without Fields**

At times we may want to create labels for a bound component that do not use fields.

Consider a drawing that shows oil well locations as points.
We create a labels component using this drawing as the parent and use the text "Oil Well" without using the names of any fields in brackets.

We can drag and drop this labels component into the same map as the Oil Wells drawing to see that it creates the same text for every object. We have used the alignment toolbar to move the text labels slightly above and to the right of each parent point and we have used the Display Options dialog to add three pixels of space via the X and Y offsets between the labels and the points as well.
Let's now create another labels component for this drawing but this time we will use a field to customize each label with the contents of the Production data field.

We can drag and drop the new labels field into the map to create another labels layer. This labels component also has the labels moved slightly and uses the format toolbar to boldface each label.

**Tech Tip: Using Bracket [ ] Characters in Labels**

Given that bracket characters [ ] are used in the Create Labels text pane to indicate a field name from which data should be taken, how can we create text that includes a bracket character? Manifold at the present time does not allow an escape sequence, such as \[ to be used to denote the next character should be taken as a literal. Instead, we must use a hack.

Create two new text columns in the drawing's table. Call one LeftBracket or similar name and call the other RightBracket or similar name. The text columns may be created as fixed-length text with a length of 1 character. Select all records in the table and double-click into the LeftBracket column and enter a [ character. Because Manifold offers the convenient shortcut of filling all selected records with the edited value this will populate the LeftBracket column with a [ character for all records. Do the same for the RightBracket column except populate it with a ] character.
Now, whenever we want to use a left bracket in labels text we simply use the expression `[LeftBracket]` and whenever we want to use a right bracket we use the expression `[RightBracket]`. For example, if we want to create a text label like `Verified [1995]` we would enter the following into the text pane:

```
Verified [LeftBracket]1995[RightBracket]
```

The contents of the "bracket" field names will be taken from the field which in all cases will be either a left bracket character or a right bracket character as desired.

Note that we can combine this technique with other field names as well. Suppose we have a `Date Verified` column in the table that has the particular year each record was verified, so that instead of hard-coding 1995 as the year we want to take the value from the field. We could do that by writing:

```
Verified [LeftBracket][Date Verified][RightBracket]
```

**Note:** It's quite likely at some future point Manifold will add an escape sequence allowing direct entry of bracket characters without the need for the above technique. However, the above technique should still be kept in mind as there may always be special characters in various fonts that can only be accessed through programmatic or other special means. In that case, an active column can be created that generates them and then the name of the active column can be used within brackets in the label text.

**A Note for Enterprise Edition Users**

It is possible to create a local labels component that is bound to a shared drawing component. This allows creation of a labels component within our project that is created based upon a drawing linked in from an Enterprise server.

Thematic Formatting and Labels
Label Display Options
Synchronized Labels

When creating bound labels we get a choice in the Create - Labels dialog to **Automatically label new drawing objects** or not. If this option is checked (the default) the labels component will be **synchronized** to the parent drawing.

When labels are synchronized to their parent drawing, if any new objects are created in the parent drawing then new labels will automatically be created for those new objects. If any objects are deleted from the parent drawing then their associated labels will also be deleted from the parent drawing. When labels are synchronized to the parent drawing we cannot delete any labels manually since their appearance in the labels component is based exclusively upon whether or not their associated object in the parent drawing exists.

When labels are not synchronized to their parent drawing, we may freely delete or (based upon objects) add labels to the labels component. We can select a subset of labels and then copy them to a new labels component (which will also be an unsynchronized bound labels component). We can add objects to the parent drawing without adding any labels, but if we delete any objects from the drawing their labels will also be deleted. That is because even an unsynchronized label is still a bound label and derives its existence from the associated object in the parent drawing. We can choose whether or not the label is shown but as long as it is bound to a parent object we cannot have the label exist on its own without the parent object that defines it.

Because labels in a bound drawing are always derived from the parent drawing in any event, choosing synchronization on or off is really a choice of how labels are created and whether or not they are deleted. It is not a choice as to the content of labels or their position.

**Example**

Let's begin with the sample **Mexico** drawing used throughout this documentation. This drawing has a **Place_name** field we can use to automatically create bound labels.

Using the **Create Labels** dialog we create labels from the **Mexico** drawing using the **Place_name** field. We use the default setting (checked) for the **Automatically label new drawing objects** option. We will call this new labels component by the default name, **Labels**.
We use the default setting (checked) for the **Automatically label new drawing objects** option. The resulting labels component will therefore be synchronized to the parent drawing.

A new labels component appears in the project pane, indented below its parent drawing because it is bound to that drawing.

We can add the resulting labels component to a map that also contains the Mexico drawing. In the above illustration the labels have been formatted so they are slightly larger than default and also so they use a style with a "drop shadow" of white background color.

With the labels component layer tab clicked in the map so that the labels layer is the active layer, we can click on the **Labels** menu to see that this labels component is **Synchronized**. It is synchronized because the labels component was created with the **Automatically label new drawing objects** option checked on.

If we desired, we could un-check the **Synchronized** setting in the **Labels** menu to turn off synchronization for this component. For now, we will leave it synchronized so we can see how a synchronized labels component behaves.
The first thing we might notice is that synchronized labels cannot be deleted. We can select all of the labels in the labels component with a **CTRL-A** (the standard Windows power user "Select All" shortcut) or by using **Edit - Select All**. If we now press the **Delete** key, nothing happens, nor is the **Delete** command enabled in the **Edit** menu.

Let's now create a similar bound labels component, but let's create this as an unsynchronized labels component.

Once again we use the **Create Labels** dialog to create labels from the **Mexico** drawing using the **Place_name** field. This time, however, we will **un-check** the **automatically label new drawing objects** option so the result is an unsynchronized labels component. We will give this new labels component the name **Unsynchronized Labels** so that we can tell at a glance in the project pane which labels component is which.

A second labels component appears in the project pane, also indented below its parent drawing because it too is bound to that drawing.

We click off the synchronized labels layer in the map so it is not visible and then we drag and drop the new labels component into the map. We will leave these labels formatted using default colors and style so it is clear in these illustrations when a synchronized labels layer is shown and when an unsynchronized labels layer is illustrated.
If we click on the **Labels** menu we can see that it reports this labels component is not synchronized: there is no check mark next to the **Synchronized** option.

Let us now try some experiments to see how unsynchronized labels behave.

We will first select two labels near the center of the view and press **CTRL-X** to cut them (or, press **Edit - Cut**).

Both labels will be deleted and copied to the Windows Clipboard. Note that it is not only possible to delete labels in an unsynchronized labels component; it is also possible to just delete some of them.

If we like, we can right click into the project pane and **Paste** to create a new labels component using the content of the Windows clipboard.

A third labels component appears in the project pane, named using the default naming scheme Manifold applies when new components are pasted. This labels component is also indented below its parent drawing because it too is bound to that drawing.

When we copy labels from a bound labels component and paste them into a project, the new labels component will inherit the bound status of the component from which the labels were copied. The pasted component will be bound to the same parent drawing, it will use the same text (including use of any fields) and it will use the same projection.
If we open the new labels component in its own window, we can see that it has two labels in it, the two labels that were cut from the original and pasted to create this labels component.

Let's go back to the unsynchronized labels layer in the map and select all of the labels.

If we press **Delete**, they will all be deleted. We can now add labels back to this labels layer with the assistance of a highly useful shortcut.

**Using the Insert Label Tool with Unsynchronized Labels Components**

The **Insert Label** command is used to insert a label. If we click with this tool into an **unbound** labels component it will pop open a dialog allowing us to enter text for that label. In a **synchronized** labels component this tool is not available, because synchronized labels always are created or disappear based on whether their parent objects in the drawing are created or disappear.
However, in the case of an unsynchronized bound labels component, the **Insert Label** tool is available. When clicked into the labels component, it will create a label at the position clicked for the object at that location. The text of the label will be taken from whatever is the current specification for labels in that bound labels component.

To continue the example, we can open our unsynchronized labels component in its own window and click into it with the **Insert Label** tool. Each time we click at a location a label will be created at that spot for the object at that spot.

For example, if we click at the location above, within the area representing **Zacatecas** province...

...a label will appear there using the **Place_name** field for that object. If we click at the next location...

...a label will appear for **San Luis Potosí** province. We can click lower and to the right...
...and a label will appear for Jalisco province. If we click in the region of Durango province to the West of Zacatecas...

...a label will appear there as well.

This technique is a very rapid way of creating labels just where we want them. We might have many objects, such as all of the provinces in a country, but want to label only some of them. A fast way of accomplishing that goal is to create a bound labels component that is not synchronized, delete all the many labels created automatically (easy to do with a CTRL-A and a CTRL-C using the Windows keyboard shortcuts for Select All and Delete) and then use the Insert Label tool to click at desired locations to create labels only where desired.

The labels will also appear, of course, within the map as well since we have used the same labels component as a layer in that map.

The technique above was illustrated using a labels window, but it works for a labels layer in a map window as well, so long as the map includes as layers both the parent drawing and the labels component bound to that drawing and the parent drawing layer is visible.
Let us now see what happens to bound labels when we delete their parent objects.

We will select the area representing Zacatecas and press Delete.

This deletes the area from the drawing. It also deletes the associated label from all labels components bound to that drawing. Note that there is no longer a label for Zacatecas. Even though we are looking at an unsynchronized labels layer, it is still bound to the parent drawing and the labels cannot exist without their parent objects.

Let us now see what happens when we add an area. First, we will turn on Instant Data mode so we can add data attributes quickly to newly-created objects.

Next, we will use the Insert Area tool to add a triangular area in the empty region formerly occupied by Zacatecas province.
When we add the new area, Instant Data mode will pop open the Object Fields dialog to allow us to add values for this new object. We will add the value Manifoldia for the Place_name of this newly-created area. "Manifoldia" strikes us as a nice name for a new province named after Manifold System.

In the unsynchronized labels layer, no new labels appear. That's because with unsynchronized labels adding new objects will not create new labels for them.

However, we can click off the unsynchronized labels layer and click on the synchronized labels layer to see what has happened there.
In the synchronized labels layer a new label has appeared for Manifoldia. That’s because with synchronized labels any new object added to the parent drawing will automatically have a new label created for it.

**Multiple Labels per Object**

Bound labels components can have more than one label for every drawing object, and the metric of each such label may be independently labeled (see the Editing Labels topic for information on editing label metrics).

There are two main ways in which an object in a drawing can have multiple labels bound to it:

- More than one labels component can be bound to the same drawing, so objects in the drawing can have labels bound to them that are in more than one different labels component.
- An individual labels component can have more than one label bound to the same drawing.

The first situation above is fairly obvious, since we can easily create more than one labels component bound to the same drawing.

It is less obvious how we could create multiple labels bound to the same drawing object within the same labels component. This is best illustrated with a small example using a bound, unsynchronized labels component as follows.

Consider a bound, unsynchronized labels component we’ve created for the sample Mexico drawing just as in the example above. The illustration shows the labels component open in its own window.

After deleting all of the labels created when the component was first created, we’ve used the Insert Label tool to create a few labels. The illustration above shows the window just as we are about to click the tool into the Northwest corner of Durango province to create a label there.
Manifold creates a label for us at the position clicked using the data for Place_name taken from the object that was clicked. Now we will click the Insert Label tool again near the center of Durango.

Once again, a label is created at the clicked spot. We can click a third time in the Southwest portion of the province...

...and a third label is created. What is going on is that we have created three new labels, all of which are bound to the area object representing Durango province.

We can see this by clicking into the drawing’s table and changing the Place_name value for this object.

If we change DURANGO in upper case to title case, Durango, the change will be immediately reflected in all three labels bound to that object.
The above technique allows us to add multiple labels per object. There are many circumstances in which we might want to have multiple labels per object.

For example, we might want to place labels near the borders of a large country or province, as seen above. The illustration (a zoomed in view of Durango) was created by turning on per-label formatting for this labels component and then selecting each label in turn and using individual rotation format values for each of the three labels.

Another common usage for having multiple labels per object is to create more than one label for a long line, such as a highway, that should be labeled at more than one location.

Notes

The above example uses the Insert Label tool. The other label inserting tools also work in this way, including the Insert Line Label and Insert Freeform Line Label tools.

Although the above example is purely interactive, we should keep in mind that using synchronized labels can be extremely useful in non-interactive settings as well when queries or other processes are used to dynamically create drawings. For example, suppose a linked drawing is automatically created from a query or from an external DBMS table. It is very useful to have any labels associated with such a drawing be automatically created using a synchronized labels component since we don't know in advance how many objects will be in that drawing or where they might be located. Such automatic creation of labels is extremely important in dynamic applications, such as Internet Map Server applications.

Thematic Formatting and Labels
Label Display Options
Formatting Labels

By default, all of the text labels in a labels component are formatted the same way based on the settings of the Format Toolbar for that labels component. See the Formatting Individual Labels topic for information on specifying formatting for individual labels.

Labels may be formatted using static settings as shown in the format toolbar, or they may be dynamically formatted in size, style, foreground color, border color, background color or rotation using thematic formatting as set forth in the Thematic Formatting and Labels topic.

At any time, we can change the formatting of any labels component by simply clicking on its layer tab in a map window or by clicking it open in its own labels window and changing the settings in the format toolbar for that labels component.

Consider, for example, the illustration shown above, which shows the Sea labels using the MS Sans Serif fault.

We can click open the Sea labels component and change the font to Monotype Corsiva with a font size of 14.
The result changes not only in any labels window for the Sea labels component but instantly in the map window as well.

At any time we can click on any labels layer tab in the map window to make it the active layer.

We can then change the formatting toolbar for that labels component. In this case we’ve changed the font to ScalaSans - Caps (a commercial font designed by Martin Majoor in Utrecht and available at www.fontshop.com) in 18 point size in "outlined" style.

Note: for the "outlined" style to work correctly the Antialias text option must be checked in Tools - Options - User Interface.

The result is an instant change in the label formatting for the Land labels layer.

Label Colors

The default label style uses foreground color only. Some label styles will embellish the label through the use of border color and background color as well. In most styles using both foreground and background color the foreground color is overlaid upon the background color. Some styles will combine the foreground and background colors to create gradients.
**Label Styles**

Different styles are used for point labels and for line labels. Line labels use text only because they can be aligned to their host line. Point labels can use styles such as boxes and highway shields.

**Example**

Consider a map of Europe over which we have created an unbound labels component. Using the **Insert Label** tool we have added a label with the text "Europe."

![Map of Europe with label](image)

The label appears in the default format.

![Default label format](image)

The format toolbar shows default settings for font characteristics such as size and the use of default colors for label foreground, border and background and default style as well.

![Font size change](image)

To change the size of the font from 8 points to 20 points we click on the font size well in the format toolbar and we select 20 from the pull-down menu of available font sizes.

![New font size](image)

The format toolbar shows the new font size and the labels component will use that new font size for labels.
Next we will change the label style to a style that draws labels in a box.

For example, we can change the **Label Background** color to white.

This will change the color of the "fill" color in the box in this style.
We can change the **Label Border** color to red.

![Label Border](image)

Instantly, the border of the label's box changes to red.

![Label Foreground](image)

Likewise, we can change the **Label Foreground** color to blue...

![Label Foreground](image)

...and the change will immediately occur in the labels display.

**Transparent Color**

Transparent color, shown with an **X** in the color well, may be used for any color attribute.

![Transparent Color](image)

To specify transparent color as the background color we click on the background color well and choose transparent color.
This makes the white background fill color disappear from the label box, so that layers below the labels layer may be visible through the box.

Using transparent color for foreground color will make the entire label disappear. This is a short-hand convenience for turning labels off via thematic formatting.

Consider a label formatted like the above. The toolbar shows white foreground, red border and black background colors to create the display shown.

If we change foreground color to transparent color the entire label disappears.

If we use any color other than transparent color for foreground color the entire label reappears.
This short-hand convenience uses foreground color as the controlling color because it doesn't make much sense in most situations to use transparent color for the foreground color of a label since foreground color is normally used for the text of a label, the salient aspect of most labels. If transparent color were to be used for the text, the text could not be seen and the label would consist of whatever background, if any, is used by the style in use.

**Enterprise Edition**

Sharing a labels component with per-label formatting to an Enterprise server will save the necessary formatting information within that component. Importing or linking a shared labels component with per-label formatting will read the necessary formatting data from the server along with the component.

**Note**

The `/slist` command line option provides a handy way of getting a list of all available label styles and their names for use by programmers. See the Command Line Options topic.

Label Display Options
Formatting Individual Labels

By default, the format settings used in the Format toolbar for labels apply to all labels in a labels component. If we change a format setting, all labels in that labels component will be changed.

There are two ways to individually format labels within the same labels component:

- For bound labels components only, we may use **Thematic Formatting** to change the format of labels based upon the values of data fields in their parent objects. See the Thematic Formatting and Labels topic for more information on this method.
- For both bound and standalone labels components, we may use **Per-Label Formatting** by turning on the **Per-Label Format** option and manually specifying the format for any labels we want to be different from the overall format specified for the component.

This topic deals with the latter method, the use of per-label formatting.

To individually format a label:

1. Open the labels component, or click on a labels layer in a map.
2. In the **Labels** menu, make sure the **Per-Label Format** option is checked.
3. Choose settings in the Format toolbar that will apply to most labels in the component. All labels will be formatted with these values.
4. Using any Selection method, select one or more labels to be individually formatted.
5. Change the settings in the Format toolbar to the desired format for the selected labels. These labels will now be uncoupled from the overall settings for the component and will retain their selection setting until they are reset to the default or until they again are selected and formatted differently.

When a labels component has **Per-Label Format** turned on, there may be two types of labels in the component:

- Those labels that use the **default format** specified by the toolbar for default use in the component. If there is no selection made, changing settings in the format toolbar when per-label formatting is turned on for a labels component will change the default format for that component. All labels using the default format will be changed.
- Those labels using a **custom format** that have been selected and re-formatted while they were selected. When labels are selected, changing settings in the format toolbar will change the custom format for those labels.

To change a label from using custom formatting back to using the default format, select the label and then use the **Edit - Reset Format** command to reset that label back into default format.

Adding a new label to a labels component assigns that label the default format.

**Example**

Let's look at per-label formatting in action. We begin by creating a bound labels component from the **Mexico** sample drawing using the **Place_name** field to create labels of place names. We open that component in its own window.
The labels component opens showing default formatting for the labels.

In the Edit menu we make sure the Per-Label Format option is checked.

If we make a change in the format toolbar, such as by changing the default Tahoma font to Times New Roman...

...it will be applied to all labels in the component.
To apply a custom format to some subset of labels we first select the desired labels. In the illustration above three labels have been selected using **visual selection** with the **Select Box** tool.

If we now change the Format toolbar, such as by pressing the **Bold** button to boldface text...

...the new format will be applied only to selected labels, which are now shown in boldfaced text. These labels have now been detached from default formatting and will be formatted only according to their custom format.

We can see this by deselecting the three labels and making a change in the format toolbar.
For example, we can change the font back to **Tahoma**.

Note that now the change in the default format does not affect the three labels which have been detached from the custom format and assigned their own custom formats. All of the other labels now use the default **Tahoma** text format but the three labels assigned custom formats have not changed.

At any time we can see what custom format a label uses by selecting it. The format toolbar will show the settings used by that label. For example, in the previous two illustrations we have selected the **Nayarit** label and can see from the format toolbar it uses boldfaced **Times New Roman** font.

If we would like to reconnect a label to the default format we can select it and choose **Edit - Reset Format**.
This will immediately restore whatever is the default format for the labels component to that label and re-attach it to the default format.

By selecting labels and then applying different formats we can create an immense range of different label formats within the same labels component.

**Custom Label Formats do not Use Thematic Formatting**

Thematic formatting can only be applied to the default format. If a label is detached from the default format and assigned a custom format, that custom format cannot be a thematic format.

It is possible to select some labels and then specify a thematic format by choosing **Theme** in the format toolbar's sample wells. However, when the thematic format is applied to one or more labels using a custom format the correct format for each particular label will be computed on a one-time basis and applied to that label. Thereafter when the label is selected the format toolbar will not report a thematic format for that label but will simply report the settings that were computed and applied on a one-time basis, as if they had been manually selected and applied.

**Tips**

Use per-label formatting with restraint. It is annoying to viewers if too many different label formats are in use within the same visual display. Usually it is best to stick to a handful of label formats.

Do not use per-label formatting as a lazy way to avoid taking the time to organize labels into subsets that are displayed in different labels components, which are then stacked up in a map to achieve the desired composite effect. It is much quicker to change the format toolbar once and thus change the formatting of all labels in a layer than it is to hunt down and change by hand each label's custom format.

In a large, complex project it can be easy to forget that a particular label was once formatted with a custom format and is now no longer attached to the default format. One technique to find labels that are not attached to the default format is to deselect all labels and then choose transparent color for the label foreground color. This will
Labels

cause all labels attached to the default format to disappear. We can then select all of the remaining labels using a visual selection method like Select Box to thus select all labels that use a custom format.

Avoid using transparent color for foreground color when per-label formatting is enabled and any labels are selected. If we select a label and then change foreground color to transparent color, the entire label will disappear. This will make it difficult to select that label using the usual visual selection tools like Select Box, since visual selection tools don’t work on invisible labels.

If this happens, don’t panic. Zoom out so that all labels are in view. The label may be retrieved by first hitting CTRL-A to select all labels (CTRL-A selects all labels whether they are visible or not). Next, change the Selection Mode to Select Subtract and then use Select Box to draw a selection box covering all visible labels. This will deselect them because selection mode is set to subtract. What will be left in the selection after all the visible labels have been subtracted will be any invisible labels. We can then change foreground color in the format toolbar to some visible color and the invisible labels will pop back into view.

Keep in mind if things get completely out of hand and we lose track of what formats have been applied to what labels it is always possible to start over by forcing all labels in a given component to be attached to the default format: Select all labels with a CTRL-A and then choose Edit - Reset Format.

Because selected objects are shown by default in red selection color it can be difficult at times to imagine how a new format will appear when the red selection color does not obscure the colors chosen in the format. That can interfere with our ability to choose pleasing color schemes. We can avoid this problem by using None for Selection Style in the selection toolbar so that selected objects are not redrawn in red color while they are selected. This does require paying closer attention to which labels are selected since red selection color will no longer make them stand out; however, usually the changes in formatting make it obvious which objects have been selected and are now being re-formatted.

Changing the formatting of labels can move labels about and cause some labels to disappear because Display Options to resolve overlaps or to optimize horizontal or vertical positioning are active. These options may be clicked off if their result is annoying or otherwise unwanted.

Label Display Options
Thematic Formatting and Labels

When bound labels are created from fields in a drawing, the labels may be thematically formatted based upon the values in the fields. The foreground color, border color, background color, size, style and rotation of a label may be controlled by a field.

If per-label formatting is turned on the thematic format specified will apply to all labels in the labels component using the default format. If per-label formatting is turned on, thematic formatting is not dynamically applied to labels using custom formats.

To thematically format a labels component:

1. Open the labels component, or click on a labels layer in a map.
2. In the Format toolbar, click on the display characteristic to be formatted. Choose the foreground color, border color background color, style or size. Rotation may also be controlled by a field.
3. In the pull-down choice menu that appears, choose Theme.
4. In the thematic Format dialog, choose the controlling Field to be used.
5. Choose the Method to be used to construct intervals. Equal Count, for example, will assign approximately the same number of objects to each interval.
6. Choose the number of Breaks between intervals. This specifies the number of intervals as well.
7. Change the Align to value if even numbers of tens, hundreds, thousands, etc, values are desired for intervals. Change the Range if the default entire range needs to be extended or contracted.
8. Press the Tally button to create the given number of intervals. If interval numbers different than those created by the Method are desired, double-click into the interval numbers to change them.
9. Either use a preset color palette or click into the interval color boxes in the Values pane to change colors to whatever range is desired. To use a palette, select it in the Palette box and press Apply to apply the preset to the intervals. Check the Preview box to try out different combinations and see how they look in the labels component without committing the changes.
10. When satisfied, press OK.

See the Thematic Formatting topic for a detailed discussion of controls in the Format dialog used for thematic formatting.

Example

Suppose we have a bound labels component created for a parent drawing of cities in the US that has a Name field and a Population field for each city. Suppose the labels were created from the drawing using the Name field using the procedure set forth in the Creating Labels from Fields topic.

In the illustration above we see the labels in a layer above a background map. The view is zoomed into a region within the great state of Texas. We would like to change the formatting of each label based upon the Population field. We'll begin by changing the size, so that labels for cities with larger population will be shown in a larger font.

In the format toolbar, click on the size button.
In the pull-down menu that appears, choose Theme.

Within the Format dialog that appears, choose the Population field as the controlling field. We'll use the Equal Count method so that there will be approximately the same number of labels of each size. To round off the interval values, we'll choose 4 as the number of digits for Align to and then choose Tally to recompute intervals to even 10,000 values.

On the right side of the Values pane are two columns of numbers. The column of numbers more to the left shows the number of objects in each interval and the column more to the right shows the current value of font size for each interval. Note that the rightmost number for each interval is 8, the default font size. By double clicking on each font size value we can change it.
For example, here we have changed the font sizes from all 8's to a range from 6 to 14. Press OK.

The result is that labels for cities with larger population will be shown in larger font sizes.

We can also change the label style, if desired. To do so, click on the label style button in the format toolbar and choose Theme.
Once again, we will choose Population as the controlling field and Equal Count as the method. We will also Align to 4 digits and press Tally to round off the intervals to the nearest 10,000.

We will change the style for only one interval, the largest, by double clicking on the style sample and choosing one with a drop shadow effect in background color. Press OK.

The result is that the largest labels are now shown in a drop shadow style.

To illustrate a change in foreground color, we can click on the foreground color button in the format toolbar and choose Theme.
As before, we will choose Population as the controlling field and Equal Count as the method. We will also Align to 4 digits and press Tally to round off the intervals to the nearest 10,000. We will choose the Spectrum palette and apply it to the intervals to color them automatically.

The result is that labels are thematically colored based upon the size of the controlling Population field for each label. In this particular case the effect is not very sophisticated given the garishness of the palette used, but it does illustrate the process of thematically formatting label foreground color.

Note that in the above example we used the same field and the same method with the same number of intervals to format size, style and foreground color. It is very easy to use thematic formatting to vary too many variables at once and so create a confusing presentation. See the comments in the Thematic Formatting Example topic for advice on avoiding overly complex, and thus incomprehensible, presentations.

View - Properties - Zooms
Aligning Labels

Manifold provides a number of commands to quickly align labels relative to their default positions. These may be used to position labels to the upper right of points they identify or other relative positions. Alignment commands are in the Format toolbar for labels.

The default positions for labels depend on the method used for their creation:

- **Unbound** labels will be created at the spot the label creation tool was clicked to create that label. The tie points of unbound labels may be moved about and the alignment of the labels relative to their tie points may be changed as well.
- **Bound** labels are automatically created at the inner centroid of an area, are placed at the midpoint of a line and are centered on the position of a point. The tie points of bound labels may not be moved about, but the alignment of the labels relative to their tie points may be changed.

Tie Points and Tie Lines

Tie points and tie lines are the point locations and line shapes to which point labels that define the location and shapes of point and line labels.

Point labels are positioned within the labels component based on **tie points**. In the case of unbound labels, the tie point is the spot clicked when we use the **Insert Label** command to insert a new label manually.

When bound labels are created automatically using data fields, the tie point is the inner centroid for the object. When bound labels are created using points the location of the point will be the same as the location of the tie point.

We can see the tie point by opening the labels component in a window and choosing the View - Structure - Tie Points command.

Label Text

If we have two labels we can see their tie points by checking on tie points.

The tie points appear as small gray boxes. We can move the labels by selecting them for editing and then moving the edit handles that appear at the tie point locations.

Line labels are drawn aligned to **tie lines** which may be seen by choosing the View - Structure - Tie Lines command.

Consider a line label that was created in a labels component by using the **Insert Line Label** command.
If we turn on **View - Structure - Tie Lines** we can see the virtual line to which the line label is anchored. Note in the above illustration that a fine gray line now appears showing the tie line to which the label is anchored.

We may wonder why viewing tie lines is at all necessary, since selecting any given label for editing with a CTRL-ALT click will show the tie line to which it is anchored as a side effect of showing edit handles.

The main reason is that turning on **View - Structure - Tie Lines** turns on tie lines for all labels in a labels component window at once, saving us from having to select each in turn for editing just to see its tie line.

Viewing tie lines for labels can be very useful in circumstances where the text specified for the label is not long enough to fill out the line at the given zoom. For example, the text in the above line label does not fill out the entire line.

By turning on tie lines we can see exactly what is the relationship between the text and the tie line defined for the label.

**Object Boxes**

Object boxes are rectangular boxes that outline the labels text. They are guides that appear only in a labels component window when the **View - Structure - Object Boxes** menu item is checked. They are used to see the alignment of labels text relative to tie points.

Suppose we have a text label that consists of multiple lines. [We will use a lengthy text label in this example because it shows the object box better.]

> Open the book to the first page and begin scanning words from left to right until their meaning is understood.

If we enable **Object Boxes** we see the outline that encloses the text.
If we enable Tie Points we see the tie point to which the text is bound and relative to which it is positioned.

The Align controls in the Format toolbar adjust the position of the label object box relative to the tie point for the label.

- We can click the Align Left button to position the text object box to the left of the tie point.
- We can click the Center Horizontally button to center the text object box on the tie point. This is the default position.
- We can click the Align Right button to position the text object box to the right of the tie point.

**Align Controls**

- **Align Left**
- **Center Horizontally**
- **Align Right**
The left-center-right and top-center-bottom buttons can be combined, for example, to create a right-bottom alignment.

**Justification**

Manifold label text justification applies to all labels in a given labels component using the *Left*, *Center* and *Right* justification buttons in the format toolbar.

For example, clicking the *Left*, *Center* and *Right* justification buttons in the format toolbar arranges labels as follows:

Open the book to the first page and begin scanning words from left to right until their meaning is understood.

For obvious reasons, justification effects are best seen with multiline labels.

**Aligning Labels to Lines**

Bound labels created automatically from fields in line objects are always aligned automatically to their parent lines.

**Note**

The text in the multiline label examples above is taken from the "How to Use This Book" section of *Mr. Bunny's Guide to ActiveX*, by Carlton Egremont III, ISBN 0-201-48536-2. One of the funniest programming texts ever written, this slim volume presents ActiveX concepts in the form of conversations between a cartoon rabbit and farmer.
Label Display Options
The View - Display Options dialog may be launched when a labels component has the focus. The dialog allows us to specify how labels will be displayed or clipped from display. The unit of measurement employed is the printer's point unit used in printing.

- **Point Labels**: Point labels are those used for points and for areas.
  - **Offset X ... points**: Distance in points in X (horizontal) displacement from the anchor point of the label. Increase distance to position labels farther away from the anchor point and to accentuate the effect of label alignment settings. 0 by default. Not used if alignment buttons are set to place the label directly upon the point.
  - **Offset Y ... points**: Distance in points in Y (vertical) displacement from the anchor point of the label. Increase distance to position labels farther away from the anchor point and to accentuate the effect of label alignment settings. 0 by default. Not used if alignment buttons are set to place the label directly upon the point.

- **Callouts**: Draw a line from the label to each point from which the label is generated.
- **Minimum length**: When a callout line is used, do not show it unless it is at least this long.
- **Optimize horizontal alignment**: Alter the horizontal alignment of labels to improve the positioning of labels.
- **Optimize vertical alignment**: Alter the vertical alignment of labels to improve the positioning of labels.

- **Line Labels**: Line labels are those used for lines.
  - **Offset ... points**: Distance in points that a line label should be offset from a line. 0 points by default.

- **Character Spacing**: Extra distance between characters in the line label text.
  - **Label each branch**: If checked (default), will place a line label on each branch of a multi-branched line. If not checked, will place a line label only on the longest branch.
  - **Multiple labels per branch**: If a particular line's branch is long enough, label it with multiple, repeating labels. This is useful for long lines.
  - **Spacing**: The minimum spacing between multiple labels on the same branch of a line.
  - **Orient labels left-to-right**: If checked (default), Manifold orients each label bound to a line to read from left to right as shown on the screen. When the option is turned off, Manifold orients each label so it flows from the beginning of the line to the end of the line.
  - **Render labels near short lines**: If not checked (default), labels bound to lines that are too short to fit the label text will be hidden. If checked, labels bound to short lines will be rendered as if they were bound to the center of the line. If a line is multi-branched the center of the first branch will be used.
  - **Resolve overlaps between labels**: If checked (default), automatically hide some labels so that labels do not overlap.
  - **Spacing**: Space allowed between labels in points before overlap resolution, when enabled, will take effect. Default is 1
Examples

With Offset for lines of 0 points the line labels appear on their parent lines.

Increasing Offset to 6 points moves the labels off the lines.

When labels are aligned to lines using the default Offset of 6 points they will be positioned six printers' points away from their line.

If we increase the Offset parameter to 24 points the labels will be positioned farther away.
Increasing **Character spacing** to 3 points adds extra space between the letters in the label text.

The **Offset X** and **Offset Y** parameters for point labels works in a similar fashion to the **Offset** parameters for lines. The default distance is seen above, using **Align right** and **Align top** alignment.

Changing the **Offset** parameter to 5 points in both **X** and **Y** directions moves the labels farther away from the point.

**Optimizing Label Alignment**

Labels are normally aligned as directed by the alignment toolbar mode buttons. Checking the **Optimize horizontal alignment** or the **Optimize vertical alignment** boxes in the display options dialog allows Manifold to override the alignment settings for any given label to improve the display.

For example, in the above illustration the rightmost point does not have a label because with current alignment settings the label is automatically clipped because it would conflict with other labels. In the above illustrations, the **Optimize** alignment boxes are not checked.

If we check the boxes, then (as seen above) Manifold can alter the alignment of the rightmost label so that it can appear immediately to the left of the point and thus not conflict with other labels.

**Orienting Line Labels**
The **Orient labels left-to-right** option allows us to orient labels to either follow the direction of the line in all circumstances or to always read left-to-right regardless of the direction of the line.

To understand this option we must understand how lines are internally constructed within Manifold. Consider the line above. A line inside Manifold is defined by a sequence of internal coordinates between which segments of the line are drawn in a connect-the-dots fashion.

We can see these coordinates by **CTRL-ALT** clicking the line to select it for editing. An edit box will be drawn at each coordinate that defines the line. Coordinates for lines are not stored at random within Manifold: each line consists of a list of coordinates from beginning to end, with the segments of a line drawn from each coordinate to the next coordinate in the list.

This means that there is always an implied **directionality** to any line in Manifold, in that each line begins at a first coordinate and then continues through the list of coordinates to a last coordinate. The first coordinate is the beginning of the line and the last coordinate is the end of the line. The line may be said to run from the first coordinate to the end.

We cannot see the direction of the line in the above illustration. Although it is obvious which two edit handles are at the end of the line, we don't know which is the first one and which is the last one in the sequence. That is, we don't know if the line was drawing beginning with the coordinate on the left and then continued to end at the coordinate at the right, or if the line was drawing beginning at the right and ending at the left.

Because English text as well as that of most other languages is read from left to right there is a great temptation to always assume lines have been drawn from left to right but that is not always the case, since we have no idea how lines in a drawing were created. They may have been created, for example, by automated processes that have drawn lines so that directionality ends up being random.

The orientation of lines is important because label text can follow the directionality of lines. However, when we print labels regardless of the directionality of the line we would like those labels to read left to right as much as possible. The **Orient labels left-to-right** option (which is checked by default) allows us to be sure that will happen. Let's see how this works:

Consider a drawing consisting of three lines with a labels layer containing three bound labels shown above it in a map. By default, we can't tell what is the directionality of any of the lines.
We can, however, show the directionality of each line by choosing an arrow line style for the drawing that shows lines with an arrowhead at the end of each line. Immediately, we can see that two of the lines have directionality more or less left-to-right while the red, selected line has directionality right-to-left.

In a simple drawing like this, which was probably created by hand, what probably occurred was that the person who created the drawing began at the central point and then created the two lines at the right by clicking the line creation tool starting at the central point. The third line was created by clicking at the central point and then clicking off to the left so the directionality of the third line ended up being right-to-left.

The default setting for the Orient labels left-to-right option causes the Base Camp Trail label to appear right-side-up regardless of the directionality of the selected line. If we un-check the Orient labels left-to-right option in View - Display Options we cause the letters of the label to follow the directionality of the line as if the line were rotated about a clock face to its current position.

Troubleshooting Labels Placement

Manifold creates one line label per line. If multiple labels are being created for what appears to be the same line, it is most likely that what appears to be one line is really composed of multiple line objects placed exactly end to end. Verify this by selecting one of the lines to see if only part of the "line" appears in red selection color. Multiple lines can be joined together into one line with the Dissolve command.

Disappearing Labels

By default, labels bound to lines will only appear if the line is long enough to fit the label text. As we zoom out from a given view and lines become shorter and shorter their labels will start disappearing as the lengths of the lines become too small to fit the label text. We can change this behavior by checking the Render labels near short lines option. When checked, this option shows labels even if the lines to which they are bound are too short to fit the label text.

Non-GDI+ Printing Limitation

Curved (rotated) or labels aligned to lines cannot be printed n Windows 9x systems if the Print using GDI+ option is turned off in the Tools - Options - Printing dialog.

Enterprise Edition

Enterprise Edition enables Display Options for read-only shared components, allowing us to view Display Options but not to modify them.
Highway Shield Labels

Manifold provides "shield" label styles that may be used to label highways and other roads. The highway shield label styles are scalable: increasing the size of the font will automatically increase the size of the label.

Highway shield labels, like other graphical label styles (such as box styles) can only be used with point labels. To use these to label lines such as highways or other roads we first create point objects from the highway lines and then we create labels from the point objects. It is easy to create point objects by using a convenient transform such as the Centroids or Points transform operators. For example, we could select the highway lines to be labeled, use the Centroids transform on the selection to create points (which will be selected) at the centroid of each highway line segment. We can then cut the selected points and paste them as a new drawing of points and then create a labels component from those points, which can then be formatted using a highway shield label style.

Labels in Manifold System normally paint the text contained within the label in foreground color. The highway shield label styles include four label styles that also use foreground color to paint the label text, but they also include four more styles that paint the label text either in black or in white. This allows the creation of three-color labels, which use foreground or background color and which also allow choice of either black or white as the text color through use of the appropriate label style.

Let's consider a sequence of examples using shield label styles, taken in the order in which they occur in the label choice pull-down dialog. Note that when label styles are reduced to fit into the format toolbar there will be only slight differences between the visual appearance of the different styles. The examples below show the format toolbar on the left and the resultant appearance of the label on the right. Styles are shown using red for foreground color and blue for background color. The first three styles are also shown using other colors to provide examples of different effects that may be obtained.

This first style uses foreground color to paint the text as well as the outline. It works well using black foreground and white background as a label for state highways.

This style also uses foreground color to paint the text as well as the outline and it also adds an upper portion of foreground color. It works well using black foreground and white background as a label for state highways.

This style uses foreground color to paint the upper part of the shield and background color to paint the lower part of the shield. Text is always painted in black. When the same color, such as green, is used for both foreground and background the shield appears in solid color, a good style for regional or state highways.
This style uses foreground color to paint the upper part of the shield and background color to paint the lower part of the shield. Text is always painted in white. When red and blue are used the result is very similar to the symbol used for US interstate highways.

Another style using foreground color to paint the text as well as the outline.

Another style using foreground color to paint the text as well as the outline plus an upper portion of foreground color.

Another style using foreground color to paint the upper part of the shield and background color to paint the lower part of the shield. Text is always painted in black.

The classic interstate highway system label, using foreground color to paint the upper part of the shield and background color to paint the lower part of the shield with text always painted in white.

Notes

Highway shield labels have been designed to work with True Type fonts using regular font settings. Some fonts with atypical proportions or with effects such as boldface may extend outside the label shield.

The initial set of such label styles is designed for use with the US interstate highway system and may be extended in future Manifold releases to include label styles used in other countries.

Label Display Options
Repositioning Labels

Only unbound labels may be repositioned. Bound labels are always automatically created at the centroids of their parent objects.

There are two ways of moving unbound labels to a different position:

- Dragging labels by their tie points to reposition them.
- Reposition an entire layer of labels in a map by repositioning the layer.

See the Repositioning Layers topic for information on repositioning the layer. This will move all the labels in the layer together.

To move a label:

1. CTRL-ALT-click on the label to select it for editing.
2. Drag the label to a new position.

Clicking on a label in general means to click on the tie point for that label. Usually the click radius is such that clicking on a label will correctly be interpreted for the label desired. However, in the case of large labels or many complex labels we might want to make the tie points visible to allow us to click more precisely on exactly the label desired.

In that case, we can show tie points in the labels component window by turning on View - Structure - Tie Points.

CTRL-ALT-click on a label tie point to select that label for editing. We can then drag and drop the label to a new position. To make it easier to click on labels, set Edit - Snap to Labels so the cursor snaps to tie points. We can then drag and drop the label in a new position by using

Example

We've manually populated a map of Mexico with place names using an unbound labels component. We then displayed tie points using View - Structure - Tie Points.

![ZACATECAS](image)

We begin by verifying that the mouse is not busy with a command mode (like zoom in or zoom out). CTRL-ALT-click a label's tie point to select the label for editing.

![ZACATECAS](image)

When we click and hold down on the tie point a small box cursor appears.

![ZACATECAS](image)

As we drag with the mouse the box cursor moves with us to show the location where the label will be dropped.
Releasing the mouse moves the label to the new position.

**Example**

Line labels require a **SHIFT** click and drag to move.

Consider a line label created on the border between two provinces. We can select it for editing by **CTRL-ALT**-clicking it, which makes edit handles appear at the coordinates that define the line label.

To move the line label, we **SHIFT**-click and drag any edit handle.
Pressing **SHIFT** while clicking and dragging an edit handle will move the entire line label.

What happens if we do not press **SHIFT** while clicking and dragging an edit handle? In that case, only that edit handle is moved and the shape of the line label is adjusted accordingly.

We can click and drag point labels by dragging the edit handle at their tie point, because the location of point labels is specified by a single coordinate, that of the tie point. Whether we click and drag that edit handle or we press **SHIFT** while clicking and dragging that edit handle the effect is the same since there is only one edit handle to move.

Line labels, in contrast, are defined by locations with more than one edit handle. If we click and drag any single edit handle only that single edit handle moves. If we want to move all of the edit handles together, we press **SHIFT** while clicking and dragging on any edit handle. In this case pressing the **SHIFT** key is a mnemonic to "shift" the entire label.

**Aligning Labels**

**Editing Objects** - Many of the selection and editing methods that apply to objects in drawings also apply to labels.
Rotating Labels

Labels in Manifold that are created from fields may be rotated using the Label Rotation Angle button in the format toolbar for labels. This topic assumes the reader is familiar with labels in general and with the techniques set forth in the Creating Labels from Fields topic.

To rotate all of the labels in a given labels component, open the labels component, press the Label Rotation Angle button and choose a rotation value. To rotate only some labels, turn on per-label formatting, select the labels to be rotated and then specify the rotation angle for those labels. See the Formatting Individual Labels topic for details on formatting some labels but not others.

Example

Suppose we have a labels component containing labels created from a drawing using a Name field. The labels show the locations of towns.

Redmond Oshkosh Marblehead
Palo Alto Wichita Round Rock

We would like to rotate all of the labels by 70 degrees.

To do so we first click on the Label Rotation Angle button.

In the pull-down menu, we choose 70. If we desired some value other than those shown in the pull-down menu, we could choose the More button and specify a value from 0 to 360.
After we choose 70 all of the labels will be rotated by 70 degrees.

Note that the orientation of labels is specified from 0 degrees to 360 degrees as seen above. A label with 0 rotation is in the normal, upright position. A label with 180 degree rotation is upside down.

**Thematically Formatted Rotation**

We can also thematically format labels so that the rotation of each label is controlled by a data field. To do so, click on the Label Rotation Angle button.
In the pull-down menu, choose Theme.

This opens the same Format dialog that is used for thematic formatting of many display characteristics in Manifold. See the Thematic Formatting topic for details on this dialog. For this example, we will use a Population field in our map with an Equal Count method to arrange the labels into five intervals. The rightmost column gives the rotation to be assigned to each. We specified the rotation values by double clicking into each value and entering a number like 0, 60, 120 and so on.
When we press OK the labels will be thematically formatted into different rotations based upon the Population field for each label.

**Example**

Suppose we have a drawing, called "Bearing Lines" with three lines, shown here formatted using a directional line style with an arrowhead indicating the direction of the line.

![Drawing](image)

The drawing's table shows that each line has a Name field containing values like "Track A," "Track B" and "Track C." The Bearing (I) intrinsic field is turned on for display. It has been formatted to show only integer values.

<table>
<thead>
<tr>
<th>Bearing Lines Table</th>
</tr>
</thead>
<tbody>
<tr>
<td>ID</td>
</tr>
<tr>
<td>-----</td>
</tr>
<tr>
<td>35067</td>
</tr>
<tr>
<td>35868</td>
</tr>
<tr>
<td>35969</td>
</tr>
</tbody>
</table>

We will create labels for each line. To do so, we right click on the Bearing Lines drawing in the project pane and choose Create - Labels.
In the Create Labels dialog we give the new labels component the name of "Bearing Labels," we double click on the Bearing (I) intrinsic field to add it to the label text and then we press OK.

If we show the labels component together with the lines drawing in a map, we can see the labels created for each line are positioned over each line.

For a cleaner effect, we can use a box style for the labels. We can format the labels in the map by clicking on the labels layer tab to make it the active layer.

In the format toolbar we set background color to white and then we click on the style well and choose a box style for the label.
The result is a nice box label style that makes it easy to read the label. Now that we would like to rotate each label according to the bearing of each line that it labels.

To do so we click on the Label Rotation Angle button and choose Theme.

In the Format dialog, we choose Bearing ($) as the controlling field and use the Unique Values method. For each value we click into the label rotation box and set the rotation to be the same as the bearing. We press OK.
Each label will then be rotated by the number of degrees in the bearing.

If we like, we can use a different label text. For example, we could open the Bearing Labels component and then choose Labels - Text to edit the text used for the label.

In the Bound label Text dialog we could delete the [Bearing (i)] specification that generated the bearing text and double click on Name to use this field to create the label for each line, labeling it with "Track A," "Track B" or "Track C."

Techniques like the above can generate a very wide range of label styles and effects.

Using different label styles, for example, we can easily alter the appearance of the labels.
A Short Cut

In the illustration showing the Format dialog we had only three lines and so it was easy to manually enter the values 116, 166 and 54 as rotation values to correspond to the bearings of the lines. If we had hundreds of lines we would like this to be done automatically.

If desired, we can also rotate each point based upon the value of the Bearing (I) field using thematic formatting. To do so, press the Label Rotation Angle button and then choose Theme. In the thematic formatting dialog that follows, choose a thematic format that sets the rotation angle by the Bearing (I) field. The fastest way to do this is to use the Continuous shading option in the thematic format dialog.

Using the values of the Bearing (I) field to control rotation:

1. Open the drawing, click the Label Rotation Angle button and choose Theme.
2. In the Format dialog, choose Bearing (I) as the field and any interval-based method, such as Equal Count as the method.
3. Choose 2 as the number of breaks.
4. Check the Continuous shading box.
5. Press the Tally button to establish two intervals.
6. Double click into the two Values cells and change the upper one to 0 and the lower one to 360.
7. Double click into the rotation values and change the upper one to 0 and the lower one to 360. Press OK.

The above procedure creates two breaks, of 0 and 360 degrees and then continuously formats all values in between. In effect, this assigns a continuous range of rotations from 0 to 360 degrees to any Directions values between 0 and 360.

**Example: Adjusting Rotation with Active Columns**

The illustrations above and below show how the text line of the label is perpendicular to the bearing of the line, because a zero rotation shows text in its normal reading position.

If desired, we can use Active Columns to create a derived Bearing field that can be used to rotate the labels at any angle relative to the lines.

![Add Active Column dialog box](image)

We begin by opening the drawing's table and adding an active column. We'll call the column as well as the function that drives it Bearing.
For a script we will provide a simple routine that subtracts 90 degrees from Bearing (I) while "wrapping" at the 0 mark so that resulting values are always between 0 and 360.

```vbnet
Function Bearing
    b = Record.Data("Bearing (I)")
    b = 90 + b
    If b < 0 Then
        b = b + 360
    End If
    If b >= 360 Then
        b = b - 360
    End If
    Bearing = b
End Function
```

For efficiency, we used the on user request setting of Compute, so to see the values computed by the active column we right click on the Bearing column heading and choose Recompute. We can see that the values of the Bearing active column are indeed 90 degrees counter clockwise from the values in the Bearing (I) column.
To use these values to control rotation, we open the thematic format for the label rotation and use the **Bearing** field instead of the **Bearing (I)** field.

The result is that labels are displayed with rotation angles that match the bearing of the lines. Lines with a bearing of 270 degrees will show the text right side up.

However, it could be that we prefer to have labels match the direction of the line but appear as much right side up as possible.
This involves a more complex routine that has a different arrangement for each quadrant between 0 and 360 as implemented above. If we use the above script for the Bearing function we get a different visual effect.

\[
\begin{align*}
\text{Function Bearing} \\
& \quad b = \text{Record.Data("Bearing \ I")}
\end{align*}
\]
\[
\begin{align*}
\text{If } b & < 90 \text{ Then} \\
& \quad b = b + 270 \\
& \quad \text{Bearing} = b \\
& \quad \text{Exit Function}
\end{align*}
\]
\[
\begin{align*}
\text{End If} \\
\text{If } b \leq 180 \text{ and } b \geq 90 \text{ Then} \\
& \quad b = b - 90 \\
& \quad \text{Bearing} = b \\
& \quad \text{Exit Function}
\end{align*}
\]
\[
\begin{align*}
\text{End If} \\
\text{If } b \leq 270 \text{ and } b > 180 \text{ Then} \\
& \quad b = b + 90 \\
& \quad \text{Bearing} = b \\
& \quad \text{Exit Function}
\end{align*}
\]
\[
\begin{align*}
\text{End If} \\
\text{If } b < 360 \text{ and } b > 270 \text{ Then} \\
& \quad b = b - 270 \\
\text{End If}
\end{align*}
\]
\[
\text{Bearing} = b
\]
\[
\text{End Function}
\]

The result is that labels appear mostly right side up, parallel to the lines, regardless of which way the lines point.

Note that the above discussion is helpful for understanding how rotations and active columns work, but the last effect can be achieved automatically within Manifold by using the Align labels to lines option when creating the labels in the first place. There is no need to use an active column or write a script to show labels mostly right side up when aligned to lines.

Labels

Editing Labels

Labels in Manifold have much in common with objects in drawings: they are formatted using the format toolbar, they are selected using the same methods that are used in drawings and they are edited using techniques analogous to those used to edit objects in drawings.

Label text may be change. The positions of point labels may be changed, and both the position and the shape of line labels may be changed, even if the label is bound to a drawing object.

Selecting Labels

Labels may be selected within a labels component window or within a labels layer in a map just like objects are selected in a drawing. All standard selection commands will work with labels. See the Selection in Drawings topic for examples of selection methods in Manifold. In particular, Smart Mouse Selection is often used.

Once selected, labels may be Cut, Copied and Pasted in the usual way. For example, a group of labels may be copied from one labels component and pasted into a different labels component. Bound labels may cut if they are not synchronized and they may be pasted into a new unsynchronized labels component bound to the same drawing.

Types of Labels

Labels are either point labels (the default) or line labels.

- Point labels are defined by the coordinates of an imaginary point that provides the center location to which the label's text is aligned.
- Line labels have their position and orientation defined by the coordinates of an imaginary guideline.

The text of a line label is arranged in the shape of the line that defines its position. Point labels are always aligned North up. Line labels always follow the orientation of their guidelines. Neither the points that define point labels nor the guidelines that define line labels are visible except when the label is chosen as the primary selected object for editing, or unless the labels component window is opened and the View - Structure command is used to show either Tie Points or Tie Lines.

Editing Label Text

How we edit text in labels depends on how the label was created.

- To edit the text of an unbound label we right click on it and choose Edit in the context menu.
- If a label is a bound labels component created from fields in a drawing, we change the text by opening the labels component and choosing Labels - Text.

Editing Labels

To change the position of a label we first select it for editing. We do this using the same methods used for drawings as described in the Editing Objects topic: using smart mouse selection (that is, with the mouse not occupied in any command mode) CTRL-ALT click on the label to select it for editing.

The easiest way to select labels is to first use View - Structure to make their tie points visible. One can then quickly click on the tie point to select the label. The illustrations below omit the tie point for greater clarity.

CTRL-ALT click on the label to select it for editing.
An edit handle will appear at the center of the label if it is a point label. We can move the label by clicking and dragging on the edit handle. If the label was a line label, there would be multiple edit handles at the coordinates of the guideline the label follows. We could reshape the line by clicking and dragging the edit handles, or move the entire label with a **SHIFT**-click and drag of any of the edit handles.

If we like, we can add or delete coordinates (and thus, edit handles) to exactly control the shape of the line. To add a coordinate we right click on the line segment where we would like it to appear and then choose **Coordinates - Add** from the context menu. A new edit handle will appear in that line segment. We can then click and drag that edit handle to move it as desired.

### Context Menu Editing Commands

Right clicking on a label that has been selected for editing calls a context menu that contains editing commands. When right clicking on an editing handle on a label selected for editing, or onto a line segment between editing handles, the context menu will also include additional editing commands.

#### General  
(Right clicking onto label)

- **Duplicate**
  Duplicate the label. It is wise to immediately move the new label while it is selected. This avoids creating coincident labels that might later cause confusion.

- **Center**
  Pan the view to center this label in the window.

- **Coordinates**
  Launches the Object Coordinates dialog to allow direct editing of the coordinates that comprise the label.

#### Branch  
(Right clicking onto a label selected for editing)

- **Delete**
  Delete this branch. Not enabled unless there is more than one branch.

- **Duplicate**
  Duplicate this branch at exactly the same position. Use **CTRL-SHIFT** to drag to a different position the new branch that is thus created (which otherwise exactly overlies the previous branch).

- **Split**
  Split this branch into two branches at the clicked position.

#### Segment  
(Right clicking onto a label selected for editing)

- **Delete**
  Delete the line segment clicked along with the edit handle coordinates to either side of the segment. Not enabled if there is only one segment left.

- **Delete / Split Branch**
  Delete the line segment clicked along with the edit handles to the left and right and also split this branch into two branches at that location.

#### Coordinate  
(Right clicking onto an edit handle)

- **Delete**
  Delete this coordinate. It is not possible to delete the last two coordinates defining a line label.

- **Delete / Split Branch**
  Delete this coordinate and also split this branch into two branches at that location.

- **Duplicate**
  Duplicate this coordinate. It is wise to immediately move the new coordinate/edit handle to avoid confusion that might be caused by coincident (redundant) coordinates.
Labels

**Coordinate**  (Right clicking onto a segment between edit handles)

- **Add**  Add a new edit handle (coordinate) at the location clicked.
- **Add on Segment**  Add a new edit handle (coordinate) on the existing line near the location clicked.
- **Add Mid-Segment**  Add a new edit handle (coordinate) at the middle of the segment nearest to the location clicked.

**Examples**

The following sequence of illustrations use line labels created for a drawing that has three lines, which illustrate three trails in a park. Initially, we see the labels in a labels layer in a map above the drawing.

![Diagram of labels in a map](image1)

We begin by **CTRL-ALT** clicking one of the labels to select it for editing.

![Diagram with edit handles](image2)

Edit handles appear.
To move the entire label, we **SHIFT** click and drag any of the edit handles.

This moves the label to a new position.

If we deselect the label we can see the text has moved.
Let's now shift gears and open the same labels component in its own labels window. When the labels component opens in its own window the objects from its parent drawing (this is a bound labels component) will appear in gray schematic color. The appearance is similar to the view in the map because the drawing is a very simple one.

We've opened the component in its own labels window because only in a labels component window can we use View - Structure - Tie Lines to see the guidelines that specify the geometric shape of the label.

We can see from the above illustration that when a bound line label is created the guideline for it is the same as the parent line object in the drawing to which the label is bound. However, even though that is how the label is created, once the label is created if desired we can edit the metric, which is the geometric definition of the label shown by the guideline, independently of the shape of the parent line object.

For example, we can delete some of the coordinates defining the guideline.

To do so we CTRL-ALT click on the label to select it for editing and then we right click on the coordinate / edit handle we would like to delete.
In the context menu that pops up we choose **Coordinate - Delete** and the coordinate will be deleted.

The illustration above shows the result after we have deleted several coordinates at the beginning and end of the guideline.

If we deselect the label so the guideline is more visible, we can see it is now smaller than it was originally.

Of course, if desired, we can delete coordinates in the middle of a label's metric as well.
Consider the above example. We’ve selected the label for editing and then we have clicked and dragged three of the middle edit handles to reshape the guideline and thus the shape of the label. We would now like to delete one of those coordinates and so we right click on it and choose Coordinate - Delete in the context menu that pops up.

If we would like to delete many coordinates at once we can use a quick trick, of splitting the label into two branches and then deleting one of the branches.

For example, we can right click on the edit handle seen above to split the label into two branches at that position.

In the context menu we choose Branch - Split to split the label into two branches.

The only visible evidence that the label is now split into two branches is quite subtle: as seen in the illustration above the label text appears to have been pushed into the left branch and there appears to be no text in the right branch. What is going on is that normally both branches would have the label text repeated in them; however, the branch on the right is too short to host the text at the given zoom level (the text won’t fit at this font size and zoom level) and so the text is not displayed on the branch on the right.

We can delete the branch on the right by right clicking it.

We choose Branch - Delete in the context menu and...
...that deletes the branch on the right.

Splitting a line label into two branches to delete one of them as a short-cut way of rapidly editing a label is usually the limit of sophistication for most people in working with branches. The idea of the same object appearing to be in more than one place at the same time (which is what can be done with branches) can very rapidly become confusing to the point of uselessness. Nonetheless, just as objects in drawings can exist as multi-branched objects labels can also so exist.

Let’s ease into this part of the example by considering the labels component above, shown in its own window. We will **CTRL-ALT** click a label to select it for editing.

Now, we will **SHIFT** click an drag the label to move the entire label to a new position.

We now **right click** on the label to launch the context menu.
In the context menu, we choose **Branch - Duplicate** to duplicate the single branch of the default label into two branches. The second branch is a copy of the first and exists at exactly the same position.

Since it is weird to have two branches of a label at exactly the same position and thus easy to forget this label has two branches located at exactly the same place, the first thing we do is move one of the branches by using **CTRL-SHIFT** click and drag.

This shows what now appear to be two labels, but both are simply different branches of the same label.

If we deselect the label we can see the same text is repeated on both branches. This is the result of the default **View - Display Options** setting to **Label each branch**, which is checked by default.
Even though broth branches are part of the same labels object, we can edit each branch independently of the other. For example, in the illustration above we have CTRL-ALT clicked the label and then moved the edit handles for the lower branch by clicking and dragging them to change the shape of the lower branch.

This results in a different shape for that branch. It is rare that we need to use multiple branches for labels, but if need be this technique may be used. The point of the example above is that for editing purposes line labels behave very much line lines, with the same editing techniques being applicable.

**Snapping Labels to Grids or Graticules**

Snap to Grid and Snap to Graticule modes may be used when repositioning or otherwise editing labels. Usually these modes are employed with use of the spacebar to toggle snap mode off and on while editing.

See the Edit - Snap To topic for an example using Snap to Grid to reposition labels.

**Non-GDI+ Printing Limitation**

Curved (rotated) or labels aligned to lines cannot be printed in Windows 9x systems if the Print using GDI+ option is turned off in the Tools - Options - Printing dialog.

**Enterprise Edition**

There are several nuances involved in working with labels components in Enterprise Edition arising from the normally read-only nature of labels that are shared components. Commands that don't make sense for read-only components (such as cutting and pasting) are disabled. Note that if a labels component is a bound labels component it is generated based upon a drawing and its table. Any commands that remove label objects from a bound labels component (such as Cut, Delete and Delete All) are disabled in Enterprise Edition.

Enterprise Edition enables Display Options for read-only shared components, allowing us to view Display Options but not to modify them.

**Converting Labels to Points or Lines**
Suppose we have a labels component consisting of unbound labels. These may have been created by hand or imported from some format as an unbound labels component. If we need to, we can create a drawing from that labels component by in the project pane Copying the labels component and then right-clicking into the project pane and choosing Paste As - Drawing. This will create a drawing with point and line objects for point and lines labels with a Text attribute in the drawing's table for each object giving the label text.
Legends
Legends

Before reading this topic, please read the Adding Legends topic for an introduction to legends.

The Legend Dialog

The Legend dialog allows us to create and to customize legends. Open the dialog by choosing View - Legend at any time the component is open for which the legend is desired. If the legend is already displayed in addition to using View - Legend we can call the Legend dialog by double clicking the legend or by right clicking the legend and choosing Properties from the context menu.

To show a legend we simply check the Show legend box in the Legend dialog to show a default legend created by Manifold. We may customize the default legend to add, delete or modify items shown in the legend. To customize a legend, we start with the default, automatically created legend. In the Legend dialog, we check the Customize legend box and then edit the legend as desired using the toolbar controls as well as options in the Customize legend section of the dialog.

Legends are edited by adding or deleting elements in the Legend dialog and then highlighting those elements and specifying their options.

Legend Dialog Guided Tour

Let's take a tour of the different parts of the Legend dialog.

Consider the legend above, a typical legend as might appear for a drawing that uses thematic formatting to color areas by a Population field.
If we double click the legend we see the **Legend** dialog above. Let's examine the different parts of this dialog.

The upper left region of the dialog contains controls that set the overall appearance of the legend.
Looking more closely we see this part of the dialog allows us to choose the **Style** of legend as well as allowing us to provide any **Caption** if desired. The colors specified will be used as foreground and background colors throughout the legend style specified.

The right hand side of the dialog consists of a pane in which legend elements are listed together with a toolbar of command buttons that operate on legend elements.

Taking a closer look at the elements pane we can see that it has an element for each item that appears in the legend. Highlighting an element by clicking on it will select it as the subject for any commands or option choices. In the above illustration we have clicked on the first element, a text element reading **Mexico Drawing**, to highlight it. Commands such as the toolbar **Delete** button will now apply to that element.
A right bracket ] shows which lines in the pane are all part of the same element. Some elements consist of only a single line. For example, the first element consists of a single line. The second element is a dynamic element that consists of more than one line. It is an automatically-generated element that reports the thematic formatting for areas. As a convenience for the user, Manifold will automatically create such elements if desired so that we don’t have to manually enter many lines of legend elements and manually specify characteristics such as colors and interval numbers for each such line.

The third and fourth elements are also dynamic elements that could show formatting, but because there are no points or lines in this drawing they show nothing. The fifth element is another text element consisting of a single line of text, the copyright notice.

When we choose an element by clicking on it to highlight it, the lower left portion of the **Legends** dialog will display options for that element.

For example, clicking on the first element to highlight it...

...will display the options related to a text element. In this case, the system shows the **Type** of the element and the **Text** that is to appear. Pressing the font control button to the right of the **Text** box will open a subsidiary dialog allowing us to specify the font characteristics (such as font, font size, attributes such as bold facing, etc.) of the text.
To see the settings for a different element we can click on it to highlight it. For example, we might click on the second element. Because this is a dynamic element all of the lines involved in the element will be highlighted when we click on this element.

The settings and options for this element are considerably more extensive than for a text element. This element type, *Format: Areas*, is one that automatically reports the formatting of areas. Options allow us to hide the element if there are no areas in the drawing and to specify what formatting characteristics should be shown in the area samples. For example, checking the *Background* box (it is checked by default) will cause this element to display thematic formatting for *background color* for areas.

**Legend Dialog Controls**

- **Show legend**: Check to show a legend in the active window.
- **Align**: Location of the legend within the display window. Choose *None* to allow repositioning of the legend by dragging.
- **Style**: Overall appearance of the legend. Use the *Transparent* style for a legend without borders and transparent background color.
- **Align caption**: Align caption to the right side, center or left side of the legend.
- **Align text**: Align text within elements to the right side, center or left side of the legend.
- **Caption**: Legend title. If no text is provided for the caption, the title bar will not appear. The font button to the right of the Caption box allows font customization for the caption. The default font is taken from the *Legend Caption* setting in the Tools - Options - Fonts pane.
- **Margin**: Blank space in points to be inserted between the body of the legend and the surrounding border or any separators. 1 point = 1/72 inch.
- **Colors**: Colors used for the legend border and body fill.
- **Customize legend**: Check to edit the elements shown in the legend preview pane.

- **Add Element**: Create a new element in the legend. A new element is always created as a text element. This can then be changed to the desired type of element in the Type box.
- **Add Samples**: Enabled for images. Create the desired number of color samples for the most frequently used
colors in the image.

**Delete Element** - Delete the highlighted element.

**Move to Top** - Move the highlighted element to the top of the legend.

**Move Up** - Move the highlighted element up one position in the legend.

**Move Down** - Move the highlighted element down one position in the legend.

**Move to Bottom** - Move the highlighted element to the bottom of the legend.

**Flatten** - Convert a composite legend item into the equivalent set of static legend items. For example, a set of automatically-created color boxes for a thematically formatted height in a surface could be converted into individual static elements.

**Type**
Enabled when customizing the legend. Choose the type of object sample to display in the legend from a variety of dynamic or static types of elements. Also available are vertical or horizontal separator lines, labels and text only lines. Use a blank text line to provide a blank vertical space between legend elements. Inserting a horizontal separator line will break the legend into multiple columns.

**Text**
Edit the main text string displayed as part of the element. The legend box will expand to fit the text provided.

Font selection for label strings and text strings used in elements.

### Adding an Element to a Legend

To add a new element to a legend we press the **Add Element** button and a new text element will be created just above whatever was the currently highlighted element. We then change the type of the element to that desired and move the element to the desired position.

#### To add an element to a legend:

1. Open the **Legend** dialog for the legend.
2. Check the **Show legend** and the **Customize legend** boxes.
3. Press the **Add Element** button in the **Legend** dialog's toolbar.
4. A new text element will be created just above the previously highlighted element. The new text element will be highlighted.
5. In the dialog's **Type** box, choose the type of element desired and choose any desired options from controls that become available for that type of element.
6. Move the new element to the desired position in the stack of legend elements and press **OK**.

To delete an element, simply highlight it and press the **Delete** key.

### Types of Legend Elements

There are two main classes of elements used in Manifold legends:

- **Dynamic elements** are automatically generated by the system and are used to show thematic formatting. Such elements are usually composite elements that combine multiple legend lines consisting of text and samples. Dynamic elements normally include samples that show thematic
Legends

formatting as well as a text line providing an overall label. Because dynamic elements take their content from the parent component automatically, their formatting (such as colors used) cannot be changed manually.

- **Static elements** are manually created and controlled. All parts of static elements may be customized, including the appearance of samples such as sample style and color. Static elements are items such as text lines, separators and manually specified sample elements. For faster workflow, we might often create static elements by first letting the system create a dynamic element and then flattening it into static elements, which we can then edit as desired to fine-tune appearance. This is often faster than manually creating static elements one-by-one.

Sample elements consist of a graphical sample that shows a color or other formatting sample and a text that explains what that sample means. For example, an element illustrating a particular thematic format for an area may include a sample of area color in the form of a small rectangle together with a text that identifies what that color means. Sample lines are normally part of dynamic elements. A wide variety of sample types is available for manual creation of static sample elements.

Let's look at examples of the above.

Consider a legend similar to that used for our tour. We have added points to the drawing and have also added a legend element for those points.

Opening the **Legend** dialog we can see that the **Copyright 2006** element is a typical **text** element consisting of a single text item with no sample. This is a static element because it is created manually.
The element for points is a typical sample element with two items, a sample and a text. The sample in this case is a sample graphic of what a point looks like in the drawing given the formatting currently applied. The text is the default text used by Manifold whenever a point format type is added, Points.

To see if the element showing points is a static element or dynamic one we can look at the options for this element. It shows that the Format: Points type is used for this element, so it is a dynamic element that now has a very simple, one-line appearance because there is no thematic formatting used for points in this example.

Legend element types that begin with a Format: are always dynamic elements because they are called upon to show thematic formatting.

If the element for points was a static element it would have used the type Point: Single type and instead of a list of formatting characteristics to show the options would consist of formatting wells allowing us to specify the foreground color, background color, style, size and rotation angle of the sample that appears in the element.

The dynamic element showing area formatting is a typical dynamic element. It consists in this case of several sample lines showing area formatting and a text line, Population. Note that even though this element consists of several lines it is still only a single element which when clicked becomes highlighted in its entirety.
If we highlight that dynamic element and press the Flatten button in the legend dialog's toolbar, we can convert the dynamic element into a series of individual static elements.

In this case, the individual elements are no longer automatically created by the system but have become static, manually controlled elements.

Flattening is a one-way process. Once a dynamic element has been flattened into individual, static elements, we cannot then "un-flatten" those individual static elements back into an automatically-created dynamic element.

Samples

Samples are small graphical elements, such as a swatch of color or a point icon, that show colors and other formatting characteristics in a particular legend element.

In drawings, samples are used in elements that describe areas, lines, points and labels. In images samples are used to show heights. In images, samples are used to show sample color swatches of colors that appear in the image. These elements have a graphical element on one side of the legend and text that describes what that sample means on the other side of the legend.

When static elements using samples are highlighted the dialog will provide controls in the lower left corner of the dialog that allow us to specify the appearance of the graphical sample used as well as the content and appearance of the text. Controls will be different for different types of samples. For example, point samples will have a rotation control that allows us to rotate the sample icon whereas sample elements for areas and lines do not have a rotation control.

Dynamic elements that show samples do so automatically with the appearance of the sample being automatically taken from the formatting in use. Dynamic elements that show objects with thematic formatting will show a range of samples to illustrate the thematic formatting and the intervals involved. Dynamic elements that show object formatting that does not use thematic formatting will illustrate the formatting in a single line element like that of a static element.

Quite often the fastest and easiest way to create a manual sample element is to first create a dynamic element (or use the default dynamic element created for a component by Manifold) so that formatting for samples is done for us automatically by the system. We can then Flatten the dynamic element into one or more manual sample elements that have the samples pre-loaded with formatting options. We can then adjust those samples as we like without having had to take the time to create them in the first place.

Dynamic elements in Drawings

Dynamic elements are used to show formatting in drawings. They will automatically create as many lines as are necessary in the legend to show all formatting attributes. Additional lines will be added as necessary if additional thematic formatting is added to the drawing.

Example

This example shows different features of a dynamic element. We begin with an empty legend and add a dynamic element showing area formatting. We show the effect of different options on that element.
We then flatten the dynamic element into numerous individual, static elements and edit those elements to achieve the legend appearance we desire.

Let's begin with the sample drawing of Mexico.

The drawing has been thematically formatted using the **Population** field to color background color for areas as seen above. There are no lines or points in this drawing.

We open the **Legend** dialog for this drawing. For the sake of this example, we have checked the **Customize legend** box and have then deleted the default elements appearing in the legend. That allows us to start with a blank legend to show the creation of a legend from the very beginning.
To add a new element to the legend we click the **Add Element** button.

This adds a new element, a **Text** element. New elements are always created as **Text** elements. If we desire a different element we highlight the **Text** element and change its **Type** to whatever type of element we want.
For example, in the Type box we can choose Format: Areas as the new type for this element.
The element will immediately be converted to a **Format: Areas** element, which by default shows a report of the formatting used for areas. The element consists of a small text line (which can be eliminated by deleting the text in the **Text** box for this element) together with samples showing thematic formatting in use.

The lower left corner of the dialog shows options used for configuring this type of legend element.

The lower pane lists all formatting characteristics that apply to areas and which can be shown in a legend of this type. The **Background** check box, for example, when checked will cause the element to show formatting for area **background color**. The other boxes list in alphabetical order all format options for areas.
If we scroll down in the option box we can see that every formatting characteristic available for areas is checked by default. Although all area formatting characteristics are listed the legend currently shows only the thematic formatting for area background color because that is the only thematic formatting that has been applied.

If we click the **OK** button a legend will be created in the drawing as seen above. The legend shows the result of the single element in this legend, the **Format: Areas** element. Because only area background color has been thematically formatted the legend is a relatively simple one that shows the range of colors and values given in that thematic format.

If we add thematic formatting for other formatting characteristics in this drawing, the legend will show them as well. For example, we can click into the area style formatting well in the format toolbar and specify a thematic format for area style.
In the above example we have used the TOTVEH_199 field, which gives the total number of vehicles in each province, to format style using a variety of styles that strike our fancy. Note that the Continuous shading box has been un-checked since we don't want interpolation between styles, which would result in styles being used that are in between those shown above.

Well, that's an interesting effect! Each area in the drawing is now formatted so that the color is set by a thematic format depending upon the total population in the province while the style used for the area is controlled by thematic formatting based upon the total vehicles in the province.

Looking at the drawing's legend, we notice one more interesting thing:
The legend in the drawing has automatically expanded to include a second set of samples that show how area style varies in the given intervals. This happened automatically when we specified the additional thematic format for style without our needing to do anything in the Legend dialog.

To see what is going on, we can double click the legend to open the Legend dialog.

The first thing we notice is that the single element in the legend, the Format: Areas element, has expanded to include multiple additional lines. It has expanded to report the thematic formatting of area style as well as area background color.
Note that the interval numbers shown for area background formatting are single numbers because that thematic format used the **Continuous shading** option. In contrast, the numbers reported for the style formatting show a range of numbers for each interval because the **Continuous shading** option was not used in that thematic format.

When we added thematic formatting for style, this legend element expanded to include **Style** because that is one of the boxes checked in the options pane for this **Format: Areas** element. We can un-check that box to see what happens.

If we scroll down to the **Style** box and un-check it, the lines in the legend element that report style formatting go away.

If we press **OK** we see that the legend in the drawing also no longer shows any lines reporting **Style** formatting.
If we launch the **Legend** dialog and check the **Style** box again...

...then once again the legend will show entries for **Style** formatting.

What is going on here is that a **Format: Areas** element is a command to create a legend element that automatically shows lines for all formatting characteristics checked in the option box if they are used for thematic formatting. Any new thematic formatting characteristic that is specified will automatically appear in the legend.
We can see this in action by specifying yet a third thematic format. We will click on the area border foreground color well in the format toolbar and specify a thematic format to automatically change the color of the area borders by changing area border foreground color.

We will use the `BUSES_1991` field that gives the number of buses in each province in the year 1991.

Adding this thematic format dials up the garish appearance of the drawing by yet another confusing notch.
And once again, automatically, a new set of samples appears in the legend to show how area border foreground color varies by number.

Note that when Manifold constructs samples if multiple formats are in play the system tries to create reasonably sensible samples that incorporate the various formatting characteristics specified. In general, each range of samples takes as the non-varying characteristic whatever is at the top of the stack from characteristics being varied.

For example, in the samples of styles since the uppermost style is one without a pattern the samples used to show area background color and border foreground color use no pattern for their style. The style and border foreground color samples use the first color, the darkest, from the area background color range. The samples for area background color and style use the uppermost border color, a hot pink, as their border colors for the samples.

If we double-click into the legend to launch the Legend dialog we can see how it has changed to accommodate this third thematic format we have added.
As expected, it now shows three ranges of samples within the **Format: Areas** element.

If we like, we can make this element shorter by un-checking some of the options.
For example, if we un-check the **Background** and the **Style** boxes the element will show only the range of thematic formats for the area border foreground color.

The legend displayed in the drawing likewise will show only samples for the area border foreground color.

Let's continue this example with an example of using the **Flatten** command, followed by examples showing editing of individual elements to alter the appearance of the legend.
We will double-click the legend to launch the **Legend** dialog. In the dialog we will check all the option boxes for the **Format: Areas** element.

With the element highlighted we press the **Flatten** button to convert the dynamic element into a series of individual elements.
The result is a series of individual elements. Note that even though the **Format: Areas** element was only partially shown the result of flattening includes individual elements for all items that were in the **Format: Areas** element, even those that were not shown because of the truncation.
We can now edit the individual elements. For example, we can select the text lines and change their text into strings like Population, Total Vehicles and Buses for more descriptive titles.
We may decide that a wide range of thematic samples leads to a confusingly large legend. Perhaps we think that only one sample for each thematic variation will suffice. In that case, we can highlight in turn each element we do not want and then press the **Delete Element** button to get rid of it.

Note, by the way, that after flattening each element is now a *static* element, that is, it is manually specified. When an element is highlighted, the options for it become a series of formatting wells that allow us to specify the appearance of the sample.
We can change the appearance of the sample by clicking into the sample wells and changing them. For example, we can change the area background color for the **Buses** sample to default gray.
Likewise, we can click on the sample above it and change the area background color to default gray and the border foreground color to default dark gray.
We click on the topmost sample element and change the border foreground color to default gray as well. The idea is to create a legend that varies only one formatting characteristic at a time from the default gray to emphasize which characteristic is being varied for that parameter.

This results in a simplified legend that shows three samples, one for each formatting characteristic that is varied by thematic formatting. While it is probably a fool's errand to try to explain clearly such a chaotic drawing (too much formatting of too many characteristics at once is difficult to comprehend), there is a possibility that a simplified legend may help people guess what is going on.

Suppose we decide that the numbers to the right of the samples are confusing. It is easy to remove them as well.
To do so, in the Legend dialog we highlight each of the sample elements in turn and then delete the text in the Text box.

This creates a legend with no text to the right of each sample. However, it could be we decide we don’t like the text titles on lines above the sample. We would like to see them on the same line as the sample. That too is easy.
In the **Legend** dialog we delete the text elements between the samples, and then we highlight each sample element in turn and in the **Text** box enter the text we want next to the sample. For example, we have entered **Buses** (using the font button to the right of the **Text** box to boldface the text) into the **Text** box for the lowest sample. Note also that we have chosen **Left** as the option in the **Align text** box to bring the text titles closer to the sample boxes.

That's a step in the right direction, but suppose we would prefer greater spacing between the sample boxes and the accompanying text.
To arrange that we go back to the **Legend** dialog and in the **Text** box for each element we add some leading space characters to the left of each text. This will move the text to the right a bit.

The result is a small but elegant legend that shows how **Population** is indicated by varying area background color, **Total Vehicles** by varying style and **Buses** by varying border foreground color.

Beginners will follow a workflow like that above, going back and forth between the **Legend** dialog and the component window, to create legends via a series of commands that change things until the legend looks right. More experienced users will tend to go straight to the desired effect by manipulating many different settings within the **Legend** dialog at once.

This is a somewhat contrived example because an experienced designer would not create such an inelegant and difficult-to-comprehend mixture of simultaneously-varying thematic formats. It is usually wise to vary only one formatting characteristic at a time for maximum comprehension.

**The Collapse Similar Formats Box**

When the **Collapse similar formats** box is un-checked, Manifold will provide a legend line for each formatting characteristic checked in an option box for elements like the **Format: Areas** type even if that formatting characteristic is not the subject of a thematic format. In the case of a default drawing with no thematic formatting...
applied the result is eight sample lines (one for each of the eight formatting characteristics of an area) that appear as identical samples.

If a single thematic format is in play, such as thematic formatting for area background color, un-checking this box will result in one thematic format range of legend samples plus seven other sample lines that all look alike. Checking the box hides the redundant seven lines.

Why provide a check box at all? In the case of a single drawing this is done so that the box may be un-checked and then the resulting element may be flattened so that each of the additional sample lines may then be manually manipulated. It's just a simple way of producing some extra sample lines, one for each formatting characteristic that may be varied.

**Types of Elements**

In addition to the **Format: Areas** type (and analogous **Format: Lines** and **Format: Points** types) Manifold provides a variety of static types with different styling of samples to show areas, points, lines and labels.

The simplest way to show examples of various type is to show them used in a legend, as above. Each of the above types may be configured manually with formatting, such as choice of colors, to provide a sample with the desired appearance. The **Colors** choices are used when creating legends of colors for images or surfaces, and may also be used to show area formatting in drawing legends as well.
Not illustrated but obvious how to use are the Label: Single type and Text type, which are simply text-oriented types.

There is a Separator type that provides a horizontal line. There is no separator type without a line, since to add an extra row of white space between lines (as seen in the above legend) we simply use a Text type with empty text.

The Vertical Separator and Vertical Separator with Line types break legends into columns, either with a vertical line between columns or without.

Legends in Surfaces

Legends are created for surfaces using the View - Legend dialog just as with other components. Surfaces use one main type of legend element, the Format: Heights type that appears in the list of types when the dialog is opened for a surface.

Example

Consider the above surface, a portion of the Montara Mountain example surface on the Manifold CD.
We have formatted the surface using the above palette in the View - Display Options dialog. Note that there is a sequence of intervals defined, 250 units apart, from 250.00 to 1750.00.
To add a legend we launch the Legend dialog and click Show legend. Checking the Customize legend box shows us the default arrangement for a legend for a surface. The legend consists of one text element giving the name of the component in boldfaced text and a dynamic element of type Format: Heights that shows formatting for the surface. The lines appear at locations specified by the numeric values for intervals given in the thematic format, in this case, at every 250 units of height.

If we press OK we see the legend consists of a continuous bar of thematic colors marked at the upper and lower ends by the upper and lower numeric values of the interval range used for thematic formatting.
Going back into the **Legend** dialog we can try different options for the **Format: Heights** element. For example, we can switch off **Lines** and turn on **Tick marks**. This adds short lines to the right of the gradient color bar instead of lines running through the bar.
We can click on Intermediate labels to show text labels for formatting intervals between the highest and lowest. The values of labels and their locations are defined by the interval numbers specified in the thematic format for this surface in the Display - Options dialog.
If desired, we can choose Left in the Align text box to move the intermediate labels closer to the color bar. We've also turned off Tick marks and have turned on Lines.

The result is a more compact legend.
Let's get back into the Legend dialog to explore other options.
Un-checking the **Use continuous shade** converts the continuous gradient bar into a discrete collection of legend lines, each with a color sample. If we ever apply the **Flatten** command to a **Format: Heights** element for a surface the result will also be a set of static elements like these single line elements.
Let's check the **Use continuous shade** box again. Suppose now we would like to eliminate the **Heights** label at the top of the Format: Heights element. Because this is an integral part of the Format: Heights element we cannot simply highlight it and delete it as we could with a text element.

Instead, we eliminate that part of the element by removing the text in the Text box for the element.
Entirely removing the text from the Text box will eliminate that line from the legend.
Let's close this example by adding a Caption, the text Altitude in 9 point font and then pressing OK to create the legend.

The result is a compact and useful legend that shows the range of heights and their colors.

**Proportional Scale Option**

The proportional scale option for the Format: Heights legend element style for surfaces controls how intervals are represented on the gradient bar. Either the ticks on the gradient bar for each interval are located in proportion
to their numeric distance from each other, or the ticks are arranged evenly at equal distances on the bar and the
color spectrum shown in the gradient bar is adjusted so that colors at each tick appear as they should.

Example

Consider the same Montara example surface, but this time colored differently using a different palette.

Opening the View - Display Options dialog we can see that the surface has been colored using intervals that are
highly uneven. The first interval runs from 250.00 to 1000.00, but the next interval runs only from 1000.00 to
1001.00. The remaining intervals are arrayed to cover a range that is about the same size as the first interval by
itself.
If we open the Legend dialog for this surface we can see that the default arrangement using **Format: Heights** draws a gradient bar with intervals marked at their proportional distance along the bar. That is, the height of the bar for the first interval is genuinely about the same as the rest of the intervals put together. We have added ticks and intermediate labels so the exact placement of intervals is clear.

Note that two intervals are so small there is no room for the 1000 and the 1001 labels as well as the 1035 label, nor is there room for two tick marks for the 1000 and 1001 intervals. Manifold will automatically clip (that is, hide) labels and tick marks for which there is not room.
If we would like a longer gradient bar we can make it taller by increasing the Size to 200 points. This provides a taller bar, which may be more useful if we have many labels we would like to show.
If we un-check the Intermediate labels box the gradient bar immediately shrinks to a standard size and intervals are provided at even distances. Note that the distance between the 1000.00 line and the 1001.00 line is the same as the other distances even though this interval is only 1 unit apart. If we compare this illustration with the preceding illustration, we can see that the color at each interval bar is the same, but that the color gradient has changed to accommodate the even spacing of the interval lines.

**Legends in Images**

By default, legends created for images are empty except for a single text line giving the name of the image.

To add color samples to an image legend, check the Customize Legend box and then use the Add Samples button to add the desired number of color samples. This button is enabled only when working with the Legend dialog for images.

Color samples show color wells for the most frequently used colors. Grayscale and palette images will report an exact result while RGB and RGBA images will report an approximate "most frequent" result based on an analysis of color frequency using a Monte Carlo algorithm. The colors used will be reported in R:G:B format.

Legends with images are useful with land cover and land use data displayed as a color-coded image. In such cases the legend elements can be customized with user-specified text replacing the RGB color captions to provide appropriate text captions for each color well.

**Context Menu for Legends**

Right clicking onto a legend calls up the following context menu commands:
Legends

Hide
Hide the legend. Equivalent to un-checking the Show legend box in the Legend dialog. To show the legend again choose View - Legend in the main menu and check the Show legend box.

Align
Choose the alignment of the legend from Left Top, Left Bottom, Right Top, Right Bottom, or None, corresponding to the Align choices in the Legend dialog.

Copy
Windows clipboard copy operation. Copies the legend onto the clipboard, flattening all legend items prior to copying.

Copy Structure
Windows clipboard copy operation. Copies the legend onto the clipboard, without flattening, so the legend is copied as is. Use Copy Structure when a dynamic legend item, such as a set of formats based on height, is to be preserved.

Paste
Enabled only if a legend has been copied onto the clipboard. Paste the legend in the Windows clipboard into this legend, replacing this legend with whatever is the content or structure of the pasted legend. To paste a legend into a drawing we must first show the existing legend and then right click onto the existing legend and choose Paste.

Paste Append
Enabled only if a legend has been copied onto the clipboard. Like Paste, but adds the items from the pasted legend to the legend that was right-clicked instead of replacing it.

Properties
Launch the Legend dialog for this legend.

It is often the case that we have a group of similar drawings or other components and want to duplicate the look and feel of a finely-crafted legend in many components. The fastest way to accomplish that task is to use Copy or Copy Structure to copy the model legend and to then open each component in turn, show its legend and then Paste into that legend.

Printing

When printing from a layout, a component within a layout can be configured to automatically show the legend it has or a new legend can be created within the layout for that component. See the Layouts topic.

Note that it is often more convenient to create a legend in a layout as a separate layout element, so that it may be easily moved about within the layout, than it is to have the legend appear as part of a map or other component within the layout.

Alignment

The legend may be automatically positioned in the display window or dragged to a given location. Position is set via the Align option in the Legend dialog. If the legend is already displayed we may also right click on the legend and choose the Align context menu for alignment options.

- Left Top
- Left Bottom
- Right Top
- Right Bottom
- None

All alignment options except None will place the legend in the same relative location in the window even if the window is resized or the component is panned or zoomed.
The **None** alignment option fixes the legend at the relative location to which it is dragged by the user. If the window is resized, the legend will move to stay in the same location relative to the size of the window. Note that it is possible to resize the window so that some parts of the legend are clipped by the window's boundary.

**Fonts**

Set the default fonts used by the legend (including the caption) in **Tools - Options - Fonts**. See the Tools - Options topic.

![Use the font control to specify the font for text and labels within the legend.](image)

The maximum size of legend font is **1440** points (approximately 20 inches high). Very large fonts are used when printing legends for very large format layouts. Legends will automatically resize to accommodate large captions. The preview pane will try to show the characteristics of the font but will show text only in the 8 to **12** point characters to preserve the usability of the preview pane.

**Styles**

The **Style** box allows choice between **Standard** and **Transparent** styles. Together with use of the color boxes and the **Caption** this allows us to specify a different appearance for the legend.

![For example, suppose we have a drawing of Mexico that is thematically formatted.](image)

We can add a legend using the **Standard** style.
This creates a legend in a box with an upper caption. The caption box is colored using the same color as the border (black) and the legend box is filled with the fill color (white).

We can change the style to **Transparent** for a different effect.

In this case the border and background disappear and the fill color is used to fill in the caption.
We can remove the Caption text.

In that case the caption disappears (the legend has been moved to a different position in the drawing for this screenshot). This is a nice effect for a simple legend that uses whatever is the background color of the component.

To see how a Standard style legend looks with no text in the Caption box, we change the Style back to Standard.
That will draw a border but no caption. The fill color (white) is used to fill the **Standard** style legend.

If we would like a border but we would like the legend to use the same color as the background in the component, we can change the fill color to a light gray color, the same as is used for the background.

That will display a legend with the same background color and also with a border.

**Interval Styles in Legends**

Thematic formats can be interval based, to assign a formatting characteristic based on a fixed range of interval values, or they can be **continuous** if the **Continuous shading** box is checked. Continuous shading results in a smooth interpolation of color between specified values and colors.
Legends will automatically adapt to the status of the **Continuous shading** box.

If the **Continuous shading** box is checked the legend will show the discrete values and colors between which a continuous range of colors is interpolated.

Dynamic legend elements will use the same number of digits beyond the decimal point that are specified for that column in table column formatting.

**Resetting a Legend**

To go back to the default style of legend, un-check the **Customize Legend** box and then show the default legend. This will clear any customized legend lines.

**Legends in Maps**

By default, legends in maps will automatically be created by combining the legends of the map’s constituent layers, with the legends being assembled in the same order as layers.
Maps have a dynamic legend element type called Component: together with the name of a layer. The Component: element type automatically incorporates into the map whatever is the current legend for that component. The Hide if turned off checkbox hides the Component: element type if that layer is turned off. Legend elements for map layers that are currently turned off are marked hidden in the legend dialog.

Columns

Columns are created by adding a new line to the legend and choosing the Vertical Separator type for that line. See the Adding a Legend example topic.

Adding a Legend to a Print Layout

See the Legends, Scale Bars and North Arrows in Layouts topic.

Tech Tips

Legends, north arrows and scale bars can be copied and pasted between components. Pasting a legend with the Paste Append command appends the new legend below the existing legend. Copying a legend and pasting it into a map can be a quick way of customizing a map’s legend when a new layer is added.

Using legends with images is a fast way to get RGB color numbers for colors used in icons, web pages and so on. Copy a screen shot to the Windows clipboard with the Print Scrn button on the keyboard, switch to Manifold and Paste As an image into the project pane. Open the image and show a legend to see the colors.
In the example above we have made a screen shot of the Windows desktop, zoomed into the Manifold icon, selected the region about the icon, cropped the image and then displayed a legend. The Manifold icon uses only a few colors. Other icons using 256 colors will require longer legends, of course.

See Adding a Legend for an example of creating a legend and then customizing it to change display styles, to use multiple columns and to use a horizontal style instead of the default vertical column style.

See the Thematic Formatting topic for more information on coloring drawings using database attributes.
Legend Text Escape Sequences

Text items in legends may contain values in square brackets [ ] that will be filled in with automatically-generated text whenever the legend display is refreshed.

Escape sequences supported by all legend items:

- [Component] Component name.
- [Computer] Windows name of the computer.
- [Coordinate System] The coordinate system of the component (same as [Projection]).
- [Date] Current date in short date format specified in Windows Regional Options. A typical Windows default is 8/27/2003.
- [Datum] Datum used in the coordinate system of the component.
- [Day] Current day in the month, from 1 to 31.
- [Description] Component description (accessible through the Properties dialog for the component, via the context menu for the component in the project pane).
- [Hour] Current hour, from 1 to 24.
- [Filename] Name plus extension of the project file. In a new project, will be empty until the project is first saved.
- [File Path] Fully qualified name of the project file. In a new project, will be empty until the project is first saved.
- [File Title] Title of the project (displayed in the main window title). Before a project is saved for the first time will be a system generated name such as Project1. After the project is saved, will be the same as the project file name without the .map extension.
- [Long Date] Current date in long date format specified in Windows Regional Options. A typical Windows default is Wednesday, August 27, 2003.
- [Minute] Current minute, from 1 to 60.
- [Month] Current month, from 1 to 12.
- [Month Abb] Current month as a three-letter abbreviation, such as Aug.
- [Month Name] Current month name, such as August.
- [Projection] The coordinate system of the component (same as [Coordinate System]).
- [Second] Current second, from 1 to 60.
- [Time] Current time in format specified in Windows Regional Options. A typical Windows default is 3:41:08 PM.
- [Unit] Unit used in the coordinate system of the component.
- [User] User login running Manifold.
- [Weekday Abb] Current weekday as a three-letter abbreviation, such as Wed.
- [Weekday Name] Current weekday name, such as Wednesday.
- [Year] Current year.

Escape sequences for area, label, line or point formats:
[Column] Name of the column used in thematic format.

[Type] Object type name, such as Areas, Lines, Points or Labels.

[Type / Column] Object type name, with name of the column used in thematic format, if any.

Tables

Tables show data organized into rows and columns. Every row in a table is a record. Every column in a table is a field. We will use the words “row” and “record” interchangeably. We will also use the words “column” and “field” interchangeably.

### Mexico Table

<table>
<thead>
<tr>
<th>ID</th>
<th>Place name</th>

<td>COAHUILA</td>
</tr>
</tbody>
</table>

**Tables and Drawings**

Every drawing in Manifold has a table associated with it. Each object in the drawing (that is, every point, line or area object in the drawing) is linked to a row in the table. Drawings have a table even if there is no data saved for each object. In that case, the drawing's table is mostly empty. It has only one field, the object ID field, for each row. The object ID field is used to link each row to its associated object and cannot be edited. It is indicated as the key field with a small key icon in the column name.

Deleting an object in a drawing will delete the object's record in the drawing's table. Deleting a record in a drawing's table will delete the associated object in the drawing.

**Other Tables**

Tables may also be database tables that are imported into a Manifold project or linked into the project from an external database source. New tables may also be created with Manifold.

Tables may be brought into projects from almost any database, even from those that have nothing to do with drawings or maps. We will often work with tables that have no geographic context. We may wish to prepare data for later use together with drawings and maps, or we might simply wish to use Manifold as a general-purpose means of viewing, analyzing, exploring and managing databases.

The illustration above, for example, shows a project with tables imported from the Microsoft Northwind Traders example database shipped with Microsoft Access.
Manifold® System Release 8.00 User Manual

If we open the Customers table we see the same data familiar to many Access users who have worked with this sample database.

### Tables and Queries

Both tables and queries appear as tables when opened in a table window. Manifold has several types of tables that may appear in a project and that are created in different ways.

<table>
<thead>
<tr>
<th>Type</th>
<th>How Created</th>
</tr>
</thead>
<tbody>
<tr>
<td>Ordinary Tables</td>
<td>Created using File - Create - Table.</td>
</tr>
<tr>
<td>Tables linked to drawings.</td>
<td>Created whenever the drawing is imported or created. Each object in the drawing will be automatically linked to one row in the table.</td>
</tr>
<tr>
<td>Tables that have been imported into the project.</td>
<td>Created using File - Import - Table from a file in one of the database formats supported by Microsoft Data Access Components (CSV, DBF, MDB, XLS, etc) or an arbitrary data source using the Data Sources dialog. Importing a table brings the entire content of the table into the project.</td>
</tr>
<tr>
<td>Tables that are linked to external files or database providers.</td>
<td>Created using File - Link - Table from a file in one of the database formats supported by Microsoft Data Access Components (CSV, DBF, MDB, XLS, etc) or an arbitrary data source using the Data Sources dialog. Linking a table leaves the data outside of the project where other programs can continue to work with it.</td>
</tr>
<tr>
<td>Queries</td>
<td>Created using File - Create - Query. Right clicking the query in the Project pane and selecting Open or double clicking the query edits its text. Right clicking the query and selecting Run runs it and displays the resulting records as a table. Action queries do not return any records. Queries can reference any table or query in the project, including tables linked from external data sources.</td>
</tr>
</tbody>
</table>

Note that all of the above tables can be opened in table windows and manipulated using essentially identical methods. Tables that are linked to drawings can be opened in their own windows just like any other table, and often are. The only difference between tables linked to drawings and other tables is the dynamic tie between drawings and their tables. Every object in a drawing is represented by a record in the table. A selection made in the drawing appears in the table and vice versa. Deleting an object or a record in the table will immediately take effect in the linked component as well. See Drawings and Tables for examples.

### Importing or Linking Tables

Once a table is imported into a Manifold project the table and the data it contains are managed by the Manifold database engine. However, the process of opening external database files or providers and getting data from them into Manifold is managed with connection technologies embedded within Manifold. When external tables
are linked into a project (instead of being imported) the desired connection technologies will be used to manage access to those tables.

All data access technologies are included even though their capabilities overlap when working with simple files. By providing all methods Manifold provides users with convenience, reliability and flexibility. OLE DB for read/write connections or ADO.NET for read-only connections are recommended for maximum speed.

Jet is the database engine used by Microsoft within Microsoft's own Access database products. The File - Import - Table menu choice uses Jet to open simple file types and to import their tables and data into the Manifold project. Providing Jet within Manifold allows users to open simple database file formats that are frequently encountered in Microsoft Office installations.

With the Import dialog, different formats may be opened by simply choosing the desired database type in the Files of type list as shown above. Using Jet also provides high reliability since this is Microsoft's own code used to open simple Microsoft file types that are widely used throughout Office and similar applications.

Choosing Data Sources in the Files of type list will allow us to connect to a data source using the Data Source dialog, which can create a data source with whatever other drivers that are on our system, such as ODBC or OLE DB drivers. Most databases, especially older types such as Btrieve, may have ODBC drivers even if they have not been updated with OLE DB drivers.

OLE DB is a newer, faster, more flexible technology that allows general connection to any database system for which there is an OLE DB provider. OLE DB has now superseded the older ODBC methodology.

OLE DB or ODBC provide great flexibility, since they are methods of connecting to any database file or provider for which we have an OLE DB or ODBC driver on our system. If we install Microsoft upgrades or new Microsoft products on our computer that install newer OLE DB providers, Manifold automatically will be able to take advantage of the new providers.

Microsoft Data Access Components includes the standard suite of Microsoft OLE DB providers, as can be seen in the dialogs used to create a new data source within the Data Source dialog.
There is one OLE DB provider of special interest for legacy database access. The Jet 4.0 OLE DB Provider essentially duplicates the capabilities of Manifold's built-in copy of Jet. Using it is equivalent to using Jet via the File - Import - Table menu choice.

ADO .NET is an even newer database access technology than OLE DB and is a standard means of accessing data for applications using the Microsoft .NET Framework. ADO .NET is known for its simplicity and performance; however, it does have the limitation that ADO .NET is generally read-only.

**Importing vs. Linking Tables**

Any of the supported connection methods can be used to import tables and their data into projects or to link to tables for which the data remains in external files or providers. Once a table is imported into a project the Manifold database engine takes over all management of the data. Therefore, once a table is imported there is no difference between tables regardless of what connection methodology was used for the import.

However, if tables are linked into a project and their data remains in external files or providers, then whichever method was used for the linkage will continue to be used to access the tables and the data they contain. In addition, performance and other characteristics will be subject to the advantages or limitations of whatever file format or provider is being used.

**Linking to External Tables and Multi-User Applications**

When linking to an external file or provider used by multi-user applications Manifold will participate correctly in any multi-user accesses that might go on simultaneously from other applications. This is true for all types of connections.

For example, if we link to a table in an external SQL Server database some other person or process could simultaneously open that table with SQL Server over our corporate network as well. They could access the table from a different machine and work on it from that other machine even as we continue to work on the same table with Manifold. Any updates or changes done by Manifold will be consistent with any locking or other protocols designed to maintain order in multi-user applications. This allows Manifold users to work with external databases from within Manifold even as they are being used by different applications.

Choose the data access method carefully when embarking on demanding multi-user applications. For example, although Jet may be used for multi-user operations with .mdb Access files it is not as robust and reliable a system for multi-user work as is SQL Server. Manifold users can always use the SQL Server Express installation available on the Manifold CD to create highly robust multi-user capable database tables.

**Linking Drawing Data Attributes to External Tables**

So far we've seen that every drawing is linked to a table and that the drawing's table is created within the project at the same time the drawing is created. All such tables exist entirely within the project. Sometimes we would like to link our drawing to an external table that is linked into the project.

Perhaps, for example, we have a drawing of European countries and we would like to color those countries with a thematic format that uses our company's sales for each country. If the company's sales are saved in a table in some corporate server it would be nice to link that external table to the drawing so that every time we open the drawing window the colors in the thematic format are taken from the actual sales recorded on that moment in the corporate server.

To do this we use a relation to link the drawing's table with an external table. See the Attaching External Tables to Drawings topic.

**Tips**

- The fastest performance for smaller tables is achieved by importing a table into a Manifold project so the data it contains may be managed directly by Manifold's own database engine. Compared to big-time DBMS packages like Oracle or SQL Server there is no advantage for medium or large tables, and in the case of very large tables it will often be faster to use an external, enterprise-class DBMS like Oracle or SQL Server.
- Tables that must be shared with other applications should be linked into the project so that their actual data remains outside Manifold where it is easy for other applications to reach the data without needing to know anything about Manifold.
• Use the most direct access method. For example, if the data is in Excel .xls files, open them directly using Jet via File - Import - Table. Don’t use the OLE DB Provider for ODBC Drivers to open an Access ODBC driver that is then used to open the .xls file!
• Tables in Manifold are limited to 4 gigabytes of size. Tables linked from external DBMS packages can be unlimited in size.
• Learn to use the Transform toolbar for fast edits and management of tables.
• Read the Queries topics as well as all the topics in the tables Help book.
• Modern Windows edition (2000 and subsequent) users can drag and drop columns in tables to move them left / right.
• By default, table windows do not use horizontal or vertical gridlines between rows and columns. Gridlines may be turned on in Tools - Options.
• From the context menu for table columns (right click onto a table column head) choose Best Fit, Best Fit All or Best Fit Titles to set width of table columns automatically.
• Manifold tables stored within a project do not support NULL values; however, tables or queries that are linked into a project will support NULL values if their originating data provider supports NULL values. Such columns are said to be NULL-able.

Examples Used

Many of the illustrations for tables are screen shots made using the Nwind.mdb sample database provided by Microsoft. This is a version of the Northwind.mdb sample database distributed with Access and thus familiar to many Microsoft Office users. Nwind.mdb is provided on the Manifold System CD as a sample.
**Importing and Linking Tables**

Tables in Manifold projects may come from a variety of sources. They may be imported into the project or left outside the project and linked into the project. In addition, when either importing or linking a table into a project we have a choice of opening common file types (such as MDB or XLS) directly, or using the Data Source dialog to connect to databases using common technologies such as OLE DB, ODBC, ADO.NET or selected native DBMS connection technologies.

Except for direct access via the Oracle Call Interface to Oracle databases (see below), ADO.NET is usually the fastest way to connect, although it allows only read-only access to tables. OLE DB is a general means of accessing almost any type of provider that is a more modern and efficient method than ODBC, an earlier technology intended to provide universal access to different databases. In comparison to ADO.NET, ODBC is dramatically slower. Manifold supports ADO.NET, OLE DB and ODBC since different databases may have either OLE DB or ODBC drivers.

To import or link a table into a Manifold project

1. Choose File - Import - Table or File - Link - Table depending on whether you wish to import the table or to link it.
2. In the Files of type box choose the access method desired, either choosing a common file type such as .MDB for direct connection or choosing Data Sources () to connect via the Data Source dialog.
3. When using a common file type, browse over to the database file and open it. When using the Data Source dialog, double-click on the data source to open it if it has already been added to the list in the Data Source dialog. Create the data source if it has not yet been added, as is shown in the Data Source dialog topic.
4. Choose the table to be imported or linked.
5. When linking tables, check Read Only if you wish a read-only link.
6. Press OK.

After the initial choice of File - Import or File - Link, all dialogs are the same. The only difference is whether the data in the table is copied into the project or if it is left outside in an external file or data source.

Alternate method to import or link a table

1. Open the Tools - Database Console dialog.
2. In the Data source box, specify a data source by pressing the [...] browse button and then choosing a data source from the list in the Data Sources dialog.
3. In Database Console, press the Refresh button to display the contents of the data source.
4. The upper pane will show the contents of that data source, including any tables and the fields they contain. Click on a table to highlight it.
5. Click on the Import button in the dialog's toolbar to import the highlighted table. Click on the Link button to link the table.

In all cases, tables that are imported or linked will appear to be part of the project like any other table. Manifold can import data from or link to a very wide range of database files and database providers. Manifold supports use of schemas when importing or linking data from SQL Server, Oracle or similar data sources.

**Importing vs. Linking**

- **Importing** a table will bring a copy of that table's data into the Manifold project file.
- **Linking** a table will leave the table's data in a file or data source outside the Manifold project.

Both methods have advantages and disadvantages depending on how the project will be used.

**Advantages of Importing**

- **Speed** - Imported tables will provide much faster performance than using an external data source that is a slow file format (such as a .csv text file or an Excel .xls file); however, tables linked from fast external data sources, such as Oracle or SQL Server will be faster for very large tables.

- **Convenience** - When tables are imported into the project, copying the .map project will automatically copy all tables in the project as well. There is no need to worry about tables that may be resident in other files or maintaining links to database systems that may be inaccessible from different systems.

- **Control** - Importing the data provides complete control over the data and assures that no external program will alter it in a way that is incompatible with its use within the project. If other programs could alter the table (if it were linked and not imported) they might alter it in a way that is incompatible with the Manifold project, for example by removing a field that is used elsewhere within the project.

### Disadvantages of Importing

- **Size Limitation** - Manifold cannot import tables that exceed four gigabytes in size. This limitation does not apply to external, linked tables.

- **Single User Tables** - Only one user can work with Manifold at a time, so that once a table is imported into Manifold it is not accessible by other programs in a multi-user way. An exception is using the Manifold ODBC interface to connect to a Manifold project from a different Manifold session. However, if that's what we have in mind it is usually more conceptually easier to remember what is going on by simply storing shared data in an external database, such as SQL Server Express or Oracle Express.

### Advantages / Disadvantages of Linking

- **External Modifiability** - The main advantage of linking tables is that it leaves the data in an external file or data source where other programs can easily modify it. Of course, if we don't want to risk uncontrolled modifications this is a disadvantage.

- **One Copy of Data** - Linking tables avoids making copies of potentially very large data sets. When a database is a standard archival source, always linking to it instead of copying it assures that the version in use in the project is the currently archived version. The disadvantage, of course, is that one must remember to make copies of linked tables when interchanging projects. Also, changes made in Manifold operations can result in unwanted alteration of the archival original.

- **Multi User Operations** - When linking to external tables, Manifold System is fully multi-user capable and can simultaneously work with, for example, an SQL Server or Oracle table on a remote server even as other users continue to work with the same database. If we are looking at an external table in which data is unexpectedly changing, we must keep in mind the possibility that users on other machines are also working on that same table at the same time and are making changes to the data it contains.

- **Larger Tables** - External (linked) tables can be much larger than the four gigabyte limit on internal (imported) tables.

- **NULLs Supported in Linked Tables** - Although native tables in Manifold do not allow use of NULL values, linked tables may use NULLs if the data source to which they are linked allows the use of NULL values. Such columns are said to be **NULL-able**.

### Important Note when using 64-bit Manifold Editions

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKx format files. This includes no access to the MDB parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut.

Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

### Linked Tables are Read / Write

A very useful aspect of linked tables in Manifold is that they are a "live" connection to the data source from which they are linked. We can make changes in the linked table and those changes will be implemented back to the data source from which the table is linked. In particular:

- A linked table allows adding or paste-appending a new column, renaming an existing column, and changing the type of an existing column.
- We can change the design of a linked table.
- It is possible to geocode records in a linked table.
Columns in a linked table work with transfer rules just like native tables.

All of the above capabilities apply to both standalone linked tables and tables bound to linked drawings. In fact, Manifold's ability to manipulate linked tables is so extensive that Manifold is often used as a front end for databases having nothing to do with GIS, to take advantage of the Transform toolbar and other facilities.

For example, if we would like to add a primary key field to a table in an Access .mdb database, we can launch the Database Console and browse to the .mdb, the browse to the table desired and use the Database console toolbar Link button to instantly link the table into our project.

Open the linked table. Choose Table - Design to see and alter the design of the table. Add a new field to be the key field using a default 32-bit integer type. In the Table Design dialog toolbar press in the View Extended Properties mode button. In the Unique column that thus appears for the key field, choose primary key as the value. Press OK.

Although we do the above work on a linked table in the Manifold project, because the linked table is a direct visualization of the table in the Access .mdb database, the changes we make to the linked table instantly take effect in the Access .mdb as well.

Unlinking a Table

A table that has been linked into a project can be converted into an unlinked table, as though it had been imported instead of linked. To do so, right click on the table in the project pane and choose Unlink. This will import a local copy of the table into the project and will eliminate the link.

Relinking a Table

A linked table may be disconnected from its data source. For example, a data source might be resident on a different machine that crashes. Use the Relink command (in the Table menu and in the context menu when clicking on a table in the project pane) to reconnect the linked table to a data source.

For example, one might create a .map file that contains a linked table that is linked to an Access .mdb file. If the .map file and the .mdb file are moved to another machine the link might not continue to work. In that case one can use the Relink command to reconnect the table in the project to the .mdb file.

Properties

We can get useful information on a linked table by right clicking on it in the project pane and choosing Properties to see the View - Properties dialog. Clicking the [...] browse button to the right of the Status information line opens a very useful dialog that shows the data source of a linked component, the link technology and the name of the rowset, if the component is linked from a table or query and the behavior of the data in multi-user editing scenarios.

Cascading Links and Refresh Data

Manifold allows cascading links, where one linked component is created from another linked component. Circular links are resolved automatically. For example, suppose we create a linked table called Table A in a project that is linked from a geocoded table called Table X in an external data source, such as a table in a SQL Server or Oracle database. We could then create a linked drawing in the project that is linked from that linked table. Let's say we call that linked drawing Drawing A.

However, when a cascading link is created in this way, refreshing the linked drawing will update the drawing to any changes made in the linked table, but it will not cause a cascading refresh backwards out of Manifold to the external database. That is, if we make any changes in Table A and we then refresh Drawing A, the drawing will show those changes. However, if we make any changes in the external Table X and then we refresh Drawing A, the changes will not appear in the drawing. We must first refresh Table A so that it incorporates the latest changes in the external Table X and then we can refresh Drawing A.

Preserving Paths to Linked Tables
Linked tables are saved within Manifold projects using relative pathnames. Moving a .map file that contains a linked table will preserve the link to the table provided that the relative path from the .map file to the linked table file has not changed.

For example, suppose we have a .map file located in C:\projects\Carson\mymap.map that contains a linked table located in the file C:\projects\Carson\tables\airport.dbf. If we move the .map file to D:\backups\January\mymap.map it will still preserve the link to the table if the table file is moved to D:\backups\January\tables\airport.dbf.

ADO.NET, OLE DB, ODBC and Common File Types

Both the File - Import - Table and the File - Link - Table dialogs allow opening a wide range of file types. In addition to common file types such as Access MDB and Excel XLS, Manifold can also open "file types" using ADO.NET, OLE DB or ODBC data sources. Choosing OLE DB or ODBC uses Microsoft OLE DB or ODBC drivers to connect to a data source. Choosing a common file type uses a direct connection via Microsoft's Jet database engine to import or to link to file formats understood by Jet.

Common file types allow import tables from CSV (comma separated values ASCII files), DB (Borland Paradox), DBF (dBase and FoxPro), HTML (tables in web pages), MDB (Access 2000 and Access 97), UDL (Microsoft Universal Data Link), WKx (Lotus) and XLS (Excel).

Using the Data Sources dialog allows us to connect using virtually any technology, such as OLE DB providers or ODBC drivers or ADO.NET or ODBC.NET providers as well.

Using Tools - Database Console launches the Database Console for interactive browsing of data sources to see what tables are available and what fields and type of fields they contain. Toolbar buttons allow importing or linking tables from data sources as can be done via the File - Import and File - Link commands. The Database Console dialog also allows interactive execution from within Manifold of command language statements to manipulate the external database.

See the discussion in the Data Source dialog topic regarding various connection technologies.

See the Tables topic for more discussion of direct connections to common file types as compared to using OLE DB or ODBC.

Files of Type Choices

We can specify many different types of data sources for importing or linking tables. Manifold's internal copy of the Microsoft Jet database engine (available when running in 32-bit mode: Jet is not available in 64-bit mode) can directly read database files in the following formats, including all the various sub-variations normally found of these. In addition, we can choose to connect using the Data Sources () option to invoke the Data Sources dialog. This will allow us to connect to more sophisticated data sources using connection technologies such as OLE DB, DSN or UDL.

</table>

We can specify many different types of data sources for importing or linking tables. Manifold's internal copy of the Microsoft Jet database engine (available when running in 32-bit mode: Jet is not available in 64-bit mode) can directly read database files in the following formats, including all the various sub-variations normally found of these. In addition, we can choose to connect using the Data Sources () option to invoke the Data Sources dialog. This will allow us to connect to more sophisticated data sources using connection technologies such as OLE DB, DSN or UDL.
No other database software in addition to Manifold System is required to read such files.

For example, virtually all .dbf format files common to dBase and similar systems can be directly read. When text file types (.txt, .asc) are opened, Manifold will open sub-dialogs as necessary to allow user assisted parsing of the text file format. Note that import of text table follows usual PC industry conventions. For example, the first line of the text table should contain the names of the fields in the table.

Choosing Multiple Tables

When using File - Import - Table or File - Link - Table we can choose to import or link more than one table at a time from a database file that contains multiple tables.

For example, if we wish to import tables from Microsoft's sample Nwind.mdb database, we choose several at a time.

Click on any table to highlight it. Click on more tables using CTRL click or SHIFT click in the usual Windows way to highlight additional tables.

SHIFT clicking on another table will highlight all the tables in between.

Note: Some databases have many tables. To see the tables in sorted order, click on the Name column head in the dialog.

Windows Locale Settings and Table Import

Manifold's table import routines will recognize Windows locale settings for .mdb, .xls, some .dbf files (depending on drivers used) and some other formats and will automatically convert text fields to Unicode when the database file locale is incompatible with current regional options. For example, an .mdb database created with Spanish locale settings will have text fields automatically converted to Unicode if it is imported on a Windows machine employing French settings.
Effect of Tools - Options Settings

When importing tables, keep in mind that the default setting in Tools - Options is to not import empty columns. Check the Import empty columns in tables option to import tables with columns that do not contain any values in the originating table.

Note also the setting of Trim strings imported from external databases (on by default). This will delete leading and trailing token separator characters from imported table strings.

The Trim strings option (just like the Trim table transform operators) removes characters listed in the Tool Properties pane’s list of token separators. By default, these are the "white space" characters consisting of the space character, tab, newline and carriage return. Note that adding any other characters to the separator list in Tool Properties will subject them to removal as well if they occur as leading or trailing characters.

Linked Tables and Disconnects

One risk with using linked tables is that the data source might not be available when we want to use the table within our project. For example, the linked table may reside within a database server on a different machine that might experience a hardware crash. To deal with such situations, Manifold uses a conservative strategy when linked tables cannot reach their data sources.

Linked tables that can not reach their data sources will not break any operations in which they participate. Instead, the linked table absorbs the error returned by the database access layer and will configure itself with the same columns that were in use the last time it was opened and the loading process will continue. As a result, occasional crashes of a database server will not break relations between the linked table and other tables in the project. Columns within the linked table will be filled with default values until the server comes back to life and we can reconnect to the server using the Refresh Data command.

One risk of this “fail safe” strategy for dealing with disconnects is that it is possible for a linked table to exist within a Manifold project after some external agency (such as an unwary database administrator) has eliminated the table from its data source. In such cases we will have to delete the linked table manually from the project. Manifold will not automatically delete such tables because in such (hopefully rare) circumstances it is better to have to manually delete in order to be able to take any necessary clean up measures should the linked table have been used in any relations, scripts or elsewhere in the project.

Properties

The View - Properties dialog for components shows the data source of a linked component (such as a linked table) and other relevant information.

The Link / Share dialog accessed from the [...] browse button for linked or shared components accessed from the View - Properties dialog will provide a summary of the link or share properties. This will show the status of a shared component and whether or not changes in a linked component will propagate back to the data source.

Enterprise Edition

If you have installed the Enterprise Edition of Manifold System you will have an additional, very powerful means of importing and linking tables. Enterprise Edition allows centralized storage of components, including tables, within Enterprise servers that are hosted by external database systems, such as DB2, Oracle or SQL Server. Tables may be imported from an Enterprise server or linked into the project while remaining resident on the Enterprise server.

See the Enterprise Edition topic for more information.

Database Console
View - Refresh Data
Table Window Menus and Controls

When we click onto a table window, Manifold will automatically change menus and toolbars so they contain those menus and controls that work with tables.

Edit, View and Table Menu

**Edit**

- **Undo**
  - Undo last command.

- **Redo**
  - Redo last undone command.

- **Cut**
  - Windows clipboard cut operation.

- **Copy**
  - Windows clipboard copy operation. Use this to "paste" a column's worth of field data into a different column of compatible type.

- **Paste**
  - Paste the contents of the Windows clipboard into this column.

- **Paste Append**
  - Append the contents of the Windows clipboard onto the bottom of this column.

- **Delete**
  - Permanently delete this field from the Table.

- **Delete All**
  - Permanently delete all records from the Table.

- **Select All**
  - Select all records in the table.

- **Select None**
  - Deselect all records in the table.

- **Select Inverse**
  - Invert selection: those records that were highlighted will be deselected while those records that were not highlighted will be selected.

- **Select Mode**
  - Choose the selection mode to be used for mouse selection:
    - **Replace** - Any selection made with the mouse will replace the previous selection.
    - **Add** - Any selection made with the mouse will be added to the previous selection.
    - **Subtract** - Any selection made with the mouse will be subtracted from the previous selection.
    - **Invert** - Any selection made with the mouse will be inverted with the previous selection.
    - **Intersect** - Any selection made with the mouse will be intersected with the previous selection.

- **Find**
  - Find a string or value using various options.

- **Replace**
  - General search and replace dialog.

- **Bookmarks**
  - Toggle (create or clear) a bookmark at the current record, Go to previous or next bookmark or Remove All bookmarks.

- **Go**
  - Go to First, Previous, Next, Last or Blank (append a new record) records.

- **Go To**
  - Go to a particular record by sequential record number or by object ID.

**View**
**Selection Filter**  Show only selected records. See Selection in Tables.

**Columns**  Show or hide columns and specify their order.

**Sort**  Launch sort dialog to allow multi-level sorts.

**Panes**  Turn on and off Manifold panes.

**Full Screen**  Show table using full screen.

**Refresh Data**  Refresh data in a linked table.

**Properties**  Show this table’s properties.

**Table**

**Open Drawing**  Enabled for tables that are linked to drawings. Opens the drawing associated with this table.

**Open Script**  If a table is created with a script, open the script that is associated with this table.

**Add**  Add a new column, a new Active Column or a new Rank Column to the table.

**Address**  Geocode the table against an address geocoding database. See the Street Address Geocoding topic.

**Match**  Spatially geocode the table using a multilevel match of fields against a drawing.

**Design**  Add or delete fields of various types to this table.

**Relations**  Form relations with other tables that will allow use of columns from those other tables in this table.

**Relink**  Enabled for linked tables. Reconnect the table to its data source when the link is severed.

**Unlink**  Enabled for linked tables. Convert the table from a linked table to a regular table. Equivalent to importing the table.

**Tools**

**Database Console**  Shows the contents of OLE DB data sources, including tables, fields and types of fields. Provides toolbar buttons to quickly import or link tables from an OLE DB data source. Allows use of whatever native command language is used by the data provider. A means of browsing and controlling databases interactively without leaving Manifold.

**Note:** Copying tables or table columns or records will copy data to the Clipboard both in internal Manifold format as well as conventional Windows tab-separated text format, which is handy for pasting into Access, Excel and numerous other Windows programs that use tables.

**Navigation Toolbar**

Clicking on a Table window will adapt the navigation toolbar with buttons relevant to Table window operations:

- **First**  Jump current record pointer to the first record in the Table and scroll as necessary to display it.
Previous  Move current record pointer to the previous record in the Table and scroll as necessary to display it.
Next  Move current record to the next record in the Table and scroll as necessary to display it.
Last  Jump current record pointer to the last record in the Table and scroll as necessary to display it.
Blank  Jump to the end of the Table to append a blank record.
Filter  Filter - Specify the criteria used to show or hide records. (Reserved for future expansion. Currently offers only a selection filter option.)
Sort  Launch sort dialog to allow multi-level sorts.

Selection Toolbar

The selection mode buttons control how a new selection made with a selection tool is combined with any existing selection. One selection mode button is always pushed in. In tables the selection mode regulates how clicking on the record handle selects that record.

Replace Selection  Replace the existing selection with the record clicked.
Add to Selection  Add the clicked record to the existing selection.
Subtract from Selection  Subtract the clicked record from the existing selection.
Invert with Selection  If the clicked record is already selected, deselect it. Otherwise, select the clicked record.
Intersect Selection  Select the clicked record only if it is already in the selection. Deselect anything not clicked. This mode usually only makes sense with SHIFT-clicks between the current record and another record.
Selection Filter  Show only selected records in the table.
Selection Style  Change the selection style in drawings to a less intrusive pattern or color or other style. The pull-down arrow next to the Use Selection Color button opens a menu of possible selection styles. This control is normally only used with tables that have an associated drawing and also have the drawing window open. Without changing context from the table one can change the appearance of selected items in the drawing.
Select None  Deselect all items.

Context Menus

Right clicking onto a column head or record handle or cell pops open a context menu with commands that may be applied. These are called "context" menus because the choices they present depend on the context of the right click.

Column Heads (Right click onto a column name)

Note: Columns are the same as fields. The words "column" and "field" are used interchangeably within Manifold.
Sort Ascending | Sort the table using values in this column so that lower numbers or letters nearer to A are at the top.

Sort Descending | Sort the table using values in this column so that higher numbers or letters nearer to Z are at the top.

Add

Add - Column | Add a new column to this table.

Add - Active Column | Add a column in which values are determined by the results of a script. See Active Columns.

Add - Rank Column | Add a column used to rank records by the results of a Decision Support System query. See Rank Columns.

Edit | Edit the definition of an active or rank column.

Edit Script | Edit code for an active column.

Flatten | Convert to a native (regular) column an active column or rank column or a column brought into the table via a relation.

Flatten All | Convert to native (regular) columns all active columns, rank columns and columns brought into the table via relations.

Recompute | Recompute values in an active column.

Cut | Windows clipboard cut operation. Copy selected records to the clipboard and delete them from the table.

Copy | Windows clipboard copy operation. Copy selected records from this table onto the clipboard.

Paste | Paste the contents of the Windows clipboard into this table, replacing selected records.

Paste Append | Paste the contents of the Windows clipboard into this table, appending them to the table.

Delete | Permanently delete selected records from this table.

Rename | Change the name of this column.

Transfer Rules | Specify how the values in this column should be transferred in operations such as those in the Spatial Overlay dialog.

Format | Specify how values should appear in this column.

Width | Specify the width of this column in pixels.

Hide | Show or hide this column. To find hidden columns, use the View - Columns command in the main menu for tables.

Change Type | Change the field type of this column. Note that not all field types may be freely converted. For example, the number 132 can be converted into a text string containing the characters “132”, but the text value “Madrid” cannot be converted into a number.

Language | Specify Windows code page to be used for this column. Different columns in the same table can use different code pages to support different languages. Enabled for ANSI text fields only.
<table>
<thead>
<tr>
<th>Order</th>
<th>Move the column to the top (leftmost position), up, down, or to the bottom (rightmost position) in the display.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Best Fit</td>
<td>Arrange the width of this column so that the values in the database will fit in it without extra space.</td>
</tr>
<tr>
<td>Best Fit All</td>
<td>Arrange the width of all columns so that the values in the database will fit in them without extra space.</td>
</tr>
<tr>
<td>Best Fit Titles</td>
<td>Arrange the width of all columns so that the full text of all column head titles is visible.</td>
</tr>
<tr>
<td>Identity</td>
<td>Select the ID column to be used in tables created with queries that have more than one identity column. See the Queries topic.</td>
</tr>
<tr>
<td>Find</td>
<td>Find a particular value in this column. Regular expressions may be used to search for patterns.</td>
</tr>
<tr>
<td>Replace</td>
<td>Find and replace values in this column. Regular expressions may be used to search for patterns and to specify their replacements.</td>
</tr>
</tbody>
</table>

**Records (Right click on record handles at left margin)**

[Note: Cut, Copy, Paste and Paste Append from the Edit Menu work on Records]

| Cut | Windows clipboard cut operation. |
| Copy | Windows clipboard copy operation. |
| Paste | Paste the contents of the Windows clipboard into this record. |
| Paste Append | Append the contents of the Windows clipboard as a new record. |
| Delete | Permanently delete this record from the Table or Query. |
| More Like… | Open a sub-dialog that allows detailed specification of how fields will be used to find additional records that are like this one. |
| More Like This Record | Highlight records that are like this one, considering all the fields that are turned on for display in the Table window. |
| More Like This Record (Sorted) | Highlight records that are like this one, considering all the fields that are turned on for display in the Table window, and sort the database so that the records most like this record are at the top and those least like this record are at the bottom. |
| Coordinates | In tables associated with drawings, show the coordinates that define the drawing object for this record. |

**Cells (Right click onto a cell)**

| Cut | Windows clipboard cut operation. |
| Copy | Windows clipboard copy operation. |
**Paste** Paste the contents of the Windows clipboard into this cell.

**Paste Append** Append the contents of the Windows clipboard to this cell. Works with text types only, and is disabled when cells contain other types.

**Delete** Permanently delete the content of this cell from the Table or Query and restore the default value. For example, using **Delete** on an integer field will reset the value to zero.

**More Like…** Open a sub-dialog that allows detailed specification of how this field will be used to find additional records that are like this one.

**More Like This Cell** Highlight records that are like this one, considering only this field.

**More Like This Cell (Sorted)** Highlight records that are like this one, considering only this field, and sort the database so that the records most like this record are at the top and those least like this record are at the bottom.
Creating New Tables

Manifold can create new database tables. Use the File - Create - Table command to create a new table in a Manifold Project.

To create a new table in a Manifold project

1. Choose File - Create - Table
2. In the Create Table dialog, click the Add Column button to add a new column.
3. Double-click into the Name cell to specify the name for the column.
4. Double-click into the Type cell to specify the type of each column. Click into any other cell to accept the type chosen from the list box.
5. Double-click into the Size cell to specify the size of each column for those field types that allow specifiable size.
6. Repeat steps 2 through 5 for each field that is to appear in the table.
7. Click on any field to highlight it and choose Move Up or Move Down to change the order in which it appears. The top field will be leftmost in the table.
8. When finished, press OK to create the table.

See the Field Types in Tables topic for a complete list of field types supported within Manifold tables.

Tables may also be altered at any time using the Table - Design dialog.

Copy and Paste As

Tables may be created from other components by using Edit - Copy to copy the other component in the project pane and then using Edit - Paste As to paste the component as a table.

Copying tables or table columns or records will copy data to the Clipboard both in internal Manifold format as well as conventional Windows tab-separated text format, which is handy for pasting into Access, Excel and numerous other Windows programs that use tables.

Example: Copy an Image into a Table

1. Click on the project pane to make it active.
2. Right-click on the image component to be copied and choose Copy from the context menu.
3. Right-click anywhere in the project pane other than onto an existing component and choose Paste As... and then Table in the context menus that appear.
4. Choose the options desired in the dialog that appears for how the image data should appear in the table. For example, for each pixel we can create separate fields giving the Red, Green and Blue channel values for that pixel.
5. This creates a new table component where each record in the table is taken from one pixel in the image. The table is "geocoded" with the pixel locations of each pixel in the image together with the values of the pixels.
For more sophisticated use, it is also usually possible to **Copy** from within a component window and to **Paste As**... the data directly into a new component in the project. For example, we can select points within a drawing and then **Copy** those points, click onto the project pane to move the focus there and then use **Paste As**... a table to create a table that contains geocoded records for each copied point.

**Autoscope**

The "scope" of a **Copy** is what is copied. When copying from an open drawing, image or other window, if a selection is present only those items (image pixels, drawing objects, table records, etc) that are selected will be copied. This is an example of **autoscope**, where the scope of the copy is automatically restricted to the selection if one is present.

In contrast, when using **Copy** to copy components that are highlighted in the project pane the entire component will be copied whether or not there is a selection within that component.

**Typical Copy and Paste As Table Combinations**

- **Drawing to Table**: Reads the coordinate locations of points and pastes them as records into a geocoded table. This is a fast way of creating a list of latitude / longitude locations for points in a map, such as a city.
- **Table to Drawing**: Paste a geocoded table as a drawing of points.
- **Image to Table**: Create a table where each record is a "geocoded" pixel from the image.
- **Table to Image**: Create an image from a table where each record represents the pixel coordinates and values for each pixel in the image.
- **Surface to Table**: Create a geocoded table where each record contains an elevation value for a given point in the surface.
- **Table to Surface**: Create a surface taking elevation values for point records specified in a geocoded table.

**Pasting Drawings as Tables**

Pasting a drawing as a table displays a dialog to select which columns to paste and then creates a table with the selected columns. The list of columns includes intrinsic columns as well as any active or rank columns or columns brought via a relation that may be defined in the drawing's table. The resulting table will have a record for each copied drawing object.

For a list of intrinsic columns, see the Intrinsic Fields in Tables topic.

<table>
<thead>
<tr>
<th>Column</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Latitude</td>
<td>Location of the centroid Y coordinate (Latitude) for the object.</td>
</tr>
<tr>
<td>Longitude</td>
<td>Location of the centroid X coordinate (Longitude) for the object.</td>
</tr>
<tr>
<td>MinimumX</td>
<td>The minimum X or Longitude value of the minimum enclosing box of the object.</td>
</tr>
<tr>
<td>MinimumY</td>
<td>The minimum Y or Latitude value of the minimum enclosing box of the object.</td>
</tr>
<tr>
<td>MaximumX</td>
<td>The maximum X or Longitude value of the minimum enclosing box of the object.</td>
</tr>
<tr>
<td>MaximumY</td>
<td>The maximum Y or Latitude value of the minimum enclosing box of the object.</td>
</tr>
<tr>
<td>NumberOfBranches</td>
<td>The number of branches in areas or lines that are</td>
</tr>
</tbody>
</table>
multiply-branched objects. Always 1 for points.

<table>
<thead>
<tr>
<th>Field</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>NumberOfCoords</td>
<td>The total number of coordinates that define the object. Always 1 for points.</td>
</tr>
<tr>
<td>ObjectType</td>
<td>The type of object.</td>
</tr>
</tbody>
</table>

The above computed field values appear in angle brackets <>. If the drawing's table already contains field names like the above, when the table is pasted they will be incremented so that instead of "MinimumY" there will appear a "MinimumY2" field. The **NumberOf...** fields will be pasted as Int32 integers, the **ObjectType** field is pasted as a variable-length Unicode text field and all the other computed fields will be pasted as Float64 floating point numeric fields.

### Pasting Images and Surfaces as Tables

Pasting an image or a surface as a table displays a dialog to select which columns are to be pasted and then creates a table with the selected columns. The list of columns includes all columns defined in the virtual table for the copied image or surface component. The resulting table will have a record for each copied image or surface pixel.

For a list of columns available in virtual tables for images and surfaces, see the Virtual Tables for Images and Surfaces topic.

<table>
<thead>
<tr>
<th>Field</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Index</td>
<td>An index into the palette. Appears as a choice only when pasting palette images.</td>
</tr>
<tr>
<td>Color</td>
<td>A decimal number representing the RGB color. The decimal representation of the six-digit hexadecimal number formed by concatenating the three, two-digit hexadecimal values for R, G and B channels.</td>
</tr>
<tr>
<td>Red</td>
<td>A value from 0 to 255 for the Red channel value.</td>
</tr>
<tr>
<td>Green</td>
<td>A value from 0 to 255 for the Green channel value.</td>
</tr>
<tr>
<td>Blue</td>
<td>A value from 0 to 255 for the Blue channel value.</td>
</tr>
<tr>
<td>Alpha</td>
<td>A value from 0 to 255 for the Alpha channel value.</td>
</tr>
<tr>
<td>Intensity</td>
<td>The intensity of the pixel as a value from 0 to 255.</td>
</tr>
<tr>
<td>Hue</td>
<td>The hue of the pixel as a value from 0 to 255.</td>
</tr>
<tr>
<td>Lightness</td>
<td>The lightness of the pixel as a value from 0 to 255.</td>
</tr>
<tr>
<td>Saturation</td>
<td>The saturation of the pixel as a value from 0 to 255.</td>
</tr>
<tr>
<td>Longitude</td>
<td>Longitude or X coordinate of the pixel.</td>
</tr>
<tr>
<td>Latitude</td>
<td>Latitude or Y coordinate of the pixel.</td>
</tr>
</tbody>
</table>

The above computed field values appear in angle brackets <>; **Longitude** and **Latitude** fields are pasted either as as longitude or latitude types or, if the **Latitude / Longitude coordinates** box is not checked as Float64 floating point numeric fields. The **Color** field is pasted as an Int32 integer. All other fields are pasted as Int8 integers.

**Color** appears as a choice only when pasting palette images; however, the RGB and Alpha values appear even if the image is not an RGB or RGBA image. In this case, they represent the R, G, B and Alpha values for the color of the pixel. Note that even though a color may be taken from a palette, it still can be described as composed of R, G and B values.

### Adding Records to a Table

Tables that are associated with drawings cannot have records added to them from the table window since each record in the table is associated with an object in the drawing. Adding a record means adding an object. This is
done in either a drawing window or a map window (if the drawing is used as a layer in a map) by inserting a new point, line or area object. When the new object is inserted into the drawing a new record for it will appear in the table.

To insert new records into tables that are not associated with drawings, click into cells in the new record row (marked with an asterisk) to edit their values. Press **SHIFT-Enter** to append the new record to the table.

Suppose we start with a table with only two records.

<table>
<thead>
<tr>
<th>First</th>
<th>Last</th>
</tr>
</thead>
<tbody>
<tr>
<td>Groucho</td>
<td>Marx</td>
</tr>
<tr>
<td>John</td>
<td>Lennon</td>
</tr>
</tbody>
</table>

If we click on the first empty cell in the new record row and press **Enter** we can begin entering a new name. In this case, we have typed **Ben**.

Pressing **Enter** will enter that value into that cell. Note that the status icon in the row handle has changed to a small pencil to show we are entering a new record. We can press the right arrow on the keyboard to move to the next cell in the row.

If we press **Enter** we can begin editing that cell. After entering the text **Franklin** we can press **Enter** once more to have the cell accept the new value.

If we are happy with our new record we can press **SHIFT-Enter** to stop editing and to append the new record to the table. Note that the editing pencil icon has been replaced with a current record icon in the usual way. A new record row appears as well.

**Specifying Languages for Columns**
Language specification in text columns varies depending on whether Unicode or ANSI text is used. Unicode text columns can simultaneously contain characters from more than one language. ANSI text columns are usually restricted to one language in addition to (possibly) English. Character data contained in an ANSI text column will be interpreted by the system according to the code page associated with that column.

By default, ANSI text columns use the system code page. If desired, any ANSI text column in a table can be set to use a different code page by right clicking on the column head and choosing **Language**.

![Column Language](image)

**Keyboards Editing**

One may also edit data in Table windows using "keyboard style" data editing. **Double-click** into a field to edit it and then push **Enter**. Move the edit box to another field by using the keyboard cursors. Push **Enter** to open the field for editing, enter the new value, and then hit **Enter** to apply the value.

The **Tab** key will move one cell to the right of the active cell. A **Shift-Tab** will jump one cell to the left of the active cell.

Keyboard editing is a rapid way of moving the cursor through columns of data and making changes as desired.

**Editing Data in Tables**
Intrinsic Fields in Tables

Fields that appear in tables are normally ordinary data fields. These may be a part of the table, or they may appear in a table as a result of a relation. For a drawing’s table, Manifold also can display fields generated by the system for each record. These are fields that describe some system attribute of the object represented by that record, or which are computed from the geometry of the object. Such system-generated fields are called intrinsic fields.

Intrinsic columns are not shown by default in tables. We can use the View - Columns command to show intrinsic fields. Intrinsic fields have an (I) as part of their name in the Columns dialog. Intrinsic fields will also appear in the Object Fields dialog, which may be called from the context menu that pops up when right-clicking on an object in a drawing.

Intrinsic fields are an intrinsic part of the table and cannot be deleted with the Table - Design dialog. They may be used as key fields for relations or for other purposes just like ordinary data fields.

Intrinsic Fields

<table>
<thead>
<tr>
<th>Field</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Area (I)</td>
<td>Object area.</td>
</tr>
<tr>
<td>Bearing (I)</td>
<td>0 for points and areas. For lines, the bearing in degrees of a straight line segment constructed between the first and last points of the very first branch within the line. Computed using ellipsoidal trigonometry. 90 is East and 270 is West.</td>
</tr>
<tr>
<td>Branches (I)</td>
<td>The number of branches (indicates topologically branched objects, such as areas with holes or islands).</td>
</tr>
<tr>
<td>Coordinates (I)</td>
<td>The number of coordinates that define the object.</td>
</tr>
<tr>
<td>Geom (I)</td>
<td>The geometry data (&quot;the object metric&quot;) that defines the position and shape of the object. Read/write. Modifying this column with, say, an UPDATE query, modifies the metric of the associated drawing objects. Setting Geom (I) to a NULL value or to a geometry value the type of which differs from that of the drawing object is not allowed.</td>
</tr>
<tr>
<td>Latitude (I)</td>
<td>Latitude of the center of the object in degrees latitude.</td>
</tr>
<tr>
<td>Length (I)</td>
<td>Object length (or perimeter).</td>
</tr>
<tr>
<td>Longitude (I)</td>
<td>Longitude of the center of the object in degrees longitude.</td>
</tr>
<tr>
<td>Selection (I)</td>
<td>Boolean: currently selected or not.</td>
</tr>
<tr>
<td>Selection Mask (I)</td>
<td>A byte giving the saved selections mask.</td>
</tr>
<tr>
<td>Type (I)</td>
<td>A lookup field for object type: area, line or point.</td>
</tr>
<tr>
<td>Version (I)</td>
<td>Current version of the drawing object. Changing the metric of a drawing object increments the value of the Version (I) column. For a linked drawing which uses a version column to facilitate multi-user editing, the values in the Version (I) column will be the same as the values in the version column.</td>
</tr>
<tr>
<td>X (I)</td>
<td>X coordinate of the center of the object in the coordinate system used by the drawing.</td>
</tr>
<tr>
<td>Y (I)</td>
<td>Y coordinate of the center of the object in the coordinate system used by the drawing.</td>
</tr>
</tbody>
</table>

Columns for intrinsic fields will be shown using a different font color, with a different color being used for read-only intrinsic fields such as the Selection Mask.
The **Geom (I)**, **X (I)**, **Y (I)**, **Latitude (I)**, and **Longitude (I)** fields are editable. Changing these fields will **move** or in the case of **Geom (I)** will **edit** the object. These fields are normally used to move the position of points. They may also be used to move the centers of areas or lines, in which case they result in a change to all coordinates defining the line or area required by the horizontal or vertical displacement of the center. See the Editing Intrinsic Fields in Tables topic and also the Geometry in Tables topic for information about geoms.

The intrinsic fields may be used like other fields in the table. For example, the table may be sorted by clicking on the column head for an intrinsic field. This allows some remarkable uses of tables. For example, one can sort all objects in the table from lowest latitude to highest (that is, from South to North) by simply clicking on the **Latitude (I)** column head. We could then click and shift-click to select objects in a desired range of latitudes.

Intrinsic fields may also be used in SQL queries, Active Column formulas and other uses where an ordinary field might be used. Note that since intrinsic fields have an "(I)" as part of their names they must be used within square brackets in SQL, as in

```sql
SELECT [Latitude (I)] FROM mytable WHERE [Latitude (I)] > 60;
```

The **Geom (I)** field is especially useful for manipulating geometry from queries, such as the following three examples:

```sql
UPDATE [A] SET [Geom (I)] = Buffer([Geom (I)],10);

INSERT INTO B ([Geom (I)]) VALUES (NewPointLatLon(30, 40));

SELECT Centroid([Geom (I)]) FROM C;
```

...where **A**, **B** and **C** are drawing names.

**Native Coordinates**

Native coordinates or native units are numbers stored within the drawing that Manifold uses internally as positional coordinates. These numbers are shown in the Object Coordinates dialog that pops up if you right-click an object and choose **Coordinates**. They are also used in the **X (I)** and **Y (I)** intrinsic field columns.

Projected coordinates are native coordinates adjusted with the local scale and local offset parameters of the coordinate system (projection) in use. In many cases, projected coordinates are the same as native coordinates (because of the local scale and offset values) but sometimes they are different.

The relationship between projected coordinates, native coordinates and the local scale and local offset parameters may be expressed in pseudo-code as:

```
ProjectedX = NativeX * LocalScaleX + LocalOffsetX
ProjectedY = NativeY * LocalScaleY + LocalOffsetY
```

**The Selection Mask**

Each object may participate in the selection and in one or more of any of seven possible saved selections. Whether or not the object is selected or is a member of one of the seven selection sets is coded bitwise into a single byte, the **Selection Mask**.

**Length and Area Units**

The **Area (I)** and **Length (I)** intrinsic fields report the area and length of the object based upon two factors:

- The coordinate system in use: latitude / longitude drawings always use degrees as units while projected drawings will report using either meters or feet.
- The setting of the **Use English measurement units** checkbox in the Tools - Options dialog. This is the same box that specifies units for the Tracker tool. If this checkbox is checked, units for projected
drawings will be reported in feet. If it is not checked, units for projected drawings will be reported in meters.

The above rules also may be summarized as follows:

- If the drawing is in Latitude / Longitude (that is, unprojected) Length (I) is reported in degrees and Area (I) is reported in square degrees.
- If the drawing is projected and the Use English measurement units option is turned off, Length (I) is reported in meters and Area (I) is reported in square meters.
- If the drawing is projected and the Use English measurement units option is turned on, Length (I) is reported in feet and Area (I) is reported in square feet.

For example, projected drawings will use coordinate systems in meters or feet, resulting in Area (I) values being expressed in square meters or square feet depending on the setting of the Use English measurement units checkbox. Unprojected drawings use coordinate systems expressed in degrees, resulting in Area (I) values being expressed in square degrees.

Because the size of a "square degree" varies considerably based on its latitude, values of Area (I) and Length (I) will normally only have acceptable accuracy if the drawing is projected to some projection that provides reasonable accuracy for the region of interest.

**Bearings**

The Bearing (I) field is only accurate when the drawing is projected and only then within that part of the projection within which the accuracy of bearings is preserved. Bearings can only be as accurate as the projection of the drawing allows them to be.

To take an example, consider the case of an unprojected drawing in latitude / longitude. What is a straight line in latitude and longitude coordinates is a curved line in the 3D spherical surface of the Earth. This means that in most cases the value of the bearing will be different at different positions along the line. In cases where the value of the bearing changes along the line, Bearing (I) returns the value of the bearing near the starting location. This can be quite different from the value of the bearing near the end of the line.

To avoid such problems, project the drawing into some suitable projection that preserves angles in the area of interest before using Bearing (I).

Note that the values reported by the Bearing (I) field are ellipsoidal bearings (computed over a 3D Earth ellipsoid), while the values used by the dialog mode of visual editing and selection tools are Euclidean bearings ("flat" bearings within whatever projection is in use). Ellipsoidal and Euclidean bearings are not the same thing and should not generally be used interchangeably. Euclidean bearings are only as good as or as inaccurate as whatever projection is used, so if bearings are important it is also important to select a projection that preserves accurate angles within the area of interest. Projections must always be selected to preserve the map characteristics of interest (see the Projections Readings topic).

**Performance**

Showing all the intrinsic fields in a table will slow down table redisplay speed, since some of the intrinsic fields require computation. Intrinsic fields are computed on the fly whenever a table is displayed. Some fields such as Area (I) are computationally very expensive and thus could dramatically slow down performance to a level unacceptable for interactive work in the case of very large drawings when working on slower machines.

One way of avoiding an interactive slow down is to not display the intrinsic fields but only to use them within SQL queries and other relatively non-interactive processes. Even in this case, though, the fields will still be recomputed on the fly so such queries could take a very long time to run when working with large drawings.

To achieve faster performance we can use the Transform toolbar to Copy an intrinsic field such as Area (I) to a new column in the table. This requires a one-time computation. After the Copy is done, we can turn off the intrinsic field and view the new column, which will be a fixed column that is stored data like all of the other columns. The new column will not be dynamically recomputed so if there are any changes made to the areas in the drawing the new column’s values will not change. In addition, the size of the table will increase as stored on disk because the new column is saved in storage and not computed as needed. Despite these minor limitations this technique is fine for use with drawings where the objects don’t change but where the values reported by the intrinsic fields must be rapidly available.
Because some intrinsic fields, for example, Area (I), take a long time to compute, Manifold caches their values whenever possible. The first time we access such a column (say, by invoking the Object Fields dialog, which queries the value of each intrinsic field, even if the intrinsic fields are initially hidden), Manifold will do the necessary computations and will save the resulting values in cache. On subsequent accesses Manifold will not need to compute the intrinsic field but can simply use values already in cache.

### Intrinsic Fields when Pasting Surfaces and Images

When copying a surface or an image and then pasting as a table, the Paste As dialog will offer intrinsic fields computed for each pixel in the surface or image.

For **surfaces**, intrinsic fields available will be:

- **Center Easting (I)**: X coordinate of the center of this pixel in native coordinate system units adjusted with the values of the local scale and local offset parameters.
- **Center Latitude (I)**: Latitude of the center of this pixel in degrees latitude.
- **Center Longitude (I)**: Longitude of the center of this pixel in degrees longitude.
- **Center Northing (I)**: Y coordinate of the center of this pixel in native coordinate system units adjusted with the values of the local scale and local offset parameters.
- **Center X (I)**: X coordinate of the center of this pixel in native coordinate system units.
- **Center Y (I)**: Y coordinate of the center of this pixel in native coordinate system units.
- **Height (I)**: Height value.
- **Invisible (I)**: 0 or 1 to indicate invisible pixels, normally used for missing height values.
- **Latitude (I)**: Latitude of the lower left corner of this pixel in degrees latitude.
- **Longitude (I)**: Longitude of the lower left corner of this pixel in degrees longitude.
- **Easting (I)**: X coordinate of the lower left corner of this pixel in native coordinate system units adjusted with the values of the local scale and local offset parameters.
- **Northing (I)**: Y coordinate of the lower left corner of this pixel in native coordinate system units adjusted with the values of the local scale and local offset parameters.
- **Selection (I)**: Boolean: currently selected or not.
- **Selection Mask (I)**: A byte giving the saved selections mask.
- **X (I)**: X coordinate of the lower left corner of this pixel in native coordinate system units.
- **X Offset (I)**: X position in pixel coordinates from the lower left corner.
- **Y (I)**: Y coordinate of the lower left corner of this pixel in native coordinate system units.
- **Y Offset (I)**: Y position in pixel coordinates from the lower left corner.

For **images**, intrinsic fields will be appropriate to the type of image. Many fields are the same as those available for surfaces.
<table>
<thead>
<tr>
<th>Field</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Center Easting (I)</td>
<td>X coordinate of the center of this pixel in native coordinate system units adjusted with the values of the local scale and local offset parameters.</td>
</tr>
<tr>
<td>Center Latitude (I)</td>
<td>Latitude of the center of this pixel in degrees latitude.</td>
</tr>
<tr>
<td>Center Longitude (I)</td>
<td>Longitude of the center of this pixel in degrees longitude.</td>
</tr>
<tr>
<td>Center Northing (I)</td>
<td>Y coordinate of the center of this pixel in native coordinate system units adjusted with the values of the local scale and local offset parameters.</td>
</tr>
<tr>
<td>Center X (I)</td>
<td>X coordinate of the center of this pixel in native coordinate system units.</td>
</tr>
<tr>
<td>Center Y (I)</td>
<td>Y coordinate of the center of this pixel in native coordinate system units.</td>
</tr>
<tr>
<td>Invisible (I)</td>
<td>0 or 1 to indicate invisible pixels, normally used for missing height values.</td>
</tr>
<tr>
<td>Latitude (I)</td>

<tr>
<td>X Offset (I)</td>
<td>X position in pixel coordinates from the lower left corner.</td>
</tr>
<tr>
<td>Y (I)</td>
<td>Y coordinate of the lower left corner of this pixel in native coordinate system units.</td>
</tr>
<tr>
<td>Y Offset (I)</td>
<td>Y position in pixel coordinates from the lower left corner.</td>
</tr>
</tbody>
</table>

In addition there are intrinsic fields specific to images:

<table>
<thead>
<tr>
<th>Field</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Color (I)</td>
<td>RGB color value expressed as a decimal number (the decimal equivalent to a hexadecimal color value in the form #rrggb).</td>
</tr>
<tr>
<td>Color Index (I)</td>
<td>A color index from 0 to 255 available for palette images only.</td>
</tr>
<tr>
<td>Red (I)</td>
<td>Red channel value from 0 to 255.</td>
</tr>
<tr>
<td>Green (I)</td>
<td>Green channel value from 0 to 255.</td>
</tr>
<tr>
<td>Blue (I)</td>
<td>Blue channel value from 0 to 255.</td>
</tr>
<tr>
<td>Alpha (I)</td>
<td>Alpha channel value from 0 to 255.</td>
</tr>
<tr>
<td>Intensity (I)</td>
<td>Intensity value from 0 to 255.</td>
</tr>
<tr>
<td>Hue (I)</td>
<td>Hue value from 0 to 255.</td>
</tr>
</tbody>
</table>
Lightness (I)  Lightness value from 0 to 255.

Saturation (I)  Saturation value from 0 to 255.

**Virtual Tables**

Images and surfaces in Manifold have virtual tables that allow queries to access the image using intrinsic fields like the above. See the Virtual Tables for Images and Surfaces topic for details.

**Pixel Coordinates**

The X Offset (I) and Y Offset (I) values give the X and Y coordinates of the pixel in column and row pixel coordinates. If an image is 8192 pixels wide (8192 columns) and 4096 columns high (4096 rows) the X Offset (I) coordinates of the pixels will range from 0 to 8191 and the Y Offset (I) coordinates of the pixels will range from 0 to 4095. The pixel in the upper left of the image (first row, first column) will have coordinates of X Offset (I) = 0 and Y Offset (I) = 0. The pixel in the lower left corner will have coordinates of X Offset (I) = 0 and Y Offset (I) = 4095. The pixel in the lower right corner of the image will have coordinates of X Offset (I) = 8191 and Y Offset (I) = 4095.

Pixels in georegistered images can cover a large region, quite possibly several kilometers in size. The positions reported by X (I), Y (I), Longitude (I) and Latitude (I) report the location of the lower left corner of the pixel.

**Tech Tip**

Note that the Selection (I) intrinsic is a Boolean. It may appear as a 1 or a 0 value or Yes or No or True or False because that is the way the column is formatted for appearance. However, when used in a query, the true Boolean value of Selection (I) should be checked as True or False.

Therefore, Selection (I) = true is a valid test in a SQL query but [Selection (I)] = 1 will not work. It is a coincidence of conversion rules that [Selection (I)] = -1 will also work.

### Field Types in Tables

Manifold supports the following field types in tables:

<table>
<thead>
<tr>
<th>Field Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Binary (fixed-length)</strong></td>
<td>Untyped binary data. Often used for programming masks and coded status words.</td>
</tr>
<tr>
<td><strong>Binary (variable-length)</strong></td>
<td>Untyped binary data.</td>
</tr>
<tr>
<td><strong>Boolean</strong></td>
<td>Yes/No, True/False, On/Off. Standard Microsoft data type.</td>
</tr>
<tr>
<td><strong>Character (ANSI)</strong></td>
<td>A single character. Standard Microsoft data type.</td>
</tr>
<tr>
<td><strong>Character (Unicode)</strong></td>
<td>A single character. Standard Microsoft data type.</td>
</tr>
<tr>
<td><strong>Coordinate System</strong></td>
<td>Coordinate system data in Manifold binary format.</td>
</tr>
<tr>
<td><strong>Currency</strong></td>
<td>Fixed length, eight-byte type used for money values. Eight bytes can specify precise monetary amounts that are greater than all the money there ever has been in the world. Standard Microsoft data type.</td>
</tr>
<tr>
<td><strong>Date and time</strong></td>
<td>Standard Microsoft date/time field type.</td>
</tr>
<tr>
<td><strong>Floating-point (double)</strong></td>
<td>Standard Microsoft data type.</td>
</tr>
<tr>
<td><strong>Floating-point (single)</strong></td>
<td>Standard Microsoft data type.</td>
</tr>
<tr>
<td><strong>Geometry</strong></td>
<td>Coordinate data combined with coordinate system data in Manifold binary format.</td>
</tr>
<tr>
<td><strong>Geometry (SDE)</strong></td>
<td>Coordinate data in ESRI SDE binary format.</td>
</tr>
<tr>
<td><strong>Geometry (SHP)</strong></td>
<td>Coordinate data in ESRI SHP binary format.</td>
</tr>
<tr>
<td><strong>Geometry (WKB)</strong></td>
<td>Coordinate data in OGC WKB binary format.</td>
</tr>
<tr>
<td><strong>Integer (8-bit)</strong></td>
<td>Standard Microsoft data type.</td>
</tr>
<tr>
<td><strong>Integer (8-bit, unsigned)</strong></td>
<td>Standard Microsoft data type.</td>
</tr>
<tr>
<td><strong>Integer (16-bit)</strong></td>
<td>Standard Microsoft data type.</td>
</tr>
<tr>
<td><strong>Integer (16-bit, unsigned)</strong></td>
<td>Standard Microsoft data type.</td>
</tr>
<tr>
<td><strong>Integer (32-bit)</strong></td>
<td>Standard Microsoft data type.</td>
</tr>
<tr>
<td><strong>Integer (32-bit, unsigned)</strong></td>
<td>Standard Microsoft data type.</td>
</tr>
<tr>
<td><strong>Latitude</strong></td>
<td>Manifold double-precision floating point Latitude.</td>
</tr>
<tr>
<td><strong>Longitude</strong></td>
<td>Manifold double-precision floating point Longitude.</td>
</tr>
<tr>
<td><strong>Percentage</strong></td>
<td>Percentage amounts from 0% to 100%. Also used as ranks when reporting Decision Support System query results.</td>
</tr>
<tr>
<td><strong>Text (ANSI, fixed-length)</strong></td>
<td>Standard Microsoft data type.</td>
</tr>
<tr>
<td><strong>Text (ANSI, variable-length)</strong></td>
<td>Standard Microsoft data type.</td>
</tr>
<tr>
<td><strong>Text (Unicode, fixed-length)</strong></td>
<td>Standard Microsoft data type.</td>
</tr>
<tr>
<td><strong>Text (Unicode)</strong></td>
<td>Standard Microsoft data type.</td>
</tr>
</tbody>
</table>
variable-length

**URL**  Internet URL. Can include protocol, server, ports, URL object and query parameters. See the Hyperlinks topic for special uses of URL columns in drawing tables.

Use variable-length types when the amount of data within the field can be varied. Variable length fields have no practical limit in size (they cannot contain data greater than 2 gigabytes). There is effectively no wasted space when variable-length fields are used. We could use them all the time except that often it is more convenient (for the design of dialog boxes or when programming) to use fixed-length fields so that we always know the maximum length of a field.

However, there is no storage penalty for using fixed length fields. Manifold uses a dynamic storage allocation strategy so that there will be no wasted space regardless of whether fixed-length or variable-length text fields are used.

**Lookup Columns**

Lookup columns are a special type of text column that is constrained to a limited set of specific text values. Instead of permitting free entry of text when editing a cell, a pull-down list of acceptable values appears from which a choice may be made.

Creating a lookup column is a three-step process: First, we create a text field in the table of the desired type (fixed or variable length ANSI or Unicode text). Second, we enter records into the table so that there is at least one example in the table of each possible text value that will be allowed. Finally, we change the column type of that text field to `<lookup>`.

To edit allowed values in a lookup table, we first convert the lookup field back into a regular text type field, add one or more new records providing examples of the desired new values, and then convert the field back into a lookup type.

**Example**

Let's create a table that will be used to keep track of inventory of parts for motorcycles. Each part will be painted black, blue, red or green.

We begin by creating a table with three columns. The **Quantity** column is a numeric column and the other two columns are Unicode text columns.
We open the table and add four records to it. Each record has one of the four allowed choices of color in the Color column. What we enter in the other cells doesn’t matter, since we are using these as “dummy” records to populate the Color column with at least one example of each of the allowed values.

Next, we Right-click onto the Color column head and choose Change Type in the context menu.

We change the type of the Color column to [Lookup] and press OK.

We change the type of the Color column to [Lookup] and press OK.
The result is a table that now has a lookup type in the **Color** column that must be one of the four allowed choices. When we add additional records, a combo box will appear allowing us to choose one of those four values.

If we like, we can delete the dummy records in the table and begin adding new records in earnest that actually reflect the inventory we have on hand of different parts in different colors.

**Lookup Column Options**

The **Value** and **Map To** options allow us to specify one to many relationships, so that more than one value that occurs in the table can map to the same value. This makes it possible to reduce tables that contain many allowed values into a smaller number of allowed values.

For example, suppose we have four colors of gas tank in stock as seen above. Due to a styling changes our company will no longer produce motorcycles in red or green so tanks in those colors will be repainted to black or blue with inventory levels adjusted accordingly.
We can launch the **Change Type** dialog again and change the **Map To** value for **Green** to **Black** and also change the **Map To** value for **Red** to **Blue**.

<table>
<thead>
<tr>
<th>Quantity</th>
<th>Description</th>
<th>Color</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Gas Tank</td>
<td>Black</td>
</tr>
<tr>
<td>1e</td>
<td>Gas Tank</td>
<td>Black</td>
</tr>
<tr>
<td>27</td>
<td>Gas Tank</td>
<td>Blue</td>
</tr>
<tr>
<td>36</td>
<td>Gas Tank</td>
<td>Blue</td>
</tr>
</tbody>
</table>

When we press **OK** we will see that all **Green** values in the table will have been changed to **Black** and all **Red** values in the table will have been changed to **Blue**.

**Use with Drawings**

When using lookup columns in tables we first create records in the table containing each of the required values and then we use the **Change Type** dialog to change the type of the column to **[Lookup]**. When working with drawings, if we don’t already have objects in the drawing that contain an example of each of the possible values we want to allow in the lookup column, we will have to add some temporary objects to the drawing with the desired values.

This is easily accomplished by adding points to the drawing with **Instant Data** turned on. Add points representing the range of allowed values for the lookup column, open the drawing’s table and convert the text column to a lookup column and then delete the points that were added.

**See Also**

**Tables**

**Intrinsic Fields in Tables**
### Selection in Tables

Clicking on a record handle in the table is the same as a **Select Touch** on that record.

In the illustration above we click on the record handle for the **Nevada** record to select it. Selecting a record will combine it with any existing selection in accordance with the selection mode (**Replace**, **Add** and so on) currently in force.

If the table is linked to a drawing it will select the object associated with that record as well. When tables are linked to drawings each record in the table corresponds to one object (a point, line or area) in the drawing. The objects in the drawing and the records associated with them become the same thing for all intents and purposes. We can then consider the table as simply an alternate way of looking at the objects in our drawing.

If a table is linked to a drawing, making a selection in the drawing will automatically select the records in the table associated with the selected objects. These records will appear highlighted in red selection color. Likewise, making a selection in a table by highlighting records will select the associated objects in the drawing.

Just like drawings and images, tables also can save selections in the Selections pane. When a table is linked to a drawing, the saved selections will be the same for both the table and the drawing. Showing a preview from the Selections pane will cause those records in the previewed selection to be displayed with light blue background color.

#### Selecting Records in Tables

We select records in tables by clicking on their record handle. Manifold supports the usual Windows "power moves" to highlight items in tables, with slight modifications to deal with selection modes.

- Clicking on a cell in a record moves the focus to that cell without changing the selection.
- Clicking on a record handle selects the record or a range of records in accordance with the current selection mode.
- Holding the **SHIFT** key down while clicking applies the selection operation to a range of records. This is often used to highlight a series of records: click on the top record and then **Shift**-click on the bottom record and all the records in between will also be highlighted.
- Holding the **CTRL** key down while clicking will extend the click to the entire record as if the record handle were clicked, thus selecting in accordance with selection modes. **CTRL** is used when tables are wider than the table window so that it is inconvenient to click on the record handle. We can then **CTRL**-click onto any cell to select that record and **CTRL**-**SHIFT**-click on a cell to select a range of records.
- To deselect a record, change the selection mode to **Subtract** and click on the record handle or **CTRL**-click on any cell in a record.

Records in tables may also be selected using the Query toolbar for rapid selection using simple query operators.

#### Showing Only the Selection in a Table

When working with large tables we may wish to pop open a table window that shows only records in the selection.

To show only the selection in a table:

1. Open the table.
2. In the main menu press in the **Selection Filter** button.
Showing a table with Selection Filter pressed in will dynamically update the table every time the selection changes either in the table or in an associated drawing. If we have a table with a thousand records in it and five are selected, then only five records will initially appear in the filtered table window and all of them will be highlighted. If we CTRL-click on one of them to de-select it (remember, CTRL-clicking on a highlighted record toggles the highlighting) it will disappear from that table.

See the View - Selection Filter topic for an example.

Query Toolbar Restricted to the Selection Filter

When the selection filter button is engaged subsequent operations of the query toolbar will apply only to those records that are shown in view by the selection filter. This makes it easy to run simple queries that refine the result of a previous query toolbar operation.

Suppose we select records with values in column A greater than 0. Suppose we now want to select records with values in column B greater than 0, regardless of what is in column A; that's easy to do as we simply run the query toolbar again.

Now suppose we again select records with values in column A greater than 0, but this time we also want to find within those selected records only those records that have values in B greater than 0 as well. After making the selection with the query toolbar to find those records with values in A greater than 0 we turn on the selection filter so that those records are shown and then next we run the query toolbar one more time to find those records that also have values in B greater than 0.

Selection using SQL

Structured Query Language (SQL) is an industry standard database query language used to select records from tables and to present those records with the fields desired. The result of an SQL query is what appears to be a new table. Although this is "selection" in the database sense of the word, the actual records and the objects with which they are associated are not selected in the Manifold sense of the word. They simply appear as their own table.

To use SQL to make a selection in the Manifold sense of the word we click open the SQL Query to see the table it creates and then we choose Edit - Select All to select all the records in that table.

See the introductory topics on SQL beginning with Queries. For reference information on SQL see the SQL Reference Guide information beginning with the SQL in Manifold System topic.

Saved Selections and Tables

Just like other components, we can open the selections pane and use it to save selections that we make in a table window. This is a very handy when making different selections and wishing to get back to a previously-made selection.

Selection Using More Like This

We can also select records in tables using the More Like commands. See the More Like This topic for more information.
**Formatting Columns**

We can change the appearance of values shown in a column by formatting the column. To do so, right click onto a column head and choose Format from the context menu. The same format will be applied throughout the entire column.

Format options will be displayed that are appropriate to the type of column. For example, a column for a floating-point field will have different **Style** options than a money field, integer field or text field.

**Style**

The overall type of format to be applied, for example, whether percentages are shown as .4565 or as 45.65%.

**Positives**

Enabled with numeric types. Controls the appearance of positive values.

**Negatives**

Enabled with numeric types. Controls the appearance of negative values. For example, negative currency values may be show.

**Separate thousands**

Enabled with numeric types. When checked, inserts a separation character to indicated thousands. The character used is determined by the current Windows locality settings, being a comma "," in the US and a period "." in various European countries.

**Alignment**

Left, Right and Center alignment. The Right alignment has the side effect of lining up decimal points when styles using a specified number of decimal places are used.

**Decimal places**

Enabled with numeric types. The number of digits to the right of the decimal point to display.

**Width**

The width of the column in characters.

**Indent**

The indent to apply in number of characters.

**Style Options**

Style options depend on the type of field. In general, style options are patterned on those found in Microsoft Office applications. Some field types have many style options while others have few options. Following are notes on the most popular options for field types that have many style options:

**Floating point**

<default> - Shows numbers without thousands separators and with as many decimal places are significant, truncating trailing zeros.

12.34 - Use the specified number of decimal places and other options.

12 1/3 (up to one digit) - Round to the nearest fraction using single digits in both the numerator and denominator. Examples: 6 5/7, 3 5/8 and 30 1/9.

12 17/50 (up to two digits) - Round to the nearest fraction using up to two digits in both the numerator and denominator. Examples: 5 21/50, 8 4/25, 3 3/4

12 1/2 (as halves), 12 1/4 (as quarters), 12 3/8 (as eighths), 12 5/16 (as sixteenths), 12 3/10 (as tenths), 12 34/100 (as hundredths) - Round to the nearest fraction using the specified denominator units.

1.23D+001 or 1.23E+001 - Scientific notation using "D" or "E" to indicate the exponential part.

1.23D+1 or 1.23E+1 - Scientific notation using "D" or "E" to indicate the exponential part with leading zeros trimmed from the exponent.

**Currency**

<default> - Same as floating point.
<no symbol> - Use the given number of decimal places without any currency symbol.

symbols - Use the given currency symbol to the given number of decimal places.

three letter codes - Use the given three letter SWIFT currency code.

Boolean <default> - Use 1 for true and 0 for false. Other options provide for the usual True / False, Yes / No and other renderings of Boolean status.

Date and Time <default> - American style month/day/year dates as in 3/09/2001. Note that date and time field types store not only the date but also the time in all cases. Whether the date, the time, or both together are visible depends on the formatting.

Latitude <default> - Standard decimal degrees where a minus sign indicates Southern latitudes and Western longitudes. Trailing zeros will be truncated.

12.3456 - Display using the given number of decimal places.

12°20.736 - Degrees with minutes and decimal fractions of a minute. A slightly dissonant format that nonetheless seems to be popular in certain GPS applications. It's used in some marine charts to note waypoints.

12°20'44.2" - Results in displays using degrees, minutes and decimal seconds formats.

N - The above styles are available in an N style, which appends an N, S, E or W to show North, South, East and West latitudes or longitudes. Otherwise, a minus sign will be used to indicate Southern latitudes and Western longitudes.

Note: Control the number of trailing digits after a decimal point with the Decimal Places option.

Percentage <default> - Show percentages using percent symbol, for example, 52.01 %

0.52 - Show percentages as decimal fractions, for example, 0.456.

options - Other options repeat the various fractional styles available in floating point numbers.

Editing

Cells that are formatted in a given column formatting style will accept edits in any compatible style. For example, if a date and time column is formatted to show dates as 3/09/2001 and one enters 9 mar during the year 2001 the entry will be accepted and shown as 3/09/2001. In this case, Manifold knows that "mar" in date and time fields means March. If the or time is not explicitly given the system uses the current system year and time. To specify all parts of the data and time value, enter explicitly those parts desired. If one enters 9 mar 99 the entry will be accepted and shown as 3/09/1999.

Latitudes and longitudes expect that a single number with a decimal point, like 90.1234 is intended as a decimal degrees value. Other numbers in the generic form of '90 2 3'-type strings will be parsed as degrees, minutes and sections using the two or three numbers with white space or almost any characters in between. This makes it easy to enter degrees, minutes and seconds values for latitude and longitude without hunting all over the keyboard for obscure ways of entering the "degree" character.

Other Uses of Column Formats

Column formats specified in tables will be used in labels and in export.
• Labels created from fields will use whatever formatting has been assigned to that field. See Creating Labels from Fields for examples.
• When tables are exported to purely text formats such as .csv or .html, the contents of the table fields will be formatted as specified by table formats.

Specifying Languages for Columns

Language specification in text columns varies depending on whether Unicode or ANSI text is used. Unicode text columns can simultaneously contain characters from more than one language. ANSI text columns are usually restricted to one language in addition to (possibly) English. Character data contained in an ANSI text column will be interpreted by the system according to the code page associated with that column.

By default, ANSI text columns use the system code page. If desired, any ANSI text column in a table can be set to use a different code page by right clicking on the column head and choosing Language.

Notes

Why the strange fractional styles for numbers? These are often used to express measurements using English units such as inches. In the USA, for example, people routinely use measurements such as 8 3/16 inches.

Tech Tips

From the context menu for table columns (right click onto a table column head) choose Best Fit, Best Fit All or Best Fit Titles to set width of table columns automatically.

Users are sometimes surprised to see numbers they expect to be values like 1.1 appear in a query or other table as 1.09999942779541, even if a floating point type is used. That is a result of the fundamental architecture of computers combined with the choice of format style used.

Floating-point values have finite precision. Some values, such as 1.2, or 0.25 can be represented precisely, but most can not. For example, neither 12.6 nor 13.7 can be represented precisely. To see what really hides behind a value shown as 12.6, set the format style of the relevant column to 12.34 and increase the number of decimal digits to 10. Try the same for 13.7.

If we subtract one approximation from another, as in the case of an SQL query, we get an approximation of the result so that an expected result such as 1.1 may appear as 1.09999942779541.

The default format style uses a Microsoft Windows API which makes some approximations, such as 12.6000..., look round but leaves others unaffected. There is some logic behind that API, but that logic is obviously not applicable to all cases. To provide fine control over desired appearance is one reason why Manifold allows setting the format style and the number of decimal digits explicitly.
Transfer Rules

This topic applies only to tables that are associated with a drawing. Transfer rules come into play when the transform toolbar for drawings is used to create new objects in a drawing or when commands such as Dissolve transfer fields between objects. A transfer rule may be set for each column (field) in the table that specifies how that field will be transferred to any new objects created by various transform operators. By default, all fields in a table are copied to the new record created for the new object.

To specify a transfer rule for a column:

1. Open the drawing's table.
2. Right click on the column and choose Transfer rules.
3. In the Transfer Rules dialog, specify the transfer method to be used for one to many (1 to N) operators. The Proportional methods available for numeric fields also require specification of a second numeric field.
4. Specify the transfer method to be used for many to one (N to 1) operators.
5. For text fields, choose any desired options to ignore case or whitespace.
6. Press OK.

Transfer rules may also be specified by opening a table using the Table - Design dialog and double-clicking into a transfer rule for a column.

The transfer rules specified for each field will be used whenever a transform operator creates a new object. There are two types of transform operators that create new objects:

- **One to Many (1 to N) Operators** - For each original object these operators create one or more new objects. An example is the Points operator, which creates a new point at each coordinate location that defines the shape of a line or area. Each line or area will therefore be used to create many new points. Operators like Centroids that create one new object for each original object are considered to be the simplest case of a one to many operator. The task for transfer rules for such operators is to specify how one value from the original object should be apportioned to the possibly many new objects created.

- **Many to One (N to 1) Operators** - These operators create a single new object from many original objects. The classic example is Convex Hull, which creates a single area object that covers a set of many points.

If a transfer rule is specified for both 1 to N and N to 1 for each column in a table Manifold will know how to transfer fields for objects created by any transform toolbar operator. By default, the Sample method is used for all fields. The Sample method is a reliable way of dealing with “many to one” (N to 1) operations so it is used by default.

Some Manifold users prefer to have the Copy method used by default for newly created fields. If the Copy method is desired, in Tools - Options - Miscellaneous check the box for the Set transfer rules for new columns to Copy / Copy.

**Note:** intrinsic fields, Active columns, rank columns and columns brought into a table via a relation do not participate in transfer rules since by definition they are computed for each object individually.

Transfer Methods

Transfer methods that may be specified in the Transfer Rules dialog include the following. Methods apply to all field types except as noted. Uncheck the Transfer column box to not transfer the field.

**One to Many (1 to N)**

- **Copy** Transfer a copy of this field's value to each new object created.
- **Equal Division** Divide equally the value by the number of new objects created and place equal shares into each new object. Numeric columns except latitude and longitude.
### Tables

<table>
<thead>
<tr>
<th>Method</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Proportional</strong></td>
<td>The field's value is distributed to the newly created objects in proportion to some other numeric column, for example <strong>Area (I)</strong> or <strong>Length (I)</strong>. This method is most often used with geographic fields such as <strong>Area (I)</strong> but could also be used to distribute values based on non-geographic numeric fields such as those that might code for budget or population.</td>
</tr>
</tbody>
</table>

**Many to One (N to 1)**

<table>
<thead>
<tr>
<th>Method</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Average</td>
<td>Transfer the average value for this field in the origin objects into the new object. Numeric columns.</td>
</tr>
<tr>
<td>Copy</td>
<td>Pick one of the &quot;many&quot; objects at random and transfer a copy of this object's field's value to the new object created.</td>
</tr>
<tr>
<td>Count</td>
<td>Transfer a count of the number of objects used to create the new object. For example, if 10 points are used to create one convex hull area object the value 10 would be transferred. Numeric columns. Note: choosing <strong>Count</strong> will dominate the transfer even if it is a 1 to N transfer.</td>
</tr>
<tr>
<td>Maximum</td>
<td>Transfer the maximum value for this field in the origin objects into the new object. Numeric, date and text columns.</td>
</tr>
<tr>
<td>Minimum</td>
<td>Transfer the minimum value for this field in the origin objects into the new object. Numeric, date and text columns.</td>
</tr>
<tr>
<td>Median</td>
<td>Transfer the median value for this field in the origin objects into the new object. Numeric, date and text columns.</td>
</tr>
<tr>
<td>Sample</td>
<td>Arbitrarily choose a value from one of the originating objects and transfer it to the new object. The default for text columns.</td>
</tr>
<tr>
<td>Sum</td>
<td>Transfer the sum of values for this field in the origin objects into the new object. The default for numeric columns.</td>
</tr>
</tbody>
</table>

When working with text fields, the maximum, minimum and median values are chosen according to lexicographic ordering for the relevant text field. For ANSI text fields, lexicographic ordering depends on the code page. Using the maximum, minimum and median transfer rules with text fields is only recommended for experts wanting to exploit the effects of lexicographic ordering with a full understanding of how it works for the text fields at hand.

### Options

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Transfer column</strong></td>
<td>Checked by default. Uncheck to prevent this field from being transferred.</td>
</tr>
<tr>
<td>(1 to N field argument box)</td>
<td>Enabled for numeric fields when the Proportional method is selected. Specify the field, such as <strong>Area (I)</strong>, to be used to allocate the value.</td>
</tr>
<tr>
<td>Ignore case</td>
<td>Enabled for text fields. Treat upper and lower case the same when making lexicographic comparisons to determine the value to be transferred. If checked, &quot;San Juan&quot; would be considered the same as &quot;san juan&quot;.</td>
</tr>
<tr>
<td>Ignore leading and trailing whitespace</td>
<td>Enabled for text fields. Ignore any whitespace characters at the beginning or end of a text string when making lexicographic comparisons to determine the value to be transferred. If checked, &quot;San Juan&quot; would</td>
</tr>
</tbody>
</table>
be considered the same as "San Juan".

Ignore internal whitespace

Enabled for text fields. Ignore any whitespace characters that occur within a text string when making lexicographic comparisons to determine the value to be transferred. If checked, "San Juan" would be considered the same as "SanJuan".

Proportional

The Proportional methods transfer values using some other numeric field (usually the Area(I) or Length(I) intrinsic fields) as a guide. Active Columns may also be used to guide Proportional transfer. Suppose we will apportion the value 30 from one object into three objects that have guiding values of 2, 2 and 1. Using Proportional will transfer the value 12 into the first and second objects and 6 into the third object.

A typical use of Proportional is to allocate values when splitting up areas. Suppose we have a single country area that we wish to break into a group of provinces using the Split with transform and a set of boundary lines for the provinces. If we have a Population field for the country and we assume that population is evenly dispersed (not usually true in most countries, but we will assume so for this example) we would like each newly created province area to inherit a proportional share of the population of the country. To accomplish this, we would set the 1 to N transfer rule to be Proportional for the Population field and we would use Area (I) as the guiding field for proportionality.

When the country is split into smaller areas, the Area (I) for each will be computed and compared to the Area (I) of the original country. Each smaller areas will get a proportional share of the Population field from the country.

Example

In this example we use Convex Hull to create areas that cover a selection of points. We use transfer rules to sum the values of a field and place the sum into the newly created area.

We begin with a drawing that shows points. We have selected six points. We have also saved this selection to the selections pane so that we can call it up later.
The drawing's table shows that each object has a **Population** field. The records for the selected points are highlighted in red selection color in the table.

To specify the desired transfer rules, we right click onto the **Population** column head and choose **Transfer Rules** from the context menu. In the **Transfer Rules** dialog we choose **Sum** as the method for **N to 1** and press **OK**. This tells Manifold that whenever a transform operator creates one object from many, Manifold is to sum up the values of the **Population** field for the many objects and to place that summed value into the **Population** field for the resultant object.

The **Convex Hull** transform operator is an operator that creates one object from many. We can apply it to the [Selection] as seen in the transform toolbar above to create a convex hull for the selected points.

When we press **Apply** on the toolbar the convex hull area appears in the drawing.

A new record has appeared in the table as well. The new record has a **Population** value that is the sum of the **Population** values of the points that were used to create it.
We can see this is the case by clicking on the saved selection for the points used to create the convex hull and then pressing the Preview button in the selections pane. This highlights the saved selection in blue preview color. We can see that 275 is the sum of the population values highlighted in blue.

We can next select the other five points. We'll also save this selection in the selections pane so we can later preview the records for these points.

Seen in the table the records associated with these points are highlighted in red selection color.
If once more we apply the Convex Hull operator to the [Selection] in the transform toolbar we create a convex hull area about these five points.

In the table window we can see that another object has been added, with a Population value of 201.

If we click the saved selection for the second set of points and press the Preview button in the selections pane we can see that 201 is the sum of the Population values for the points (highlighted in blue preview color) used to create the convex hull area.

For Advanced Users

The "1 to N" and "N to 1" categories of transfer methods may make it seem that either one or the other method is used in any given situation. In actuality, both methods are used all of the time in all cases. First the N to 1 method is applied to the source set and then the 1 to N method is applied to the destination set of values. Careful contemplation of the operators involved will show that results will always be the same as if only one or the other method were used, except in the case of the Count operator in "1 to 1" operations.
The simultaneous operation of \(1 \text{ to } N\) as well as \(N \text{ to } 1\) can be seen by considering a case of \(1 \text{ to } 1\) transfer. Suppose we make a copy of a drawing of areas. The original we call drawing \(A\) and the copy we call drawing \(B\). Suppose we delete all data attribute values from \(B\). We make changes to values in \(A\) and then we want to transfer the new values to \(B\). Because \(B\) was originally a copy of \(A\) we know that the areas in \(B\) are exactly coincident with the areas in \(A\). This is a "1 to 1" transfer since the value of each area in \(A\) will be transferred to one, and only one, area in \(B\).

Our question is which transfer methods operate... the \(1 \text{ to } N\) or the \(N \text{ to } 1\)? The correct answer is "both" as we can see from the following examples, each of which consider what happens to a value from a single area \(A\) with a numeric value of 5 that is transferred to the corresponding area \(B\):

Let's say our \(1 \text{ to } N\) rule is "copy" and the \(N \text{ to } 1\) rule is "maximum". When transferring values from \(A\) to \(B\) the system will first apply the \(N \text{ to } 1\) rule to the source set of values (consisting of a single value from area \(A\)) yielding a "maximum" of 5, and then second apply the \(1 \text{ to } N\) rule with a target set of values (consisting of the single value of area \(B\)) "copying" 5 from the previous step to each value. The value of \(B\) will be set to 5.

Let's now say our \(1 \text{ to } N\) rule is "equal division" and the \(N \text{ to } 1\) rule is "sum". When transferring values from \(A\) to \(B\) the system will first apply the \(N \text{ to } 1\) rule to the source set of values (consisting of a single value from area \(A\)) yielding a "sum" of 5, and then second apply the \(1 \text{ to } N\) rule with a target set of values (consisting of the single value of area \(B\)) distributing 5 from the previous step "equally" to each value. The value of \(B\) will be set to 5.

Let's now say our \(1 \text{ to } N\) rule is "sample" and the \(N \text{ to } 1\) rule is "count". When transferring values from \(A\) to \(B\) the system will first apply "count" to \(A\) to yield 1, and then second will "sample" 1 to \(B\). The value of \(B\) will be set to 1.

Summarizing the above, a "1 to 1" transfer will almost always result in copying the value from source object to target object, unless the \(N \text{ to } 1\) rule is set to "count", in which case the result will be 1.

Note that in cases that are truly many to one the resultant value always appear as if only the \(N \text{ to } 1\) rule is consulted. That is because Copy, Equal Division, Sample and Proportional all have the same effect when applied to the target set of values if the target set only has one member. Likewise, in cases that are truly one to many the resultant value always appears as if only the \(1 \text{ to } N\) rule were consulted. That is because all of the possible \(N \text{ to } 1\) operators have the same effect when there is only one member in the source set.

A fine point: although both \(N \text{ to } 1\) and \(1 \text{ to } N\) rules should always be understood to be in force Manifold will optimize execution so that no \(N \text{ to } 1\) computations are performed if it is clear that only one item would be in the "N" set.

**Tech Tips**

Have a lot of columns in your table and want to see all the transfer rules at once? Open the table and then choose Table - Design to see a summary.

Transferring column values between objects in a linked drawing using Sample or Copy N-to-1 aggregates will choose blank strings over NULLs.

Transform Toolbar - Drawings and Transform Operators - Drawings for information on using the transform toolbar in drawings.

Spatial Overlay - Spatial overlays are a different concept than the idea of using transfer rules to aggregate or to allot values when creating objects with transforms. However, it is a related concept in that aggregations or allotments are used to transfer field values between objects.

Transfer Contour Line Height to Points - A simple example using Spatial Overlay and transfer rules.

Color Areas by Counts - A simple example using Spatial Overlay and transfer rules to color areas by the number of points they contain.
Shortest Path over Land - A complex example that uses Spatial Overlay and transfer rules.

Intersection Overlays - A small, but sophisticated, example that uses Transfer Rules, Split with, Clip with (Intersect) and Spatial Overlay commands with areas.
Relations

Relations are connections between two tables in a Manifold project that allow one table to show columns from another table. A relation between tables uses a key field with unique values common to both tables to connect the two tables. The same field type must be used in the columns being related. This allows data that appears in one table to also appear in another table without having to physically duplicate the data.

To form a relation between two tables

1. Open the table that is to display the additional fields and click on Table - Relations.
2. Click on the New Relation button. This launches the Add Relation dialog.
3. In the Add Relation dialog, choose another table from the list box.
4. In the Add Relation dialog, click on one field for each table that will be used to match records and press OK.
5. Back in the Relations dialog, check the desired columns from the other table. Press OK.

Note: The New Relation button will not be enabled unless there is at least one other table in the project. To form a relation with a table using an external data source, first link a table in the project from that external data source. This creates a new, linked table in the project. We can then form a relation with that new table.

Columns that are "borrowed" from another table will appear in the table with yellow background color to indicate they are imported. They may be used like any other column, for example, for sorting, filtering, within formulas, within rank columns or for thematic formatting. Tables may have more than one relation with more than one other table.

Columns that are included from other tables may not be used as a key field to form a new relation. Columns can only be linked through one relation. They cannot be passed on in turn through yet another relation. For example, if table A has a relation with table B so that columns B1 and B2 appear in table A, table C cannot form a relation with table A and "borrow" columns B1 and B2 from table A. To include columns B1 and B2 in table C, table C must form a relation directly with table B.

Relations Dialog Commands

- New Relation - Add a new relation.
- Delete - Delete highlighted relation.
- Include All - Show all columns from the related table in this table. Check all checkboxes.
- Include None - Do not show any columns from the related table in this table. Uncheck all checkboxes.
- Include Inverse - Show all columns from the related table that were hidden and vice versa. Toggle all checkboxes.
- Properties - Edit the highlighted relation by calling the Add Relation dialog.

Example

Relations are used to add columns to tables from other tables.
Suppose we have a Customers table with a CustomerID field and a ContactName field.

Suppose also we have an Orders table with OrderID, CustomerID and an OrderDate field.

We would like to create a relation that shows in the Customers table the OrderID and OrderDate columns so that for each customer we can see all orders for that customer as well as the date of order. To do this, we open the Customers table and choose Table - Relations.

In the Relations dialog we click the New Relation button to add a relation. This opens the Add Relation dialog.

In this dialog we choose the Orders table in the list box and then highlight CustomerID as the linking field in both the Customers table (the left pane) as well as in the Orders table (the right pane, under the list box showing the Orders table). Note that we could have used any two fields that contain matching values even if they are named differently. However, as a matter of sensible database organization it makes sense to give the same name to the field used to save customer identification in all tables. We press OK.
The result back in the Relations pane is that we have a new relation listed as CustomerID: Orders.CustomerID. This is a shorthand way of saying that this relation is determined by matching values in the CustomerID field in this table to the CustomerID field in the Orders table.

We check the fields (columns) we would like to include from the Orders table and press OK.

The result in the Customers table window is that two new columns appear, the contents of which are taken from the Orders table. These contents are shown in yellow, which is a generic background color used to indicate values that are computed or otherwise derived.

Converting to Regular Columns

Right click on a relation’s column head and choose Flatten to convert the column to a regular data column. The current value of each cell will be used to populate the regular column and the link to the other table will no longer exist.

Notes

A table may have more than one relation. For example Table A might include two columns, B1 and B2, by way of a relation with Table B and Table A might also simultaneously include one more column, C1, by way of a relation with Table C.

Relations can exist between any tables that exist in the project. In particular, a drawing’s table can have a relation with another table.
Relations can exist between tables that are imported into a project and tables that are linked into a project. If we only have one table in a project we cannot form any relations because there is no other table with which to form a relation.

When including fields from tables that are linked into a project, keep in mind that tables linked into a project may be provided by files or OLE DB providers that might be participating in multi-user sessions with other programs. That's usually the objective of including such external tables, of course, but one should not be surprised if data in columns that are included from external tables appears to change without user intervention.
Attaching External Tables to Drawings

External tables may be attached to drawings by using relations. Relations allow us to "borrow" columns from the external table and to show them and use them as if they were a part of the drawing's own table. In this topic, an external table is meant as any table other than the drawing's own table. It can be a native table entirely within the project, or it can be a linked table that might possibly get its contents from some other data source.

To attach an external table using a relation, we need to have at least one field in the drawing's table that can be used to form the relation with the external table. Once the relation is formed we can include fields from the external table within the drawing's table.

To Attach an External Table to a Drawing

1. Link the external table into the project using File - Link - Table
2. Examine the drawing's table and the external table to find a field in each with values in common.
3. Open the drawing's table and use Table - Relations to form a relation with the external table using the fields in each that have values in common. Include in the drawing's table those fields from the external table that are desired.

Note that the drawing's table must have at least one field that can be used as a key field to form a relation with the external table.

Example

We have a drawing called Mexico with an associated table called MexicoTable. The drawing shows provinces in Mexico as areas.

In addition, we have used File - Link - Table to link an external table, called Sales, into the project as seen in the project pane shown above. The Sales table originates in an Access database that is part of our sales management system. Note that the Sales table is shown with the "table and cylinder" icon that is used to denote external tables that are linked into a project.

If we open MexicoTable, we see it has only two fields: the object ID field connecting the records in the table to the drawing's objects and a Place_name field that gives the name of each province.
If we open the **Sales** table, we see it has two fields: a **Sales** field giving sales numbers for each province and a **Province** field giving the name of each province.

![Add Relation Dialog](image)

If we click on the **MexicoTable** table to move the focus onto that window and choose **Tables - Relations** we can create a relation between that table and the **Sales** table. Shown above is the **Add Relation** dialog in this procedure, where we have clicked on the **Place_name** field in the **MexicoTable** pane and on the **Province** field in the **Sales** pane to indicate that values in these two fields should be matched to form the relation. In the **Relations** dialog we check the box for the **Sales** field in the **Sales** table to show it within the **MexicoTable** table.

![MexicoTable](image)

The result is that the drawing's table becomes equipped with a new column, called **Sales**, which is borrowed from the external **Sales** table using a relation. This **Sales** column behaves exactly as though it was a native part of the drawing table, however, it originates in the external table outside of Manifold. If our sales management system changes the Access database from which the **Sales** table is maintained, the values in the drawing's table will change as well.

**Notes**

The example uses simple tables with only one relation in the drawing's table. We can use more than one external table if desired by specifying more than one relation with external tables.

What do we do if we would like to use an external table with a drawing but there are no fields in the drawing? For example, suppose we have downloaded a drawing of Mexico with areas but there is no "place_name" or equivalent field in the drawing? In that case, we will have to manually add a field to the drawing's table and manually add a unique identifier to each record that can be used to match records with the external table we would like to use.
A nuance: We have used a simple drawing that has only one area object for each province. As a result, there is only one record for each province. The sample Mexico drawing imported from the BTS North American Transportation Atlas Database provided with Manifold System is not such a simple drawing. Several of the provinces in that drawing are made up of two or three areas to represent major islands that are part of the provinces. Such provinces have two or three records for each province in their tables.

Drawings and Tables
Geometry in Tables

This topic discusses the storage of geometry within tables, whereby binary data representing the shapes and locations of objects is stored within the table. That is a more advanced usage than the relatively simple case of geocoded tables, where some columns give lists of X/Y or latitude and longitude locations. For the more simple case of geocoded tables, see the Linked Drawings from Geocoded Tables topic.

Let's begin with a refresher on nomenclature: the objects in a drawing are the areas, lines and points that make up that drawing. A drawing's table has a record, a horizontal row, for each object. If there are any data attributes attached to the drawing's objects, those attributes will appear as columns in the table. The information that defines the locations of points and the locations and shapes of lines and areas is called the geometry of the drawing. The metric of a specific object is the geometric data that defines that object.

When working with drawings in Manifold we quickly become used to the idea that there are two parts to a drawing: the drawing component itself and the drawing's table.

When we pop open the drawing component in a drawing window it paints the objects in the drawing for us.

![Drawing Component]

Because GIS as done interactively is primarily a visual activity, drawings and other visual displays take the lead role in Manifold’s user interface.

When we pop open the drawing's table in a table window we see any data attributes in a classic row and column tabular presentation. Data attributes in tables are normally the sort of information that is easiest to comprehend and edit within a classic, text, row and column tabular user interface.

The way Manifold is taught to beginners together with the routine use of drawings and the tables of drawings conveys the idea that the geometry of objects is stored within the drawing and the data attributes are stored in the
drawing's table, as if they were two different storage locations. But the truth is deeper, more general and more powerful than that.

The truth of the matter is that inside Manifold all information for drawings, both geometry and attributes, is stored within tables. It is just a question of how different types of information are best displayed and used. Since geometry is best understood using a visual interface, by default the geometry in a table is shown using a drawing. But the geometry is still in the table.

We can see the geometry data within every drawing's table by turning on the Geom (I) implicit field. The Geom (I) column reveals the geometry column of a table, wherein the metric of each object is stored using Manifold's own Geom data type, a form of binary data that encodes an object's metric.

![Drawing Table](image)

<table>
<thead>
<tr>
<th>ID</th>
<th>Color</th>
<th>Geom (I)</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Red</td>
<td>&lt;geom, area, branches: 1, coords: 3&gt;</td>
</tr>
<tr>
<td>2</td>
<td>Blue</td>
<td>&lt;geom, area, branches: 1, coords: 6&gt;</td>
</tr>
<tr>
<td>3</td>
<td>Green</td>
<td>&lt;geom, area, branches: 1, coords: 32&gt;</td>
</tr>
<tr>
<td>4</td>
<td>Yellow</td>
<td>&lt;geom, area, branches: 1, coords: 4&gt;</td>
</tr>
</tbody>
</table>

It is impractical in a text, tabular presentation to convey a visual impression of geometry so instead when the Geom (I) column is turned on a table will report some summary information about the metric for that object: the type of geometry data, the type of object (area, line or point), the number of branches and the number of coordinates.

Since geometry is best comprehended visually, Manifold uses a visual, drawing user interface to present geometry. But the geometry that is displayed or edited in a drawing window is still ultimately stored within the table.

When we edit the shape of an object in a drawing, we are simply taking advantage of the drawing as a handy, visual user interface to edit the contents of the Geom (I) field for that object in the table. For example, we can select an object for editing in a drawing.
The object's row is also selected in the table. We can use that to follow along in this example.

Deleting a coordinate in the object changes both the geometry and the visual appearance of that object.

We can see by the coords: 6 value changing to coords: 5 that the geometry in the table has also been changed (there is now one less coordinate in the metric). The drawing is simply a visual interface to geometry stored in the table.

When we create a drawing the two part user interface system for visualizing drawings and drawing tables is automatically put in play by Manifold.

Manifold automatically creates a drawing component with the drawing's table indented under it in the project hierarchy to indicate the association between the two. But this is just a choice of user interface to present two icons, a drawing icon and a table icon, upon which users can click depending on whether they want to see the
data as a visual drawing or as a table. A different choice in user interface design might have simply used one icon and then given users the choice to click it open as a drawing or to click it open as a table.

In fact, within Manifold we can create tables that contain geometry which do not automatically have a drawing window user interface associated with them.

In the above example, we can copy the **Drawing Table** component and paste it as a new table called **Drawing Table 2**. This is now simply a table not associated with any drawing.

![Drawing Table 2](image)

After simplifying the illustration by hiding undesired columns and renaming the geometry column (to emphasize for the purposes of this illustration that it is not an intrinsic column anymore), we get the display seen above. This is now simply a table that contains a geometry column. We can link a drawing to it, write a query that grabs a subset of data from it, export it to an external DBMS or do many other things with it.

**Exploiting Geometry in Tables**

Once we understand that geometry is stored in tables we can exploit that understanding in many useful ways. We can:

- Store tables within external databases, including the geometry of objects.
- Translate geometry within tables from Manifold format to other formats for geometry.
- Export tables containing geometry to external databases, in effect a way of storing drawings within external database systems.
- Import tables containing geometry from external databases, in effect a way of importing drawings stored in databases.
- Write queries that dynamically select desired geometry from tables.
- Link drawings from queries that select geometry.
- Link drawings from tables in external databases, in effect a way of letting a DBMS system maintain a drawing that potentially thousands of simultaneous Manifold users might be editing simultaneously.

If an external DBMS can store data in binary form (as can all of the big-name DBMS packages), we can store drawings within external DBMS servers by simply exporting tables containing geometry to those servers.

Note that the realization that the geometry of a drawing is encapsulated within the drawing's table as a **Geom (I)** column is different than the simple notion of a geocoded table. A geocoded table is a way of maintaining a list of point locations in a table. It is simply a table that for each record contains latitude and longitude columns specifying where that record is located.

Geocoded tables are useful mainly for points and cannot store areas at all and lines to only a limited degree. Geocoded tables are a low performance, limited solution. Drawings linked from geocoded tables are read-only and cannot be edited. The main reason Manifold provides a simplified way of linking drawings to geocoded tables
is that lists of latitude / longitude locations in tables are extremely common and it is likewise a common desire to see such locations displayed in a map. So Manifold provides a simple way of doing that.

In contrast, tables that contain a geometry column have the ability to fully specify drawing geometry with all the characteristics sophisticated GIS usage requires of objects: that they can be areas, lines or points; that they can be multi-branched for topological sophistication, that they can exist within a specific coordinate system. To distinguish tables containing a geometry column from simple geocoded tables we often refer to them as **spatial tables** within Manifold documentation.

When stored within a fast DBMS spatial tables can be a very high performance solution that scales well for use by the very largest enterprise applications. Spatial tables provide tremendous flexibility and power. Drawings linked from spatial tables are editable, assuming the connection technology used is read/write and the user also has write permissions for the DBMS table used.

The usual way of storing spatial tables is within a spatial DBMS. Manifold makes it easy to store geometry data within spatial DBMS.

### Using Geometry Data in Tables

Why store geometry within spatial tables? Doing so allows use of linked drawings that are dynamically created from tables or queries containing geometric data. Because of the great flexibility of SQL the ability to create linked drawings from tables or queries makes it possible to create drawings on demand to suite a wide variety of purposes that cannot be fulfilled by static drawings.

Besides the obvious benefit of creating linked drawings on the fly as desired, there are many practical gains from storing geometry data in tables. To name just a few examples:

- We can store metric data in geometry columns in order to centralize all spatial data within a database, perhaps a central DBMS using SQL Server.
- We can store metric data in geometry columns to have more than one metric for a drawing object. For example, we could associate one object with another object without using any intermediate columns such as IDs, thus avoiding any risks of broken associations. Or perhaps we might want to store different versions of an object’s metric for different projections or for different users.
- We can use geometry values to store temporary results of geometric computations within queries.
- We can edit the **Geom (I) intrinsic field** in tables associated with drawings to edit the objects in the drawing.
- We can transform geometry data into different types to enable interoperability with different GIS systems.
- We can transform geometry data into native geometry types provided by spatial DBMS products like Oracle Spatial, to take advantage of server-side facilities provided by such products.
- Drawings linked from geometry in tables can be edited.
- If we use Enterprise Edition, drawings linked from geometry in tables can be edited by multiple users at the same time.
- If we use Enterprise Edition and a spatial index within a spatial DBMS, drawings linked from a spatial table can be restricted to a given area of interest. This enables desktop Manifold installations to be used to work with a manageable subset of what could be an immensely large data set.

### Geometry Types in Tables

Tables can contain geometric data columns that may use the following data types:

- Oracle **SDO_GEOMETRY** data, within Oracle databases that support this data type. This data type occurs only within Oracle tables and is dynamically mapped on the fly back and forth between Manifold's own **Geometry** type within tables in Manifold projects during OCI connections.
- IBM **ST_GEOMETRY** data, within IBM DB2 databases that support this data type. This data type occurs only within IBM tables and is dynamically mapped on the fly back and forth between Manifold’s own **Geometry** type within tables in Manifold projects during native DB2 interface connections.
- The **Geometry** type (also called **Geom**) is specific to Manifold System and contains the object type, the object metric and the coordinate system. **Geom** data can be stored within Manifold projects or saved into almost any DBMS system that supports binary “blob” storage, such as Access or SQL Server or MySQL. Exchanging data with Oracle data sources via the Oracle Call Interface (OCI) automatically maps Manifold **Geometry** values into Oracle **SDO_GEOMETRY** values (collections of geometric
Geometry, Geometry (SDE), Geometry (SHP) and GeometryWKB data types are referred to as Geom, GeomSDE, GeomSHP and GeomWKB as SQL data types and in coding. Therefore, these shorter names for these geometry data types are the usual way experienced Manifold users refer to these data types. For example, a Manifold user might say “I need to convert that Geom to a GeomSDE here.” In addition, the GeomWKB type is often abbreviated even more to simply WKB. This documentation will use either the longer forms or, more frequently, the shorter names for these data types.

Geom, GeomSDE, GeomSHP and GeomWKB data types can be implemented within any DBMS that can store binary data. In addition to tables within Manifold System, many modern database systems, such as SQL Server, Oracle and Access can store data in this form. Manifold can work with external tables in an external DBMS provider and save in Geom, GeomSDE, GeomSHP or GeomWKB form.

Geom and GeomWKB can be used within SQL Server using the Manifold Spatial Extender for SQL Server. This is by far the highest performance for storing drawings with a spatial index in SQL Server, especially when Geom is used. See the Spatial DBMS topic for information on the spatial extender.

GeomSHP and GeomSDE are somewhat similar approaches with differences in binary data organization. GeomSHP stores coordinates as double-precision floating point values. GeomSDE stores coordinates as integer values which are compressed using a simple run-length encoding scheme. The coordinate values must be scaled and shifted using the information stored in metadata tables.

Because GeomSDE depends upon metadata tables for meaning, some assumptions must be made when converting other geometry types into GeomSDE or when importing or linking a drawing from a table using GeomSDE. In both cases the integer coordinate values within GeomSDE values are assumed to use offsets of 0 and a scale of 1.

The Geom data type captures coordinate system information, but the GeomSDE, GeomSHP and GeomWKB types don’t. When used with projection-aware algorithms, values of the GeomSDE, GeomSHP and GeomWKB types are assumed to be in Latitude / Longitude. Working with values of these types in a projection other than Latitude / Longitude requires assigning these values the correct projection, for example, by converting to the Geom type and then using the AssignCoordSys query function.

Oracle SDO_GEOMETRY is available only within Oracle DBMS products. Manifold Geom data and Oracle SDO_GEOMETRY data are seamlessly mapped into each other during exchange whenever OCI is used to connect to Oracle databases. To force use of generic, binary-style storage instead of the native Oracle SDO_GEOMETRY storage within Oracle, connect to the Oracle data source using OLE DB or ODBC or (read only) ADO .NET.

Similarly, IBM ST_GEOMETRY is available only within IBM DBMS products. Manifold Geom data and IBM ST_GEOMETRY data are seamlessly mapped into each other during exchange whenever a native DB2 interface is used to connect to IBM DB2 databases. To force use of generic, binary-style storage instead of the native IBM ST_GEOMETRY storage within DB2, connect to the DB2 data source using OLE DB or ODBC or (read only) ADO .NET.

A simple rule for choosing from the above types is to always use a spatial DBMS vendor's native type. Use SDO_GEOMETRY with Oracle and ST_GEOMETRY with DB2, for example. Otherwise, use Manifold’s Geom type. In rare cases where interoperability with open source foolishness is more important than performance or reliability, we might be forced into using WKB. It almost never makes sense to use the ESRI types unless for the very limited case of interoperability with data held hostage in ESRI form.
Choosing a Geometry Data Type for Interoperability

One reason to store geometry in tables within database systems is to allow other applications to use such data. If we don't care about legacy applications and simply want our spatial DBMS to run as fast as possible while enabling multi-user concurrent editing we can simply use Manifold Geom type and either SQL Server with the Manifold spatial extender or Oracle (with Geom being automatically mapped into Oracle's SDO_GEOMETRY for us) or IBM DB2 (with Geom being automatically mapped into IBM's ST_GEOMETRY). If we want interoperability with other applications we have to decide what DBMS to use and also what geometry type to use.

When database tables containing columns of the above geometry types are saved from Manifold to an external DBMS provider, Geom values will be mapped to SDO_GEOMETRY if native Oracle interfaces are used or ST_GEOMETRY if native DB2 interfaces are used. In other cases, the data in such columns will appear as generic binary data

If the geometry data is in GeomWKB form, any application that understands GeomWKB will be able to use it. Although there are some, mostly academic, applications that can read or write GeomWKB, very few commercial applications have been deployed that use it (for reasons set forth below).

If the data is in Oracle SDO_GEOMETRY data then any application that understands SDO_GEOMETRY will be able to use it. Using Manifold + Oracle therefore will usually be the default choice for many people since more commercial applications can directly read or write SDO_GEOMETRY geospatial data than any other format.

IBM DB2 spatial users will want to use ST_GEOMETRY to allow interchange with any application that understands ST_GEOMETRY. DB2 also has a strong following, albeit with fewer applications than Oracle at this writing that can exchange spatial data with existing data sources managed by Oracle at this writing that can exchange spatial data using IBM's ST_GEOMETRY data type.

At first glance GeomSDE or GeomSHP might appear to be a way to allow easy interoperability with ESRI products, but what are commonly understood as ESRI "geodatabase," "ArcSDE" or "personal SDE" formats are not at present well supported by GIS industry products (not even by all legacy ESRI products) nor has ESRI encouraged interchange by other vendors using these data types. They remain closed, largely undocumented formats that have not been widely adopted outside ESRI. They also suffer from dependencies upon external metadata which makes them harder to use than self-contained types. The primary use for these types in Manifold is to facilitate data exchange with existing data sources managed by ESRI products. Their use in other cases makes little sense.

Choosing Between Geom and GeomWKB Types

Suppose we are working with a DBMS like SQL Server or MySQL that requires us to choose between GeomWKB and Manifold's own Geom type. Given that other applications are emerging that also understand GeomWKB, why would Manifold have a Manifold Geom type for storing geometry in tables? Would it not be easier to always use GeomWKB?

The reason Manifold has its own Geom type in addition to GeomWKB is that GeomWKB is limited. It does not contain the coordinate system in use, nor does it provide the ability to embed a variety of useful geometric information such as location precision or other data that can be cached to improve performance.

A good plan, therefore, is to use GeomWKB if one must have interoperability with existing applications that support it and use Geom for all other things. The storage impact for coordinate system and other data that are stored in Geom is not very large (typically less than 40 bytes and sometimes as little as 2 bytes per record) so using GeomWKB instead of Geom does not provide significant space savings.

On the other hand, using Geom lets us transfer tables with geometric data between machines without having to worry about coordinate systems. It also lets us have a table with objects that are in different coordinate systems, which will be automatically re-projected to the coordinate system of the linked drawing when it fetches data from the table.

Geom is also the native geometry type of Manifold itself. This has the utility of being always available in any drawing within Manifold without need of conversion to a generic GeomWKB type.

GeomWKB (WKB) and WKT

WKT is the "well-known text" format used by OpenGIS and similar standards. It is a human-readable text analog of GeomWKB. When viewing WKB data in tables, the data can be reported either in &lt;geom wkb, type&gt;
condensed format (the default), which only shows the type, or in WKT format, which shows both the type and the coordinates. To switch between the formats, right-click the WKB column, and select Format.

We can also transform GeomWKB data into WKT with CStr or CAST to create a text column containing WKT:

```
SELECT CStr(CGeomWKB(Geom(ID))) FROM [Drawing];
```

Queries and Geometry

Queries are used to create and alter columns containing geometric data. The SQL name of the Geometry type is Geom. The SQL name of the Geometry (SDE) type is GeomSDE. The SQL name of the Geometry (SHP) type is GeomSHP. The SQL name of the Geometry (WKB) type is GeomWKB. Using queries we can create geometric data from existing objects or literal values, we can convert geometric data between various representations and we can transform geometric data within tables. We can also use queries to create subsets of geometric data or to combine data from different tables. See the Spatial Extensions topic for a list of SQL functions that operate on Geom, GeomSDE, GeomSHP or GeomWKB data.

Creating a Table with Geometry

Tables storing geometry data are created from drawings with queries using the Geom (I) intrinsic column or the Geom(ID) call (which takes the value of the ID column and extracts the Geom for that value using the Geom(I) function).

Creating a Table storing a Drawing’s Geometry

1. Create or import the drawing into the project.
2. Write a query extracting the geometry data from the drawing.
3. Run the query.
4. Save the query results as a table.

A typical query that captures a drawing’s geometry as the Geometry column type as well as all data fields in the drawing would be...

```
SELECT Geom(ID) AS [Geom], [Drawing].* FROM [Drawing];
```

...where Drawing is the name of the drawing.

The query can then be used to create a table. To capture a drawing's geometry as the GeomWKB column type we first use Geom(ID) as above and then use the CGeomWKB(geom) function to convert the data to WKB form. These two functions may be nested, as in

```
SELECT CGeomWKB(Geom(ID)) AS [GeomWKB], [name of drawing].* FROM [name of drawing];
```

To covert geometry in Geometry or GeomSHP form into GeomWKB form, use CGeomWKB. To covert geometry in Geometry or GeomWKB form into GeomSHP form, use CGeomSHP. For example, after creating a drawing containing a GeomWKB column using the query above we could create another drawing containing the same data within a Geometry column using

```
SELECT CGeom(GeomWKB) AS [Geom] from [name of geom drawing];
```

An alternate way of creating a table that stores a drawing’s geometry is to use a Select Into query. This is used when creating a table in the same project. Create and run a query like the following:

```
SELECT Geom(ID) AS [Geom], [Drawing].* INTO [Table] FROM [Drawing];
```
where **Drawing** is the name of the drawing.

**Example**

In this advanced example we will create a table containing geometry from the **Mexico_eg** example drawing found on the Manifold CD. We will then use that table to create a linked drawing.

This is a very artificial example in that normally the use of spatial data is with a spatial DBMS. When Manifold exports a drawing to the spatial DBMS there is no need to explicitly create a geometry column within a drawing and to literally and explicitly export that geometry column. Manifold will simply export geometry to the spatial DBMS as needed when exporting a drawing. This example takes a different approach in that it exports geometry in a highly manual way, as if it were a binary field, without taking advantage of the automatic export of geometry for drawings to a spatial DBMS as is normally done.

However, for advanced users there is useful education to be had in explicitly creating geometry and then exporting it to a table. This exposes the inner workings of geometry and shows how it plays a role in defining objects in drawings.

![Mexico_eg Drawing](image)

![Mexico_eg Table](image)

We import the **Mexico_eg** file into our project to create a drawing and the drawing’s table.

![Mexico_eg Drawing](image)

The **Mexico_eg** drawing shows the provinces of Mexico. It is in latitude / longitude projection.

</tbody>
</table>

If we open the drawing’s table we see that it has various fields for each province.

We will use this drawing to create a table that captures both the drawing’s geometry and all data fields in the drawing within the table.
To do so, we create a query with the above text and run the query.

```
SELECT Geo.ID AS [Geom], [Mexico_eg Drawing].* FROM [Mexico_eg Drawing];
```

The query captures all of the drawing's fields and includes a new geometry field. Manifold reports statistics for `Geom` type fields including the type of object, how many branches it contains and the number of coordinates that define it.

The query also captures the object `ID` field from the drawing because the query text we used simply selected all of the fields from the drawing. We don't need to capture this field since it will not necessary to capture the geometry of each object. We are including it simply because it is easier to write a query that selects all columns than it is to write a query that selects all of the columns instead of the `ID` column.

We can save this query to a database table. In this example we will save it to an Access `.mdb` file in a temporary folder. To do so, with the focus on the query results window we choose `File - Export - Table`.

In the `Export` dialog we choose `MDB Files (*.mdb)` in the `Save as type` box and provide a name for the file.
In the Export MDB File dialog we choose Access 2000 as the MDB Subtype and press OK. [Moments after pressing OK we realize that we could have unchecked the ID box to not export that field, but that's OK - we will drag it along even though we don't need it.]

At this point we have created an Access .mdb file called Mexico_eg Geometry in our tmp folder. The .mdb file contains one table that contains a record for each object in the Mexico drawing. Each record has a column for geometry data defining the area object and columns for the various other data attributes. In an Access .mdb file, the geometry data is stored as binary data. Manifold can interpret that geometry data to create the line, point or area objects within a linked drawing.

Let's now pretend that we've not just created this table, but rather that it was sent to us by a colleague. We know the table contains geometry data that can be used to create a Manifold drawing, so we will link it into our project and use it to create a linked drawing.

We begin by linking the table from the external .mdb file into our project. To do so, we choose File - Link - Table.
In the Link dialog we choose MDB Files (*.mdb) in the Files of type box and then we navigate to the .mdb file and double-click on it.

Manifold will pop up a subsidiary dialog asking what table we want to import, and we choose the only table in the .mdb file. The default name of the table in the file is "Query," which is confusing, so as soon as we link the table into our project we rename it to something more sensible, namely Mexico Geometry. (This step is not illustrated).

The result is that now we have a linked table in our project called Mexico Geometry.

If we open this table we see that it has all of the fields from the original drawing plus a field called Geom that contains binary data. Note that the field containing binary data could be called anything. It happens to be called Geom because that's what we named it in the query that created this data from the original drawing. That's a useful name to use for such columns so that right away we know they contain Geometry data if we encounter them in tables.

To create a linked drawing from this table we choose File - Link - Drawing and then in the Link dialog choose This Project () in the Data Source dialog.
In the Link Drawing dialog that follows we choose Table with geometry column in the Type box and the Mexico Geometry table in the Source box. For this example, we have left all of the column boxes in the Columns pane checked. This means that all of them will be imported and available as columns in the drawing's table. However, we don't need either the ID column or the Geom column in the drawing's table. The ID column gives the object IDs for the original drawing.

The column name to use for geometry has already been loaded with the name of the only binary column in the table, Geom, and the type of geometry column has been loaded with Geometry. We press OK.

This creates a new linked drawing, called Mexico Geometry Data in the project. (Importing or linking a drawing from a table or query in the same project will inherit the name of the drawing from the table or query.)
If we open the drawing we see it is just like the original Mexico_eg drawing. It has automatically opened in Latitude / Longitude projection. We can use this drawing to create labels, to create themes, as layers in maps and for just about any other purpose we use a drawing in Manifold.

Let's now do something interesting and create a query that selects only some of the records from our spatial table. We can then create another linked drawing from that query.

We create another query, called Query 2, and write the above text into it to select all records from the Mexico Geometry table for which the SQMI value is greater than 30000. This selects only those records representing larger provinces in Mexico.

To create a linked drawing from the query, we choose File - Link - Drawing and then choose This Project () in the Data Source dialog.
In the Link Drawing dialog we choose **Table with geometry column** as the **Type** and **Query 2** as the **Source** to use. Since we don't need the **ID** field we uncheck it. Press **OK**.

The result is that a second linked drawing, called **Query 2 Data**, appears in our project.
If we open this drawing we see that it contains only the larger provinces in Mexico, those with square mile area greater than 30,000 square miles.

Let us now illustrate the dynamic power of linked drawings by editing the table from which our linked drawing is generated, which will result in changes to the drawing.

We open the Mexico Geometry table and select the record for Durango, a large province in the middle of Mexico.

We press Edit - Delete to delete the record. Even though this is a linked table brought into the project from an external .mdb file, we can delete records in the table because when we linked the table we did not link it in read-only mode. Deleting the Durango record in the linked table actually deletes it in the external .mdb file as well.
If we click on the `Query 2 Data` linked drawing and press **View - Refresh Data** to refresh the drawing, we compel the drawing to refresh itself from the query from which it is created. The query in turn refreshes itself from the linked table and the external `.mdb` file in which the (now altered) data ultimately resides.

We can see that the drawing no longer includes a **Durango** area. The red arrow indicates the empty space where Durango used to be. [Note for the very literal-minded: Manifold does not actually draw red arrows when objects are deleted - the red arrow was added to the illustration.]

If we like, we can open the **Mexico Geometry** table again and click **Edit - Undo** to restore the **Durango** record. This restores it in the external Access `.mdb` file as well.

If we click back onto the `Query 2 Data` linked drawing and press **View - Refresh Data** we see that **Durango** has been restored. Refreshing a linked drawing created from a table that resides in an external data source will refresh the table. Refreshing a drawing linked from a query will recompute the query.

One last thing: if we like, we can use **Edit - Projection** to re-project the `Query 2 Data` drawing into **Orthographic** projection, using the **Suggest** button to choose sensible parameter.
Even though the geometric data in the originating table is in Latitude / Longitude projection, Manifold will re-project on the fly to create the drawing in Orthographic as we have specified.

**Example Scenarios**

Linked drawings created from tables or queries have great flexibility. In addition to the above example, consider these scenarios:

**Scenario 1** - We have a drawing of states and want to create a separate drawing of states for each region. We want to keep all geometric data in the same place so all geometric transforms run in the same context, for example, with the same location precision.

We create a query for each region such as...

```sql
SELECT Geom([ID]), [Region] FROM [States] WHERE [Region] = "East";
```

... and we link a linked drawing from each query. We can then modify the source drawing as desired and thereafter launch a script to update regional drawings so they use the latest data.

**Scenario 2** - We have several different drawings of roads that cover different areas in our area of interest. We want to combine these drawings into a "master" drawing so we can operate upon all roads as a whole. We could create a master drawing using copy and paste, but the drawings are regularly updated and having to repeat the copy and paste process to re-create the master drawing each time a drawing is updated is not very convenient.

We create a query that joins the drawings together in the following form...

```sql
SELECT Geom([ID]) FROM [West]) UNION (SELECT Geom([ID]) FROM [East]);
```

... and we link a drawing from this query. When one of the source drawings is updated, we can update the linked drawing using View - Refresh Data.

**Scenario 3** - We have a drawing of WiFi access points with an operational radius for each access point stored in the drawing’s table. We want to display all WiFi access points in the given area as circles of appropriate size.

We create a query such as...

```sql
SELECT Buffer(Geom([ID]), [Radius], "mi") FROM [Access Points]
```
WHERE EXISTS (SELECT * FROM [Areas] WHERE Contains([Areas].[ID], [Access Points].[ID]));

... and we link a drawing from the query. Note the use of the buffer operator to create circular objects. In this case instead of formatting a point to be larger or smaller we actually create a circular object that is larger or smaller for display.

Scenario 4 - We have an ESRI geodatabase file in .mdb format. We can create a drawing from this geodatabase by choosing File - Import - Drawing and choosing .mdb in the Files of type box to open the .mdb file.

In the Import MDB File dialog we choose Geometry (SHP) in the Type box and press OK. The result is an imported drawing. We could have also used File - Link - Drawing to link a drawing from the geodatabase if preferred.

Note: This too is an artificial example in that if we want to work with ESRI personal geodatabases we can simply import or link to the geodatabase using Database Console. Manifold will automatically detect personal geodatabases and can import or link to them.

Display of Geometry Data within Tables

Tables will display the contents of specialized data types as a descriptive word within angle brackets <> Tables display binary data as <binary>, coordinate system data as <coordinate system> and geometry data as <geometry>

Right clicking on a geometry column head and choosing Format allows us to change the format of how the column is reported. For example, a coordinate system column can be switched between the default format and XML format, which will output XML formatted coordinate system information into each cell. This format is mainly used for debugging or when one wishes to capture a text / XML reporting of coordinate system structure.

For example, if we want to capture the coordinate system from a drawing of Mexico we could write a query called Q as follows:
SELECT CCoordSys(Geom(ID)) INTO X FROM [Mexico Drawing];

Running the above query creates a table called X that has one column containing the coordinate system data.

If we opened table X we could see that by default it reports the coordinate geometry data as `<coordinate system>`.

We can right click on the column heading, choose Format and change the display style from `<default>` to XML.

The result is that each cell reports the coordinate system used using a (lengthy) XML phrase. If we wanted to capture the XML we could click into a cell to edit it, copy the XML and then paste it wherever we wanted.

**Importing or Linking from Spatial DBMS / Exporting to Spatial DBMS**

This topic has discussed the internal mechanics of geometry stored in tables. When drawings are stored in a spatial DBMS there is no need to work directly with geometry columns. Simply use the Database Console to connect to the desired spatial DBMS and then link or import drawings as desired. Manifold will automatically transform the geometry type within the spatial DBMS into Manifold types, either automatically translating the spatial DBMS package’s native geometry type into Manifold Geom or if a Manifold geometry type is already stored into the spatial DBMS using that type to create a drawing directly.

Likewise, when exporting a drawing to a spatial DBMS, if Manifold Enterprise Edition or greater edition is used Manifold will automatically export the necessary geometry data into the DBMS as required.

**Open Data Source Command**

Right clicking a component that is linked from an external data source in the Project pane and then choosing Open Data Source will open the Database Console and connect to the component data source.

Opening a component linked from an external data source in its own window, and then choosing the Open Data Source command in the component menu (for example, choosing Drawing - Open Data Source when a linked drawing window is open) does the same thing.
Invalid or Missing Geometry

At times we might encounter tables or the results of queries that contain invalid geometry. This might happen for a variety of reasons, such as a bug in a third party program that attempts to write geometry or even something as simple as damage to a data set. This is unfortunate, but it would be a shame to lose regular attribute information in such cases, or, even if there is not attribute information it would be a shame not to be alerted to the problem that some objects do not have valid geometry. Manifold will try to salvage what information it can.

Manifold deals with invalid geometry in tables or queries by replacing the invalid metric (that is, the invalid geometry) for each such object with a synthetic metric consisting of a single coordinate located at the \((0,0)\) origin of the drawing's coordinate system. The effect of this is to create such objects with invalid geometry as points at the \((0,0)\) location of the drawing.

For example, if we link a drawing from a table that supposedly contains only areas and we find that some points have appeared at the \((0,0)\) origin of our drawing's coordinate system, we know that some of those areas had invalid geometry. If our drawing is in latitude / longitude, those points will appear all stacked over one another at the intersection of the Equator and the Prime Meridian in the ocean off Africa.

Why does Manifold use the \((0,0)\) location? The points representing objects with invalid geometry have to be put somewhere and this location has the advantage of being easy to remember and, in many common projections, not usually occupied by something else. Experienced GIS users also know that various projection problems will often toss objects into a tiny speck off the coast of Africa so this helps us remember just where Manifold places objects with invalid geometry.

Is it inconvenient to put all points from objects with invalid geometry at the same spot? Not really, since it is easy to select them with a Select Box or other mouse selection method and then we can open the drawing's table, filter on the selected items and see what objects we have at that location.

"Multi-point" geometry values generated by AllCoords and several other query functions are handled the same way: the result of the query function will be a point at the \((0,0)\) origin of the drawing.

When Manifold replaces invalid geometry with a synthetic point metric the IDs of the first ten objects with invalid geometry and a replaced metric will be logged into the History pane.

Limitations with IBM DB2

IBM DB2 Express-C Edition may be used for Enterprise Edition Enterprise Servers without any technical limitations. However, two small usage limitations apply when DB2 Express-C is used for storing geometry in tables within the database to support subsequent concurrent, multiuser editing. When a drawing is linked from a DB2 Express-C data source the following limitations apply:

- Adding a new object and immediately editing it without refreshing the drawing creates an editing conflict.
- Adding a new object and immediately deleting it without refreshing the drawing will fail.

Therefore, when ever editing drawings linked from a DB2 Express-C data source make sure to refresh the drawing after adding a new object before attempting to edit that object or to delete that object.

Notes

Refreshing a linked drawing created from a table that resides in an external data source will refresh the table. Refreshing a drawing linked from a query will recompute the query.

Refreshing a query will refresh all linked drawings descended from that query.

In the example above we could have created a table containing the geometry data in WKB form from the Mexico drawing using the `SELECT … INTO` construction in an action query:

```
SELECT CGeomWKB(Geom(ID)) AS [Geom], [Mexico_eg Drawing].*
```
INTO [WKB Table] FROM [Mexico_eg Drawing];

**Tech Tip**

Remember, ADO.NET connections are read-only. If we are link a drawing from a DBMS table using ADO.NET, we will not be able to edit the drawing. To link a drawing so it is editable we must use some read/write connection technology such as OLE DB or ODBC.

Virtual Tables for Images and Surfaces

Every image and surface in a Manifold project has a virtual table associated with it. Unlike the tables associated with drawings, a virtual table is not listed in the project pane. It is a "virtual" table in that it does not explicitly appear in the project but nonetheless the fields in it may be used. An image's or surface's virtual table may be used within queries by using the name of the image or surface.

Each pixel in an image or surface corresponds to a record in that image's or surface's virtual table. The virtual table includes the following columns, which are directly analogous to the built-in intrinsic fields of a drawing's table. These fields are the same that are used when an image or surface is copied and then pasted as a table.

- **Center Latitude (I)**: Latitude of the center of this pixel in degrees latitude.
- **Center Longitude (I)**: Longitude of the center of this pixel in degrees longitude.
- **Center Easting (I)**: X coordinate of the center of this pixel in the coordinate system of the image or surface adjusted with the values of the local offset and local scale parameters.
- **Center Northing (I)**: Y coordinate of the center of this pixel in the coordinate system of the image or surface adjusted with the values of the local offset and local scale parameters.
- **Center X (I)**: X coordinate of the center of this pixel in the coordinate system of the image or surface.
- **Center Y (I)**: Y coordinate of the center of this pixel in the coordinate system of the image or surface.
- **Color (I)**: RGB color value expressed as a decimal number (the decimal equivalent to a hexadecimal color value in the form #rrggbb). Read-only for surfaces. Writeable for images.
- **Red (I)**: Red channel value from 0 to 255. Read-only for surfaces. Writeable for images.
- **Green (I)**: Green channel value from 0 to 255. Read-only for surfaces. Writeable for images.
- **Blue (I)**: Blue channel value from 0 to 255. Read-only for surfaces. Writeable for images.
- **Alpha (I)**: Alpha channel value from 0 to 255. Read-only for surfaces. Writeable for images.
- **Invisible (I)**: Boolean: pixel is invisible or visible. Writeable for surfaces. Writeable for images.
- **Selection (I)**: Boolean: currently selected or not. Writeable for surfaces. Writeable for images.
- **Selection Mask (I)**: A byte giving the saved selections mask. Writeable for surfaces. Writeable for images.
- **Height (I)**: For surfaces only: the height of a pixel using whatever data type is used by the surface. Writeable for surfaces.
- **Easting (I)**: X coordinate of the lower left corner of this pixel in the coordinate system of the image or surface adjusted with the values of the local offset and local scale parameters.
- **Latitude (I)**: Latitude of the lower left corner of this pixel in degrees latitude.
- **Longitude (I)**: Longitude of the lower left corner of this pixel in
degrees longitude.

Northing (I)  Y coordinate of the lower left corner of this pixel in the coordinate system of the image or surface adjusted with the values of the local offset and local scale parameters.

X (I)  X coordinate of the lower left corner of this pixel in the coordinate system of the image or surface.

Y (I)  Y coordinate of the lower left corner of this pixel in the coordinate system of the image or surface.

X Offset (I)  X position in pixel coordinates from the upper left corner.

Y Offset (I)  Y position in pixel coordinates from the upper left corner, with the Y axis pointing down.

Writeable fields are only writeable if the queried component is writeable. If the queried component is read-only (for example, if it resides in a read-only .map file or is shared but not checked out from an Enterprise Edition server), then all columns in its virtual table also will be read-only.

The following relationships may help to understand the relationship between different intrinsic columns:

- X Offset (I) equals X (I)
- Y Offset (I) equals Y (I) counted from the top down
- Center X (I) equals X (I) + 0.5
- Center Y (I) equals Y (I) + 0.5

Note: Because the maximum number of records in a Manifold table is 4 gigabytes, images and surfaces that have more than 4 gigabytes of pixels (slightly more than 65500 x 65500) are currently not supported with virtual tables. Their virtual tables do not exist and they cannot be used in queries.

There are three main uses of virtual tables associated with images or surfaces:

- **Storage of Images in Tables** - We can use a query to select all columns for all pixels in an image’s virtual table and then export that query as a table into an .mdb file or to some other database storage. This is a way of storing images within tables in virtually any database.

- **Linked Images, Surfaces or Drawings** - Virtual tables allow us to use the power of spatial SQL to utilize all or part of an image or surface in a query. Other components can then be linked from that query. This allows us to create linked images or surfaces from the query. If the query creates point, line or area objects we can even create linked drawings from the query by linking a drawing to the query.

- **Editing** - Because some columns in virtual tables are writeable (using an update query or a script), virtual tables can be used to edit an image or a surface. The Red (I), Blue (I), Green (I), Alpha (I), Color (I), Selection Mask (I), Selection (I), Invisible (I), and Height (I) columns in virtual tables are writable. Writing to Red (I), Blue (I), Green (I) or Color (I) columns in a virtual table for a palette image can only use colors in the palette for that image. Attempting to write some other color will result in writing a color from the palette that is the nearest match to the attempted color.

- **Analysis** - Virtual tables allow us to analyze images and surfaces with sophisticated SQL statements. For example, virtual tables make it easy to determine the number of pixels occurring within a given height or intensity range, or to create a table of all heights in a surface along with their relative frequencies.

For detailed examples of queries that use virtual tables, see the Queries and Images or Surfaces topic.

**Other Manifold Technologies for Image Storage in Tables**
The topic above discusses image storage in tables either as virtual tables or as the storage of columns in tables that are taken from virtual tables. In addition, Manifold provides two other means of storing images within external databases:

- **Enterprise Edition** - Using Manifold Enterprise Edition we can share images into a Manifold enterprise server. In that case, the DBMS hosting the Enterprise server is simply being used as a big file cabinet and to facilitate collaborative use of such shared image components.

- **Oracle Spatial** - Manifold Enterprise Edition can save images into Oracle Spatial databases using Oracle's GeoRaster technology. This is a very fast technology that scales well for images that are many gigabytes or even terabytes in size. It also allows us to share such images with any other software that is Oracle GeoRaster compatible. See the Oracle Spatial Facilities topic.

Active Columns

Active Columns are columns in tables that show the results of a script function. Active Columns are used to show automatically computed values in each cell of the column, similar to how a spreadsheet is used to automatically show computed values for a formula in a cell. This makes it easy to create columns in tables where the values are, for example, computed from other columns in the table.

Active columns might be used in a simple way, for example, to show values given in English height measurements within a table as Metric height measurements (using a simple multiplication by a conversion factor), or they could involve considerably more sophisticated computations using table look-ups or even specialized programming objects. Use Table - Add - Active Column to add an active column to a table. Creating an active column creates a new, special script component that is bound to the table.

Each active column is assigned a script function within the new script component. The script component can contain other functions and subprocedures that are not displayed in any active column. For example, common subprocedures used by more than one active column could be written into the script component. Global variables and other elements of scripts can also be written into the script component for use by any active column in that table. The type and size (for types like fixed-length ANSI strings that require a size) of an active column are set by the script/active column author.

Use of active columns requires the ability to write functions in an ActiveX scripting or .NET language. For example, simple functions are very easy to write in Visual Basic Scripting and may be created by non-programmers. For more advanced use, any ActiveX scripting language or any .NET language supported on the system may be used. For example, the script that powers an active column may be written in Jscript, the Microsoft implementation of Javascript.

To create an Active Column:

1. Open the table.
2. Right click on a column head and choose Add - Active Column or choose Table - Add - Active Column from the main menu.
3. Specify the function name, the name to appear on the column head and the data type returned by the function.
4. Make sure the Compute option is not set to on the fly. Press OK.
5. A script component will be created under the table and opened for editing. Write the function to be used by the Active Column. Close the script component.
6. Once the script and active column are verified to work correctly, if desired the computation mode may be changed to on the fly. Use of on the fly mode will prevent most script editing operations in the script window.

Active Columns can contain programs written in any ActiveX scripting language or any .NET language available in your system.

Add Active Column Dialog

<table>
<thead>
<tr>
<th>Function</th>
<th>Name of the function called by this Active Column.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Language</td>
<td>Choose an ActiveX or .NET language in which the Active Column script will be written.</td>
</tr>
<tr>
<td>Add references for standard .NET modules</td>
<td>Adds references to standard .NET modules for active columns written in .NET languages.</td>
</tr>
<tr>
<td>Name</td>
<td>Name of the Active Column in the table.</td>
</tr>
<tr>
<td>Type</td>
<td>Data type returned by the function and hence the type of the column in the table. If the called function returns a type other than this, Manifold will try to convert the data into this type.</td>
</tr>
<tr>
<td>Size</td>
<td>Specifies size for data types (such as fixed length text types) requiring a size.</td>
</tr>
</tbody>
</table>
Compute  Computation method to be used for this Active Column:

- **on demand** - Compute the column when the table is first opened and cache the values. Thereafter, recompute values on a user Recompute command.

- **on demand, recompute after changes to script** - Same as on demand, but also recompute values if the script is edited.

- **on the fly (no cache)** - Always recompute cells dynamically whenever necessary without ever caching values. The slowest mode, but always up-to-date. Use of this mode will not allow most editing of scripts. To edit a script associated with an active column, first change the Compute mode to some other mode, edit the script as desired, verify it runs and then change the Compute mode back to on the fly.

- **on user request** - Recompute cell values only when the user issues a Recompute command. The fastest mode and the default.

Once formula results are computed for the table, the Active Column may be used like any other column. It may be used for thematic formatting or in an SQL expression, for example. The table may be sorted by clicking on the Active Column head.

**Computation Controls**

Manifold provides a Compute control to specify how the Active Column should be computed. The Compute parameter is specified when the Active Column is created. It may be changed at any time by right clicking on the Active Column head and choosing Edit to launch the Active Column dialog again. Different Compute modes are provided to allow user control over when the script in the Active Column is executed to update the values in the column.

Although Active Columns are conceptually similar to spreadsheet cells in that the values are intended to be automatically computed, the formulas used within Active Columns can often be very large and complex scripts (large programs consisting of many subroutines). In the case of drawings containing many objects, and thus many records in the drawing's table, it could take a long time to recompute the Active Column for all records. Accordingly, unlike spreadsheets that are set by default to automatically recompute every cell when anything in the spreadsheet is changed, the default behavior of an Active Column is to recompute the values in the column only when the Recompute command is issued by the user, the on user request setting.

When an Active Column is recomputed using the on user request or the on demand settings the values in the Active Column will be cached, that is, held unmodified in the column, even if values upon which they depend from other columns have been changed. This can be changed by using the on the fly setting, which results in behavior similar to that of spreadsheets where cells are always automatically recomputed.

If caching is turned off for on the fly recomputation, any such action using the Active Column will cause a dynamic recomputation of the values in the column. For simple formulas the difference between on the fly and other modes is very slight; however, for more complex functions or major programs written into an Active Column the difference is substantial. In such cases the on user request mode should be used.

The Recompute command is highly optimized to avoid unnecessary context switches when refreshing values in cacheable Active Columns. This makes the Recompute command the fastest way to compute values in Active Columns. Invoking the Recompute command on an Active Column whose function can not be found will display an error message when the script cannot be executed.

**Tech Tip**

Why does on the fly mode not allow editing of the active column's script? On the fly mode causes the active column, and thus the script, to respond to any changes. Suppose we attempt to edit a script's text or even to enter the initial text: when we make an edit, the change in text (even just one character) will be detected by the system as a change. In response the table window will attempt to compute the values for any active column cells that are visible; however, it is quite likely that the script as changed is not yet functional. The script engine
therefore signals an error and the script window selects the text it thinks is incorrect (which might be just a single character the user has just typed).

Avoid this restriction on editing by using one of the following techniques:

- Create an active column with another computation mode, make sure it works and then switch computation mode to "on the fly."
- Avoid execution of active column code by making the active column invisible, that is, by hiding it in the table window or by closing the table window itself for the editing period.

**Example**

We will open the **Order Details** table from the **Nwind.mdb** sample database and add an active column to it.

We've opened the table and have hidden all fields except **Order ID**, **Unit Price** and **Discount**.

To create an Active Column we choose **Table - Add - Active Column** from the main menu.

In the **Add Active Column** dialog we enter **Discounted** for the name of the function to use, **Price with Discount** as the name of the column and we choose **Floating-point (double)** for the type of our column. For this example we will choose **on user request** for the computation method. Press **OK**.
A script component called **Order Details Script** is created in the project pane underneath the **Order Details** table. If this is the first Active Column, the script component is popped open for editing in a script window using default template code.

```
Function Discounted
    Discounted = Nothing ' Record.Data("Column")
End Function
```

The template code is not a functioning Active Column script - it simply reminds us what the structure of a Active Column script should be.

```
Function Discounted
    Discounted = Record.Data("Unit Price") * (1 - Record.Data("Discount"))
End Function
```

We edit the script component to add the above text. Note how script windows in Manifold will color the different parts of a script to help us keep track in our coding. Advice to newbies: pay careful attention to details and check for keyboarding errors. "Unit Price" is not the same thing as "UnitPrice".

<table>
<thead>
<tr>
<th>Order...</th>
<th>Unit Price</th>
<th>Discount</th>
<th>Price w...</th>
</tr>
</thead>
<tbody>
<tr>
<td>10000</td>
<td>27</td>
<td>0</td>
<td>27</td>
</tr>
<tr>
<td>10000</td>
<td>22</td>
<td>0</td>
<td>22</td>
</tr>
<tr>
<td>10000</td>
<td>21.35</td>
<td>0</td>
<td>21.35</td>
</tr>
<tr>
<td>10003</td>
<td>43.7</td>
<td>0.05</td>
<td>41.9145...</td>
</tr>
<tr>
<td>10004</td>
<td>85</td>
<td>0</td>
<td>85</td>
</tr>
<tr>
<td>10004</td>
<td>30.7</td>
<td>0</td>
<td>30.7</td>
</tr>
<tr>
<td>10005</td>
<td>34</td>
<td>0.15</td>
<td>28.9000...</td>
</tr>
<tr>
<td>10006</td>
<td>4.2</td>
<td>0</td>
<td>4.2</td>
</tr>
<tr>
<td>10006</td>
<td>11.3</td>
<td>0</td>
<td>11.3</td>
</tr>
<tr>
<td>10008</td>
<td>7</td>
<td>0</td>
<td>7</td>
</tr>
<tr>
<td>10008</td>
<td>37.1</td>
<td>0</td>
<td>37.1</td>
</tr>
</tbody>
</table>

When we close the script window an Active Column appears. Right click on the **Price with Discount** column head and choose **Recompute**. The Active Column uses a different background color to indicate it contains computed values. Foreground and background colors for Active Columns may be set in the Tools - Options dialog. The values it shows are those computed using the function we wrote.
We can widen the column to see the full name we specified. We can right click on the column and choose Format to format the columns to only two digits after the decimal point. To change the column so that it re-computes automatically, we right click on the Price with Discount column head, choose Edit and change the Compute value to on the fly.

Syntax and Conventions for Active Columns

When used within an Active Column script, ‘Record’ refers to the context record that has the following properties:

- ID: The ID of the drawing object. Only for drawing tables.
- SequentialNumber: Sequential number of the record within the table.
- Data: A collection of values within a given record.
- DataText: A collection of values with a given record represented as formatted strings.

Active Column scripts can reference other components and can even reach any other scriptable objects installed within the system such as Microsoft Office applications.

Context Menu Commands for Active Columns

Right click on an Active Column head to call up a context menu of commands. In addition to the usual table column commands, Active Columns have:

- Edit: Edit the definition of the Active Column using the Edit Active Column dialog (functionally equivalent to the Add Active Column dialog).
- Edit Script: Enabled for Active Columns. Edit the script associated with this column.
- Flatten: Enabled for Active Columns, Rank Columns and Relations. Convert the column to a regular column by using the current values in the cells.
- Recompute: Recompute the values in an Active Column.

Debugging

If you have purchased the Debugger option for Professional Edition or if you have licensed Enterprise Edition (which includes the Debugger) you can use the Debugger to debug Active Column scripts written in ActiveX languages that support Microsoft specifications for debugger interfaces. Scripts associated with Active Columns can run in the debugger. To debug an Active Column script, place one or more breakpoints within the script, right click on an Active Column cell and choose Run under Debugger from the pop up menu. Doing this runs the function while generating values for the Active Column in the context of the clicked cell. The resulting value will be discarded. All regular runs of Active Column functions are done without the debugger.
Converting to Regular Columns

Right click on an Active Column head and choose Flatten to convert the column to a regular data column. The current value of each cell will be used to populate the regular column.

Notes

Active columns can only reliably refer to non-active columns. Using one active column from another will not force re-computation and will either return the last cached value or no value at all. A "no value" return is the value with a 'no value' flag that is supported by all ActiveX scripting hosts.

Choosing an unexpected type for the column in the Add Active Column dialog will force a conversion to that type if possible and will return no values if a conversion is not possible.

We can manipulate drawings from Active columns. The following Active column operates on a drawing's table and returns the number of points in the first branch of the object.

```ironpython
Function PointsInFirstBranch
    Set objSet = Table.Owner.ObjectSet
    Set obj = objSet(objSet.ItemByID(Record.Data("ID")))
    PointsInFirstBranch = obj.Geom.BranchSet(0).PointSet.Count
End Function
```

IronPython scripts intended to be used for active columns should only include the body for a single script function.

See Also

See the Scripts topic for information on scripting. See Active Columns using VBScript and Active Columns using Jscript for examples using active columns and script functions written in VBScript and Jscript.
Finding Data in Tables

There are several ways of finding data in tables. Some methods of finding data involve making selections.

- Find / Find Next commands may be used to search for a value or a regular expression that is a pattern. Searches can be restricted to only one field if desired.
- Manual sorting using the Sort Ascending or Sort Descending context menu commands from the table context menus can be used to sort the table by a column. The table can then be manually scrolled to find the records desired.
- Tables may be sorted by clicking on a column head to sort by that column or by using the View - Sort dialog to sort records using several fields at once.
- An Active Column can be created to compute values by sophisticated rules. The table can then be sorted by the Active Column to bring desired ranges of values generated by the rule to the top of the table.
- More Like This commands are a fast way of finding more data like a particular record or the contents of a particular cell.
- The Decision Support System provides a sophisticated means of finding records through flexible criteria.
- Queries may be used to create classic database queries that find and display records from tables using Structured Query Language (SQL).
- The Query Toolbar provides a fast means of using simple queries to select records in tables.
- ViewBots can be used to find data in tables by selecting the records picked out by the ViewBot.
- If the table is a drawing's table, selection operations in the drawing can be used to find records in the table that are otherwise impossible to distinguish. For example, using Select Circle to select all points in a drawing that fall within a particular cluster will also select the records associated with those points in the drawing's table. See the Selection topic.

If we are looking for a specific value the fastest way is usually to use Find. If we are looking at a record that is similar to those we want we can use the More Like This system. For browsing, tables may be sorted either by columns or by using Sort and browsed by scrolling through the table. This can be a remarkably fast approach even for large tables.

When working with large tables it is often convenient to open the table in two windows at once. One of the windows is used to make selections and the other window is used to show just the selected records.

Press in the Filter Selected filter button in one of the table windows to show only selected records in that window.

For example, in one window we might use More Like This Cell (Sorted) to sort records by their similarity to the value in a particular cell. We can then add the top five or ten records to the selection and see them appear in the table window that is filtered to show only the selection. We can then click on the full table window and do a different procedure to add to the selection. In this way we build up a list of selected records in the

Once we find the data we want in a table we might want to make a selection of interesting records and then save that selection in the Selections pane. We might also want to use bookmarks to note records.
More Like This

Manifold's More Like This commands operate within tables to help us find records that are similar to those we see. They provide a shortcut way of using Manifold's Decision Support System in a rapid, one-click way.

More Like This Cell / More Like This Cell (Sorted)

To find more records that have similar values to a given cell, right click on the cell and choose More Like This Cell from the context menu. Other records that have a value "like" that will be selected. Choosing the (Sorted) version of the command will sort the table so that records with values in this cell most like the target cell will be placed at the top of the table and those records that are least like the target cell will be placed at the bottom of the table.

The More Like This system ranks exact matches the highest, and then ranks records in decreasing similarity based on a flexible comparison to the target cell. For example, suppose we open the Customers table in the Nwind sample database and try to find more records that have "USA" in their Country field. If we right click onto a "USA" cell and choose More Like This Cell (Sorted) the table will be sorted so that "USA" records come first, followed by a "usa" record and then a series of "UK" records. After that, the table sort will be so "unlike" the specified "USA" cell that the sort order will not be very helpful. However, all the "USA" and "UK" records will be at the top.

More Like This Record / More Like This Record (Sorted)

Right clicking onto a record handle and choosing More Like This Record will find additional records that are "like" that record. The (Sorted) version of the command will sort the table so that records most like the given record are at the top and those records least like the given record will be at the bottom.

The command works by examining all the fields that are displayed in the table and launching a Decision Support System flexible query that seeks to find records that have values in their fields like those that are displayed in the given record. Columns that are hidden will not be considered.

More Like This Record (Sorted) Example

Suppose we open the Customers table in the Nwind.mdb database in two different table windows.

In the window shown on the left in the illustration above we've hidden all fields except CustomerID and ContactTitle. In the window on the right we've hidden all the fields except CustomerID and Country. In both cases, we will right click on the "BLAUS" customer ID record and choose More Like This (Sorted).

For the table on the left we are therefore looking for more records that have "BLAUS" for customer ID and "Sales Representative" for the contact title. For the table on the right we are looking for more records that have "BLAUS" for customer ID and "Germany" for the country.
The result on the left found records that were like the one indicated considering that only the **CustomerID** and **ContactTitle** columns were displayed in the table. Unsurprisingly, the top records in the sorted table all have "Sales Representative" as the value for the **ContactTitle** field. Because "BLAUS" is a unique value for **CustomerID** the **More Like This** consideration of this field places that particular record at the top of the table.

The table on the right shows the result of a **More Like This** search on the same record. However, in this case only the **Country** field was displayed so the **More Like This** reckoning looked for records that also had "Germany" for country.

**More Like... Dialog**

The **More Like** dialog allows custom control over which fields are reckoned in the **More Like This** query to find records that are "like" the target record.

**To Use the More Like... Dialog:**

1. Right click on the record handle for the target record. Choose **More Like...** from the context menu.
2. All columns displayed in the table will be listed in the dialog. For each column that is to be used, double click into the **Similarity** cell and choose how that column should be used (from "slightly similar" to "extremely similar" to find possibly similar records.
3. In the **Select** box, choose which records are to be selected. The choice is either all those records that rank higher than a given percentage or those records that are in the top given number of records.
4. Check the **Sort results by rank** box if the table should be sorted by the **More Like** ranking.
5. Press **OK**.

The **More Like This** system functions by creating a Decision Support System query within Manifold based on the columns and similarity criteria desired and then ranking all the records in the table by how well they match that DSS query. Records are ranked as a percentage from 0 % (not at all like the target record criteria) to 100 % (identical to the target record criteria).

The **Similarity** choices allow specification of how similar the selected fields will be to the target record's fields. The default choice is normally **similar**. Choose other **Similarity** options from the list box to force stronger or weaker similarity for that field.

**More Like... Dialog Commands**

- **Column**: Column names that are currently enabled for display in the table.
- **Similarity**: Double click into the **Similarity** cell for each column that is to be used in the search.
- **Select ranks higher than ... %**: Select all records whose DSS
similarity ranking is greater than the given percentage.

top … records - Select this number of the highest ranking records.

Sort results by rank - If checked, sort the table by the DSS ranking of each record for the given criteria.

**Similarity Options**

- **slightly similar**: Weakest similarity required. Equivalent to using an Is Slightly hedge in the DSS query. Would require a 12.5% ranking to get the same effect as a 50% ranking achieved with similar.

- **somewhat similar**: Weaken similarity required. Equivalent to using an Is Somewhat hedge in the DSS query. Would require a 25% ranking to get the same effect as a 50% ranking achieved with similar.

- **similar**: Use a standard DSS profile to rank desirability of values.

- **very similar**: Strengthen similarity required. Equivalent to using an Is Very hedge in the DSS query. Would require a 70% ranking to get the same effect as a 50% ranking achieved with similar.

- **extremely similar**: Strongest similarity. Equivalent to using an Is Extremely hedge in the DSS query. Would require a 79.4% ranking to get the same effect as a 50% ranking achieved with similar.

**Notes**

The screen shots for this topic were done in a "live" Manifold session with two table windows open at the same time into the Customers table. Note that different windows into the same table can have different arrangements of columns visible and can be sorted independently.

See the Tables - Context Menus topic for a reference listing of context menu commands in tables.

The More Like… dialog creates and launches an internal Decision Support System query. This is a simple way of using DSS without learning about profiles or queries. For those interested in the details, the similar choice for Similarity is equivalent to using a criterion profile in the DSS query that (for numeric fields) uses a Gaussian bell curve about one standard deviation wide to either side of the target value. Choosing other Similarity options is the same as using hedges in the DSS query to make the Gaussian bell curve wider (weaker similarity) or narrower (stronger similarity).

The internal profile is created by considering the actual values that occur throughout the table. This assures the target More Like This profiles are a reasonable match to the actual data in the database.
Rank Columns

Rank Columns are used to construct a Decision Support System query and to report the results. A rank column reports percentages. The Manifold Decision Support System (DSS) provides a way to select records using flexible criteria with queries. DSS results are reported as percentage values from 0 to 100 percent within a rank column in a table. Creating a rank column creates a DSS query, the results of which are reported in the column.

Instead of using fixed criteria such as "greater than 50" in a query, DSS can handle a situation where the criterion might be more than 50 most of the time but that sometimes a value near 50 is also acceptable. The science of using flexible criteria is generally referred to as "fuzzy" logic. See the Introduction to Decision Support topic for more information on fuzzy logic.

Decision Support describes objectives for each data field using criteria. Criteria are curves that show which values for the data field are more desired and which are less desired. One or more criteria may then be used in a ranking query to find records that are a good fit to the combined requirements of all the criteria used. The results will be reported using a rank number, a percentage from 0% to 100% that appears within a Rank Column in the table. Records that fit the query well will be ranked at or near 100%. Records that fit the query less well will be ranked at increasingly lower percentages.

Records may then be organized by clicking on the Rank Column heading to sort the table in order of DSS ranking.

To select records using Decision Support:

1. Open the table of interest.
2. Use Table - Add - Rank Column to add a Rank Column to the table.
3. In the Add Rank Column dialog, specify the name of the column.
4. Press New to add a new criterion to the Criteria pane.
5. In the Add Criterion dialog, choose the name for the criterion, the field (column) to be used and the type of criterion. Types such as High and Low provide presets that are automatically computed based on the data in the table. Press Apply to see the effect of the Type and press OK to create the criterion.
6. Continue adding criteria using steps 4 and 5 above for all the fields you wish to use. Criteria appear organized in a hierarchical diagram under the names of the fields they use.
7. Create a query by dragging and dropping criteria from the upper pane into the lower pane. Change the Junction from Or to And as desired by double clicking onto the Or. Place a Not in front of a criterion if desired by double clicking into the Not column and choosing Not.
8. Press OK and a Rank Column giving DSS values for all the records will appear in the table. Sort the column by clicking on the column head to see the records displayed in rank order. Records with a rank value of 100% most closely match the rank query.

Another way to make a selection using DSS is to use a ViewBot in the ViewBots pane. For example, suppose we have created a Rank Column named Ranking. We could add a ViewBot that reported for the Ranking field the records Greater or Equal To .90. This would report all records where the total Ranking was greater than 90%. We could then click Replace Selection in the ViewBots pane to select those records. Note that we use a value of .90 in the ViewBot since rankings are percentages.

Percentages are numeric values from 0 to 1.00 that are normally multiplied by 100 and followed by a percent sign for reading convenience. For example, an 85% value shown in a rank column is actually the number .85.

Once created for any rank column all the criteria in the Add Rank Column pane will be available for use in any other rank column in that table.

Rank columns can only be created using numeric columns that are native to the table, intrinsic or foreign columns. ["Foreign" columns are columns mapped from other tables through relations.] They can not be created using other rank columns or using Active Columns. Rank columns can be created with tables imported into the project or linked into the project from external files or providers.

Converting to Regular Columns

Right click on a Rank Column head and choose Flatten to convert the column to a regular data column. The current value of each cell will be used to populate the regular column.

Add Rank Column Dialog - for details on options within this dialog.

Editing Tables

Editing Data in Tables
We may edit data in tables interactively by clicking into individual records, by using Find and Replace and by making global edits using the Transform toolbar. Editing data in tables that have been imported into Manifold will change the data only within the Manifold project. Editing data within external tables that have been linked into a project will change the data in the external table.

We can change fields in records by double-clicking on the field and entering a new value. Press Enter to apply the new value. If we change our minds after clicking a field, we can hit the Esc key to abandon the edit. Some fields in some databases may be limited to certain values, in which case choice boxes or other dialogs will pop up as necessary to provide allowed choices.

For "global" edits that affect an entire column throughout the entire table or selection use the Transform toolbar. Most table editing commands will be accomplished by a series of steps using the transform toolbar.

To edit individual records, we can use standard Windows power moves as set forth below:

Editing Cells

The contents of cells may be edited by double clicking into the cell, by pressing Enter or by clicking on the cell to highlight it (or by moving the highlighting using arrow keys) and pressing F2. When finished editing, press Enter to accept the value or click with the mouse anywhere outside the cell to accept the value.

Cells will only accept values that are compatible with the data type of that field. For example, double clicking into an integer field and attempting to enter the value 425 Main Street will result in no changes made on pressing Enter. Attempting to enter a floating point value such as 3.1415 into an integer cell will result in only the integer part of the value (3) being entered on pressing Enter.

Cells that are formatted in a given column formatting style will accept edits in any compatible style. For example, if a date and time column is formatted to show dates as 3/09/2001 and one enters 9 mar during the year 2001 the entry will be accepted and shown as 3/09/2001. In this case, Manifold knows that "mar" in date and time fields means March. If the or time is not explicitly given the system uses the current system year and time. To specify all parts of the data and time value, enter explicitly those parts desired. If one enters 9 mar 99 the entry will be accepted and shown as 3/09/1999.

Editing the value of a fixed-length text column in a table window limits the length of the editable text to the maximum length accepted by the column.

Right clicking onto a cell brings up a context menu of choices. Note that the Delete command will reset the value of the clicked cell to the default value for that column. For example, using Delete on a cell in an integer column will reset the value of that cell to 0.

Adding Records to a Table

Tables that are associated with drawings cannot have records added to them from the table window since each record in the table is associated with an object in the drawing. Adding a record means adding an object: this is done in either a drawing window or a map window (if the drawing is used as a layer in a map) by inserting a new point, line or area object. When the new object is inserted into the drawing a new record for it will appear in the table.

To insert new records into tables that are not associated with drawings, click into cells in the new record row (marked with an asterisk) to edit their values. Press SHIFT-Enter to append the new record to the table.
Suppose we start with a table with only two records.

If we click on the first empty cell in the new record row and press **Enter** we can begin entering a new name. In this case, we have typed **Ben**.

Pressing **Enter** will enter that value into that cell. Note that the status icon in the row handle has changed to a small pencil to show we are entering a new record. We can press the right arrow on the keyboard to move to the next cell in the row.

If we press **Enter** we can begin editing that cell. After entering the text **Franklin** we can press **Enter** once more to have the cell accept the new value.

If we are happy with our new record we can right click on the record handle (editing pencil icon) or on the new cells and choose **Append** to append the new record to the table. Choosing **Cancel** will cancel the operation and choosing **Clear** will clear all values from cells so we can begin again. Keyboard shortcuts: use **SHIFT-Enter** to append and **SHIFT-Backspace** to cancel.
If we append the record a new record is added to the table. Note that the editing pencil icon has been replaced with a current record icon in the usual way. A new record row appears as well.

**Changing Fields in Many Cells at Once**

When changing the value of a specific cell, that field will be changed to that value for all selected records:

<table>
<thead>
<tr>
<th>Accounting Manager</th>
<th>Rue de</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sales Representative</td>
<td>Carrier</td>
</tr>
<tr>
<td>Sales Representative</td>
<td>City, Ci</td>
</tr>
<tr>
<td>Sales Associate</td>
<td>8 John</td>
</tr>
<tr>
<td>Marketing Manager</td>
<td>Garden</td>
</tr>
<tr>
<td>Sales Associate</td>
<td>Maube</td>
</tr>
<tr>
<td>Sales Representative</td>
<td>67, av</td>
</tr>
<tr>
<td>Sales Manager</td>
<td>1 rue</td>
</tr>
<tr>
<td>Marketing Assistant</td>
<td>1900</td>
</tr>
</tbody>
</table>

Suppose we wish to change the title to "Sales Person" in all selected records.

<table>
<thead>
<tr>
<th>Accounting Manager</th>
<th>Rue de</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sales Person</td>
<td>Carrier</td>
</tr>
<tr>
<td>Sales Person</td>
<td>City, Ci</td>
</tr>
<tr>
<td>Sales Person</td>
<td>8 John</td>
</tr>
<tr>
<td>Marketing Manager</td>
<td>Garden</td>
</tr>
<tr>
<td>Sales Person</td>
<td>Maube</td>
</tr>
<tr>
<td>Sales Person</td>
<td>67, av</td>
</tr>
<tr>
<td>Sales Person</td>
<td>1 rue</td>
</tr>
<tr>
<td>Marketing Assistant</td>
<td>1900</td>
</tr>
</tbody>
</table>

Press **Enter** or double click into the field in any of the selected records and enter "Sales Person" and then press **Enter**.

The value will be changed in that field in all of the selected records.

This above behavior can be turned off by unchecking the **Apply table cell editing to all selected records** box in the Tools - Options dialog.

**Keyboard Editing**

One may also edit data in Table windows using "keyboard style" data editing. **Double-click** into a field to edit it and then push **Enter**. Move the edit box to another field by using the keyboard cursors. **Push Enter** to open the field for editing, enter the new value, and then hit **Enter** to apply the value.

The **Tab** key will move one cell to the right of the active cell. A **Shift-Tab** will jump one cell to the left of the active cell.

Keyboard editing is a rapid way of moving the cursor through columns of data and making changes as desired.
Finding and Replacing Data

Data in tables can be found and, if desired, replaced with the Edit - Find, Edit - Find Next and Edit - Replace dialogs. These are very similar to the analogous dialogs in Microsoft Office applications. See the Finding / Replacing Data topic. For details on options in the Find and Replace dialogs, see the Edit - Find / Find Next and Edit - Replace topics.

Note: Manifold Find and Replace operate from the current record position forward to the end of the table. To being a search at the beginning of the table, press the Restart dialog in the Find or Replace dialogs.

Copying and Pasting Columns

Entire columns of data may be copied and pasted or copied and appended as new columns into tables.

Consider a table containing columns of data like the above. We would like to copy the contents of the SQMI column and paste it into another column. To do so, we first right click onto the column head for the SQMI column.

In the resulting context menu, we choose Copy.

Suppose we would like to paste the contents into the Square Miles column: we right click that column header...
... and in the resulting context menu we choose Paste.

<table>
<thead>
<tr>
<th>ID</th>
<th>SQMI</th>
<th>Square Miles</th>
<th>AUTO</th>
<th>BUSES...</th>
<th>Place_name</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>63068</td>
<td>63068</td>
<td>88881</td>
<td>1373</td>
<td>SAN LUIS POTOSI</td>
</tr>
<tr>
<td>2</td>
<td>73252</td>
<td>73252</td>
<td>52567</td>
<td>1400</td>
<td>ZACATECAS</td>
</tr>
<tr>
<td>3</td>
<td>125181</td>
<td>125181</td>
<td>68060</td>
<td>1401</td>
<td>DURANGO</td>
</tr>
<tr>
<td>4</td>
<td>192050</td>
<td>192050</td>
<td>172500</td>
<td>3004</td>
<td>SONORA</td>
</tr>
<tr>
<td>5</td>
<td>58328</td>
<td>58328</td>
<td>121750</td>
<td>3111</td>
<td>SINALOA</td>
</tr>
<tr>
<td>6</td>
<td>79384</td>
<td>79384</td>
<td>281275</td>
<td>3536</td>
<td>TAMAUHULAS</td>
</tr>
<tr>
<td>7</td>
<td>64524</td>
<td>64924</td>
<td>352345</td>
<td>4857</td>
<td>NUERO LEON</td>
</tr>
<tr>
<td>8</td>
<td>69201</td>
<td>69201</td>
<td>441081</td>
<td>2549</td>
<td>BAJA CALIFORNIA</td>
</tr>
<tr>
<td>9</td>
<td>73475</td>
<td>73475</td>
<td>45747</td>
<td>375</td>
<td>BAJA CALIFORNIA</td>
</tr>
<tr>
<td>10</td>
<td>69201</td>
<td>69201</td>
<td>441081</td>
<td>2549</td>
<td>BAJA CALIFORNIA</td>
</tr>
<tr>
<td>11</td>
<td>149982</td>
<td>149982</td>
<td>234115</td>
<td>4277</td>
<td>COAHUILA</td>
</tr>
</tbody>
</table>

The values from the SQMI column will be pasted into the Square Miles column.

Suppose that instead of choosing Paste in the context menu, we had right clicked onto Square Miles and had chosen Paste Append?

<table>
<thead>
<tr>
<th>ID</th>
<th>SQMI</th>
<th>Square Miles</th>
<th>AUTO</th>
<th>BUSES...</th>
<th>Place_name</th>
<th>SQMI 2</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>63068</td>
<td>0</td>
<td>88881</td>
<td>1373</td>
<td>SAN LUIS POTOSI</td>
<td>63068</td>
</tr>
<tr>
<td>2</td>
<td>73252</td>
<td>0</td>
<td>52567</td>
<td>1400</td>
<td>ZACATECAS</td>
<td>73252</td>
</tr>
<tr>
<td>3</td>
<td>125181</td>
<td>0</td>
<td>68060</td>
<td>1401</td>
<td>DURANGO</td>
<td>125181</td>
</tr>
<tr>
<td>4</td>
<td>192050</td>
<td>0</td>
<td>172500</td>
<td>3004</td>
<td>SONORA</td>
<td>192050</td>
</tr>
<tr>
<td>5</td>
<td>58328</td>
<td>0</td>
<td>121750</td>
<td>3111</td>
<td>SINALOA</td>
<td>58328</td>
</tr>
<tr>
<td>6</td>
<td>79384</td>
<td>0</td>
<td>281275</td>
<td>3536</td>
<td>TAMAUHULAS</td>
<td>79384</td>
</tr>
<tr>
<td>7</td>
<td>64524</td>
<td>0</td>
<td>352345</td>
<td>4857</td>
<td>NUERO LEON</td>
<td>64524</td>
</tr>
<tr>
<td>8</td>
<td>69201</td>
<td>0</td>
<td>441081</td>
<td>2549</td>
<td>BAJA CALIFORNIA</td>
<td>69201</td>
</tr>
<tr>
<td>9</td>
<td>73475</td>
<td>0</td>
<td>45747</td>
<td>375</td>
<td>BAJA CALIFORNIA</td>
<td>73475</td>
</tr>
<tr>
<td>10</td>
<td>69201</td>
<td>0</td>
<td>441081</td>
<td>2549</td>
<td>BAJA CALIFORNIA</td>
<td>69201</td>
</tr>
<tr>
<td>11</td>
<td>149982</td>
<td>0</td>
<td>234115</td>
<td>4277</td>
<td>COAHUILA</td>
<td>149982</td>
</tr>
</tbody>
</table>
In that case, a new column called SQMI 2 would have been created and the values from the SQMI column would have been pasted into that new column.

The above example shows copy and paste within the same table; however, Manifold also supports copy and paste of binary data in table columns through the Windows clipboard when other applications are used. For example, we can copy a column from an Excel spreadsheet and paste it into a Manifold table column.

**Using Regular Expressions**

Regular expressions are a concise and flexible notation for finding and replacing patterns of text and are used in the Find and Replace dialogs.

See the Regular expressions topic for information on using regular expressions. These are a much more sophisticated and flexible method than simply using the * and ? characters.

**Tech Tip: Changing Ordinary Fields in Tables does not Move Objects**

The positions of objects in drawings are embedded within the geometry of the drawing without need to have latitude and longitude values listed in a table. Sometimes we create drawings from geocoded tables that have a latitude and longitude for each record. We might wish to have the latitudes and longitudes that were used to position the points immediately at hand in the drawing’s table and so when pasting the geocoded table as a drawing we may tell Manifold to bring along the latitude and longitude fields along with the other fields.

Whatever the motive or process that was used to create a drawing, it is often the case that "latitude" and "longitude" numbers will be copied to fields in a table as well as being embedded within the geometry of a drawing. GIS beginners often mistakenly think that the positions of items in the drawing are determined from the listings of latitude or longitude fields in the table, so that editing these fields will move the objects. That's not the case.

We can use intrinsic fields to display in a table the actual latitudes and longitudes of objects associated with records. However, intrinsic fields are special, system-generated fields and are different than "latitude" and "longitude" fields we might bring into a table that are ordinary text or numeric fields. The rest of this topic explains why this is so.

Drawings are often created in Manifold from geocoded tables. A geocoded table is a table where each record has latitude and longitude fields that specify the location of that record.

Suppose we have an Access database that contains a list of towns together with their latitude and longitude coordinates:
We can import this Access table into a table in Manifold (either by importing the data or by linking to the external table):

To create a drawing from this table we use Edit - Copy to copy the table and then we use Edit - Paste As - Drawing in the project pane to create a new drawing based on the data in the table. Each geocoded record will appear as a point in the drawing.
We can combine this new drawing in a map together with a base map of the United States to see at a glance where the various points are located.

When we use the Edit - Paste As - Drawing command to create a new drawing, Manifold will automatically create the associated data attribute table for that drawing. By default, that new table will have at least one field, the object ID field. During the Paste As operation Manifold will give us the option of copying additional fields from the original table into the new data attribute table for the drawing. The dialog presents a list of check boxes for each field in the original table. We can copy any of the fields we desire.

For example, if our geocoded table is a list of customer records containing fields such as name, address, city, state, and so forth together with a latitude and longitude for each record, we might wish to copy the name, address and other informational fields. There is no particular technical reason to copy the latitude and longitude fields (these fields in the original table will be used automatically to position the points in the drawing for each record) but we can do so if for some reason we want to have this information in the table.

If we do copy the latitude and longitude fields into a table associated with the drawing, we will see them in the table window when the table is opened. It is very important to realize that these are just table fields that were copied from the original table. They are not a "handle" into the geometric coordinates that define the position of the points within the drawing's internal structure. Altering the values will not move the points, nor are the fields even necessary to keep the points "positioned" at the right spots.

<table>

</tr>
</tbody>
</table>

For example, in the Table window we could delete the "Longitude" field.
We could delete the "Latitude" field as well. If we do so the points do not magically disappear from the drawing. They will still be there. All that we have done is delete a field from the data table associated with the drawing. The points in the drawing have already been created when Manifold read the original database. Changing the text data in the table (either the original one or the new table created with the drawing) changes nothing about those points and does not alter the coordinate numbers inside the drawing.

The above discussion may seem obvious to experienced GIS users; however, for new users it is easy to look at a table full of records with latitude and longitudes and to forget that changing the values in the table does not actually move the points about.

Changing the Location of Points

How then can we change the actual location of points? There are three main ways:

- We can show the Latitude and Longitude intrinsic fields and then change their values. See Editing Intrinsic Fields in Tables. This is the best method when points must be moved to given coordinates.
- We can right click on individual points in the drawing and use the Object - Coordinates dialog to change the location of the geometric coordinates that define the points. This is a seriously tedious approach.
- We can use any one of a wide variety of interactive editing tools in a map or drawing window to move the points by selecting them and dragging them to a new location.

Note that neither of the above options will change the contents of any "latitude" or "longitude" text fields we might see in a table window.

Specifying Languages for Columns

Language specification in text columns varies depending on whether Unicode or ANSI text is used. Unicode text columns can simultaneously contain characters from more than one language. ANSI text columns are usually restricted to one language in addition to (possibly) English. Character data contained in an ANSI text column will be interpreted by the system according to the code page associated with that column.

By default, ANSI text columns use the system code page. If desired, any ANSI text column in a table can be set to use a different code page by right clicking on the column head and choosing Language.
Editing Intrinsic Fields in Tables
We can move objects in drawings by editing intrinsic fields in tables. Before proceeding with this topic, please take a moment to read:

- Intrinsic Fields in Tables
- Editing Data in Tables

Most intrinsic fields are read-only; however, intrinsic fields that report location coordinates may be edited. Changing a coordinate intrinsic field will move the associated object.

The relevant intrinsic fields are:

- **Geom (I)** The geometry data ("the object metric") that defines the position and shape of the object. Read/write. Modifying this column with, say, an UPDATE query, modifies the metric of the associated drawing objects. Setting Geom (I) to a NULL value or to a geometry value the type of which differs from that of the drawing object is not allowed.

- **X (I)** X coordinate of the center of the object in native units.

- **Y (I)** Y coordinate of the center of the object in native units.

- **Latitude (I)** Latitude of the center of the object.

- **Longitude (I)** Longitude of the center of the object.

The X and Y fields report the location of the object using native projection system coordinate units. If a drawing has been projected into some projection other than the Latitude / Longitude projection, these units will be the meter-based units used in that projection. Editing such coordinates is an expert-level task.

Most often we will edit the Latitude and Longitude fields, which report the position of the center of the object in ordinary latitude and longitude degrees. The usual task is to adjust the position of a point to match some specified location given in latitude and longitude degrees. For example, we may have a drawing representing a nautical chart that shows the position of various buoys. Perhaps we have checked the position of those buoys by visiting them and noting their actual location with a GPS and now we wish to adjust the buoy positions in the chart to match our measurements.

There are three main ways of editing intrinsic fields:

- Open the drawing's table, use View - Columns to show the desired intrinsic fields in the table and then edit them like any other field. This is a good method when many items are to be edited, or when other fields in the table (such as, perhaps, a "place name" field) will be used to identify which record is to be edited. This is also a good method when an object will be selected first so that it is obvious which record is to be edited.

- Right click on the object to be moved in the drawing and choose Object Fields context menu. Intrinsic fields will also appear in the Object Fields dialog. This is a good method when objects will be identified by their position.

- Use SQL with an UPDATE query or similar method to edit the Geom (I) intrinsic field. This topic does not cover the use of geoms and instead focuses on the above two methods. See the Geometry in Tables topic for details on working with geoms.

The first two methods are the most interactive for tasks such as adjusting the position of points. Which method is used will largely depend on which provides the easiest identification of the points to be moved. Some drawings may have many thousands of objects and so it is not always easy to find the right record to edit in a table.

**Latitude and Longitude Notation in Editing**

Manifold tables show latitude and longitude intrinsic fields using decimal degrees notation by default. When editing intrinsic fields, Manifold allows entry of values in either decimal or in degrees, minutes, seconds notation using almost any separator between the degrees, minutes and seconds values.
For example, if we want to enter a value of -122.55125 degrees we can double click into the Longitude (I) box and enter any of the following:

-122.55125
-122d33m4.5s
-122 33 4.5
-122°33'4.5"
122.55125W
W122d33m4.5s

Manifold will interpret any non-numeric character in between the numbers other than a decimal point as a separator between degrees, minutes and seconds values. The letters W and S either before or after the other characters are commands to make the value a negative (west) longitude or negative (south) latitude.

Note that case is significant in NESW notation, so that 22d33m4.5s would be a North (positive) latitude and 22d33m4.5S or 22d33m4.5sS would both be South (negative) latitudes.

Whatever notation style is used to enter the new value, it will be displayed using the column format specified for that column.

Moving Areas and Lines

The four coordinate intrinsic fields listed above report the center of the object. In the case of points, the center of the object is the same as the location of the point. Lines and areas, though, are usually defined by many coordinates, so the X, Y, Latitude and Longitude fields for lines and areas will report the centroid location of these objects. This is a considerably more abstract idea than the location of a point.

It's possible to move lines and areas by moving the "center" reported by intrinsic fields. Whatever changes in horizontal or vertical displacement are made will be applied to all of the coordinates defining the object. So, if we moved the center of an area Westward by one degree longitude then all of the coordinates defining the area would be moved Westward one degree.

This capability is less frequently used than moving points by specifying their location via intrinsic fields; however, changing the values of intrinsic fields can be a very handy way of "nudging" areas or lines horizontally or vertically into a desired location.

Objects like areas and lines as well as points can be altered in a mass way by using SQL with an UPDATE query or similar method to edit the Geom (I) intrinsic field. See the Geometry in Tables topic for details on working with geoms.

Native Coordinates

Native coordinates or native units are numbers stored within the drawing that Manifold uses internally as positional coordinates. These numbers are shown in the Object Coordinates dialog that pops up if you right-click an object and choose Coordinates. They are also used in the X (I) and Y (I) intrinsic field columns.

Projected coordinates are native coordinates adjusted with the local scale and local offset parameters of the coordinate system (projection) in use. In many cases, projected coordinates are the same as native coordinates (because of the local scale and offset values) but sometimes they are different.

Advanced Uses

Intrinsic fields can be used like other fields in a table. For example, we could compute altered latitude and longitude coordinates via an Active Column and then copy the Active Column into the Latitude and Longitude fields using the transform toolbar.

Enterprise Edition
When working with Enterprise Edition, editing an intrinsic field for a shared drawing will not be possible if the drawing and drawing table are both read-only. Check out the drawing and the table to edit intrinsic fields.

**See Also**

See the Add Points with Instant Data example topic for an example of moving points by editing intrinsic fields.

See the Geometry in Tables topic for details on working with geoms.
Regular Expressions

Regular expressions are a concise and flexible notation for finding and replacing patterns with the Edit - Find, Edit - Find Next and Edit - Replace dialogs. There are several different syntax styles used for regular expressions in computing. Manifold uses the regular expression syntax used in the Microsoft .NET framework, the latest edition of the Microsoft regular expression syntax familiar to many from Microsoft ActiveX scripting languages. Note that .NET introduces slight changes from the regular expression syntax used in both Jscript and VBScript. Microsoft regular expression syntax is very similar to that used in UNIX/Linux grep command. ("grep" = "global regular expression processor").

Special characters and sequences are used in writing patterns for regular expressions. The following table describes these characters and includes short examples showing how the characters are used.

<table>
<thead>
<tr>
<th>Character</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\</td>
<td>Marks the next character as either a special character or a literal. For example, &quot;n&quot; matches the character &quot;n&quot;, &quot;\n&quot; matches a newline character. The sequence &quot;\l&quot; matches &quot;\l&quot; and &quot;\t&quot; matches &quot;\t&quot;.</td>
</tr>
<tr>
<td>^</td>
<td>Matches the beginning of input.</td>
</tr>
<tr>
<td>$</td>
<td>Matches the end of input.</td>
</tr>
<tr>
<td>.</td>
<td>Matches any single character except a newline character.</td>
</tr>
<tr>
<td>(pattern)</td>
<td>Matches pattern and remembers the match. The matched substring can be retrieved from the resulting Matches collection, using Item [0]...[n]. To match parentheses characters ( ), use &quot;(&quot; or &quot;)&quot;.</td>
</tr>
<tr>
<td>x</td>
<td>y</td>
</tr>
<tr>
<td>n</td>
<td>is a nonnegative integer. Matches exactly n times. For example, &quot;o{2}&quot; does not match the &quot;o&quot; in &quot;Bob,&quot; but matches the first two o's in &quot;fooood&quot;.</td>
</tr>
<tr>
<td>{n}</td>
<td>n is a nonnegative integer. Matches at least n times. For example, &quot;o{2,}&quot; does not match the &quot;o&quot; in &quot;Bob&quot; and matches all the o's in &quot;foooood&quot;. &quot;o{1,}&quot; is equivalent to &quot;o+&quot;, &quot;o{0,}&quot; is equivalent to &quot;o*&quot;.</td>
</tr>
<tr>
<td>{n,m}</td>
<td>m and n are nonnegative integers. Matches at least n and at most m times. For example, &quot;o{1,3}&quot; matches the first three o's in &quot;fooood&quot;. &quot;o{0,1}&quot; is equivalent to &quot;o?&quot;.</td>
</tr>
<tr>
<td>[xyz]</td>
<td>A character set. Matches any one of the enclosed characters. For example, &quot;[abc]&quot; matches the &quot;a&quot; in &quot;plain&quot;.</td>
</tr>
<tr>
<td>[^xyz]</td>
<td>A negative character set. Matches any character not enclosed. For example, &quot;[^abc]&quot; matches the &quot;p&quot; in &quot;plain&quot;.</td>
</tr>
<tr>
<td>[a-z]</td>
<td>A range of characters. Matches any character in the specified range. For example, &quot;[a-z]&quot; matches any lowercase alphabetic character in the range &quot;a&quot; through &quot;z&quot;.</td>
</tr>
<tr>
<td>[^m-z]</td>
<td>A negative range characters. Matches any character not in the specified range. For example, &quot;[^m-z]&quot; matches any character not in the range &quot;m&quot; through &quot;z&quot;.</td>
</tr>
<tr>
<td>\b</td>
<td>Matches a word boundary, that is, the position between a word and a space. For example, &quot;er\d&quot; matches the &quot;er&quot; in &quot;never&quot;</td>
</tr>
</tbody>
</table>
but not the "er" in "verb".

\B Matches a nonword boundary. "ea*ri\B" matches the "ear" in "never early".

\d Matches a digit character. Equivalent to [0-9].

\D Matches a nondigit character. Equivalent to [^0-9].

\f Matches a form-feed character.

\n Matches a newline character.

\r Matches a carriage return character.

\s Matches any white space including space, tab, form-feed, etc. Equivalent to [ \f\n\r\t\v].

\S Matches any nonwhite space character. Equivalent to [^ \f\n\r\t\v].

\t Matches a tab character.

\v Matches a vertical tab character.

\w Matches any word character including underscore. Equivalent to [A-Za-z0-9_].

\W Matches any nonword character. Equivalent to [^A-Za-z0-9_].

\num Matches \num, where \num is a positive integer. A reference back to remembered matches. For example, "(\.)\1" matches two consecutive identical characters.

\n Matches \n, where \n is an octal escape value. Octal escape values must be 1, 2, or 3 digits long. For example, "\111" and "\011" both match a tab character. "\0011" is the equivalent of "\001" & "1". Octal escape values must not exceed 256. If they do, only the first two digits comprise the expression. Allows ASCII codes to be used in regular expressions.

\n Matches \n, where \n is a hexadecimal escape value. Hexadecimal escape values must be exactly two digits long. For example, "\x41" matches "A". "\x041" is equivalent to "\x04" & "1". Allows ASCII codes to be used in regular expressions.

For details on options in the Find and Replace dialogs, see the Edit - Find / Find Next and Edit - Replace topics.

Regular Expressions in Find and Replace

Regular expressions can be used in the Find box to find items and also in the Replace box to specify how they should be replaced. For example, Europeans will often denote decimal places with a comma instead of a period as is used in the US. This transformation can be easily done with a Replace command using regular expressions.

Strings like "101.999" can be transformed to "101,909" (comma instead of period) by supplying a Find string of \([0-9]{3}\).\([0-9]{3}\) and a Replace string of $1, $2.
Note that the above is a search and replace on a *string* (that is, a text) value. Changing the period or comma notation in numeric values is done in the Windows localization settings.

### Regular Expression Examples

The following examples list a regular expression in **bold face** that can be used to search for various patterns. Each regular expression is then followed by sample strings and whether or not the string would be OK in that regular expression or if it would fail the test posed by the regular expression.

These examples show how regular expressions can be used to find certain patterns. They do not purport to be definitive filters for the various examples given. For example, a rigorous filter for URLs would be a more complex regular expression than that that provided below since it would exclude characters such as # that are not allowed in domain names. The last example, for email addresses, shows a more robust regular expression that can be used as a true validation filter for acceptable email addresses.

Adding or Deleting Fields in Tables
Deleting a field from a table is easy: right click on the column header for the field to be deleted and choose Delete from the context menu.

Add a field by right clicking on any column head and choosing Add from the context menu. We can also add a field through the Table - Design dialog.
Changing Field Types in Tables
Change field types in tables between compatible types by using the Transform toolbar.

To change field types:

1. Open the table that contains the target records.
2. Right click onto the column head for the field that is to be changed and choose Change Type from the context menu.

Note that field type conversions are only possible between compatible types. Conversions are also subject to the limitations of their types. For example, any number can be converted into a text string but not every text string can be converted into a number.

Conversions between text strings and numbers will follow Microsoft conventions. For example, a text string such as "(254)" will be converted into -254, a negative number, since numbers in parentheses are normally used in accounting tables to indicate negative numbers.

Conversions can also alter data. For example, converting from a floating point number or a text string such as "3.1415" to an integer will round down to an integer value of 3 while copying a floating point number or a text string such as "3.6" will round up to 4. Rounding occurs, of course, because integers cannot show fractional values.

If Manifold's conversion routines cannot make sense of a requested conversion then no conversion will occur.

Example

We have a table with a field called Area Codes that is a text field. We wish to convert it to a numeric field. We first create a new integer field called temp in the Design dialog. Next, we use the transform tool bar loaded with:

Area Codes  Copy to  temp

Press Apply to copy the contents of the Area Codes column into the temp column. The transform Copy to operation will automatically translate field types on the fly between compatible types, so that text strings of the form "702" will be converted to the integer number 702.

We can now delete the original Area Codes column and rename the temp column to be called Area Codes.

Transform Toolbar - Tables

<table>
<thead>
<tr>
<th>Target box</th>
<th>Operation box</th>
<th>Source / Argument box</th>
</tr>
</thead>
<tbody>
<tr>
<td>Discount</td>
<td>Acid</td>
<td>.05</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Apply</td>
</tr>
</tbody>
</table>

The Transform toolbar makes changes to an entire column (field) throughout the table. If a selection is present it will operate only on those records in the selection. If no selection is present it will apply to all records in the table.

The Transform toolbar consists of three boxes, from left to right: a target box, the operation box, and a source / argument box.

Target box Also known as the scope box. The column that will be affected, altered or which will control the operation. The target box will be pre-loaded with the names of all fields in the table. The illustration above shows the Discount field has been chosen.
### Operation box

The function to be applied. The operation box is context sensitive and will show only those operations that make sense for the field type of the target column. For example, arithmetic operations such as **Add** will only be enabled for numeric fields.

### Source / Argument box

The value to be used. Depending on the operator, this may be another column or a value entered by the user. A few operators (such as **Clear**) do not require a source or argument. The source / argument box will not be enabled for such operators. The illustration above shows we have entered `.05` as a value in the source / argument box.

We use **dark blue**, **black**, and **violet** bold face fonts in this topic to distinguish the three boxes to make examples and explanation more clear. In real life Manifold uses the same black font color in all three Transform toolbar boxes.

### Using the Transform toolbar

1. Open the table that contains the target records.
2. Make a selection if the operation is to be applied just to the selection.
3. Choose the target column in the target box.
4. Choose the desired operator in the operation box.
5. Choose or specify a value in the source / argument box, if this operation requires it.
6. Press **Apply**.

### Target box

The left-most box specifies the target field. This is the column that will be affected, altered or which will control the operation. Choosing the name of a column will apply the Transform function to only that field. The example above shows we will apply the Transform function to the **Discount** column in the table. If a selection is present then whatever operation we apply with the Transform toolbar will act only on those records that are part of the current selection. If no selection is present the transform operation will apply to all records in the table.

Note that the function of the leftmost box is slightly different when the Transform toolbar is used with tables as compared to images or drawings. The target box with tables is used to specify the name of a column to which the function should be applied. The scope (that is, all records or only the selection) is automatic based on whether there is a selection present or not.

With images and drawings the leftmost box is known as a **target box** and is just an information box. It is automatically loaded with the scope (all objects/pixels, or the selection, if one is present) based on whether there is a selection present or not.

### Operation box

Choose a function from the long list of operators available in the operation box. The example shows **Add**, which is enabled for numeric fields and which adds the value in the source / argument box to all values in the target column. The Transform Operators - Tables topic lists operators available for use with tables.

### Source / argument box

`.05`
Some operators do not require any parameters. For these functions the source / argument box will be disabled. Other functions will require specification of an additional parameter. This may be another column (such as the choices in the target box), or it could be a parameter that is entered by the user as illustrated above. To enter a parameter, click into the source / argument box, enter the value using the keyboard and then press Enter.

Examples

[Discount] Add .05 - Add .05 to the value in the Discount field. (Sounds like we're giving everyone an additional 5% off!)

[Elevation] Multiply by .3048 - Multiply all values in the Elevation field by .3048 (Clearly, we are converting a database of elevations given in feet into meters).

[Elevation] Multiply by [Offset] - For each record, take the value of the Elevation field in that record and multiply it by the value of the Offset field in that record and put the result into the Elevation field.

Type Conversions and Compatibility

There are four field type families in Manifold tables for transform toolbar purposes:

- **Date** - Date and time field type.
- **Numeric** - Currency, integer, floating-point, latitude and longitude field types.
- **Percentage** - Percentage field type.
- **Text** - Text and URL field types.

Manifold will automatically convert types on the fly when copying from one data type to a compatible data type using transform operators. Within the same field type family most operations will be performed automatically with few issues other than the most obvious: floating point numbers will be rounded when converted into integers.

When using transform operators between fields of different types not all conversions are possible, since not all data can exist in compatible forms for all data types. For example a text field can contain text values like "123" and "1984" that can be converted into numbers; however, spelled out numbers like "one two three" and mixed values like "43-B5" cannot be converted into numbers. If we copy values like "43-B5" from a text column into an integer column the result will be zero. Manifold will do the best job possible given standard type conversion conventions as applied within Windows Visual C++ and Visual Basic programming.

A few operators don’t make sense unless the field types in the target box and the source / argument box are in the same field type family. These are the homogeneous statistic functions (impress your friends with that nomenclature!): Fill with Maximum, Fill with Minimum, Fill with Median, Make at Least and Make at Most. For these transform operators the target box and the source / argument box fields must be of the same field type. For example, one cannot take a text field and use Make at Least to make it at least like the contents of an Integer field. As a theoretical matter, Manifold could have been internally arranged to make conversions on the fly in a way that would have allowed these functions to have been applied in one step between incompatible field type families. As a practical matter doing so would have involved numerous operational subtleties that are very difficult for most people to understand on the fly.

Instead, such functions are applied between different field type families using a two step process: The correct way to apply a homogeneous statistic function between fields from different field type families is to first make a conversion using a copy and then to apply the statistic function. For example, to apply Make at Least to a text field based on an integer field, first apply Make at Least between the integer field into another integer field and then copy the value of that integer field into the target text field.
Transform Operators - Tables

When used with tables, the Transform Toolbar provides numerous functions for use with fields of various types.

The leftmost box in the Transform toolbar is the Target box. The rightmost box is the Source / argument box. Some operators require choice of a field in the source / argument box while other operators allow either a value entered by the user or choice of a field.

The list of operators in the operation box will vary depending on the type of field chosen in the Target box. For example, Round, Round Up, and Round Down will be listed in available operators only with float or double types and not with integers. Conversely, the Binary And and similar operators will not be listed with float types because these are bitwise operators that make sense only with integers.

When working with tables, it is at times important to know what data type each field is. For example, the value 486 could either be an integer type or it could be a text string consisting of the characters "4", "8" and "6". When working with a column that contains such values, if the operators you expect to see are not there remember to double-check the field type in case it is different than expected.

Some operators that appear to be numeric in character will appear with text fields. Such operators will place their resulting numbers into the text field as a string.

With text fields, "values" mean text strings or characters. All characters are taken literally. "Maximum" and "minimum" functions employ lexicographic arithmetic taking the order of characters in the character set as the numeric value of the character.

Tokens are explained in the Transform - Using Tokens and Text Strings topic.

Date / Time Decrement and Increment Operations

Manifold System date-time operations will automatically "rollover" when incrementing or decrementing. For example, if the Inc Minute command is applied to a time of 2:59 the result will be 3:00. Applying the Dec Minute command to 3:00 will result in 2:59.

Impossible Operations Ignored

Manifold has a simple way of dealing with impossible operations such as division by zero. All such operations are ignored and any records that would be subject to such operations are left unchanged. It is therefore important when using operations such as Divide by to first check the parameter involved (say, by sorting on that column) to see if there are any zero values.

Span Excluding / Including Operators

See the topic Transform - Span Excluding / Including for discussion and examples.

Date/Time and URL Fields have Subparts Called "Sections"

A Date/Time field may be subdivided into subparts such as, for example, the hour, minutes and seconds value of the time. These subparts are called sections. Likewise, the date part of a Date/Time field has sections such as the year, month and day. URL fields also have sections such as the object, parameters, port, protocol and server.

Any operator that works on date/time or URL field sections will apply only to that section. So, for example, using Copy Year from with Date time fields in both the target box and the source / argument box will copy only the year from the parameter date field to the target box's year section.

The only two exceptions to the above are the Copy Month Name From and Copy Weekday Name From operators, which can only copy from a date time field section to a text field or a URL section. The reason is that these operators convert date/time data into a name, such as "Tuesday", which is a one-way conversion. Any particular date can unambiguously be converted into a day of the week; however, simply knowing a day is "Tuesday" does not pick out unambiguously a calendar date.
**Text Operators**

- **Append** Append given text or field to original field.
- **Clear** Clear all values in Field.
- **Copy Day Name from** Examine the date/time in the Parameter field and copy the name of the day to Field using local language settings.
- **Copy First Token from** Copy the first token from Parameter into the Field. If Parameter contains John/Paul/George/Ringo the result would be to copy John into Field.
- **Copy from** Copy the value from the Parameter into the Field.
- **Copy Last Token from** Copy the last token from Parameter into the Field. If Parameter contains John/Paul/George/Ringo the result would be to copy Ringo into Field.
- **Copy Month Name from** Examine the date/time in the Parameter field and copy the name of the month to Field using local language settings.
- **Copy URL Object from** Copy main part of URL field.
- **Copy URL Parameters from** Copy query parameters, if any, in URL.
  - Example: "\texttt{?pq=q\&sc=on}\" from http://www.mydomain.com/cgi-bin/query?pg=q&sc=on
- **Copy URL Port from** Return port, if used, from URL string.
- **Copy URL Protocol from** Return protocol used by the URL.
  - Example: "\texttt{http://}\" from http://www.manifold.net
- **Copy URL Server from** Return the server from the URL: Eg: "\texttt{www.manifold.net}\" from http://www.manifold.net/news/news.html
- **Decode with** Decrypt Field using a password given in Parameter.
- **Delete Containing** Clear values in original field that contain the given text or field.
- **Delete Containing Match** Clear all values that contain a match to the given regular expression pattern.
- **Delete Containing Token** Clear all values that contain the given token.
- **Delete Ending with** Clear values in original field that end with the given text or field.
- **Delete Ending with Match** Clear all values that end with a match to the given regular expression pattern.
- **Delete Ending with Token** Clear all values that end with the given token.
- **Delete First Token** Delete the first token in the Field together with the separator (if any) following it. If applied to John/Paul/George/Ringo the result would be Paul/George/Ringo.
<table>
<thead>
<tr>
<th><strong>Delete Last Token</strong></th>
<th>Delete the last token in the Field together with the separator (if any) preceding it. If applied to John/Paul/George/Ringo the result would be John/Paul/George.</th>

<tr>
<td><strong>Leave Ending with Token</strong></td>
<td>Clear all values except those that end with the given token.</td>
</tr>
<tr>
<td><strong>Leave Left</strong></td>
<td>Clip all text from the Field except the first n characters, where n is a number specified by the value given in the Source / argument box.</td>
</tr>
<tr>
<td><strong>Leave Matching</strong></td>
<td>Clear all values except those that match the given regular expression pattern.</td>
</tr>
</tbody>
</table>
Leave Right  Clip all text from the Field except the last \( n \) characters, where \( n \) is a number specified by the value given in the Source / argument box.

Leave Sounding Like  Clear all values except those that sound like the given word. Not for the faint of heart. A better idea is to use a viewbot to select all that sound like the given word and then take a look at the selection, invert the selection and then delete.

Leave Starting with  Clear all values in original field that do not start with the given text or field.

Leave Starting with Match  Clear all values except those that start with a match to the given regular expression pattern.

Leave Starting with Token  Clear all values except those that start with the given token.

Make Lower Case  Convert all characters in the Field to lower case.

Make Sentence Case  Capitalize first character in sentences. Example: "small green tree" becomes "Small green tree"

Make Title Case  Capitalize first character in words. Example: "small green tree" becomes "Small Green Tree"

Make Upper Case  Convert all characters in the Field to upper case.

Prepend  Prepends given text or field to original field.

Reverse  Reverses the order of characters in the Field.

Reverse by Tokens  Reverses the order of tokens in the Field. If applied to John/Paul/George/Ringo the result would be Ringo/George/Paul/John.

Reverse Token at  Take the token in the Field at the position given by the number in the value box and reverse its characters. If applied to John/Paul/George/Ringo with a value of 3 would result in John/Paul/egroeG/Ringo.

Span Excluding  Start at the first character in the Field and see if it occurs anywhere in the text string in the Source / argument box. If it does not occur, continue to the next character and see if it occurs in the text string in the Source / argument box. Continue until a character is encountered that is in the text string in the Source / argument box and stop. Take the characters checked thus far in order and place them in the Field. Order in the Field is preserved, while the order of characters in the text string in the Source / argument box or field does not matter.

Span Including  Start at the first character in the Field and see if it occurs anywhere in the text string in the Source / argument box or field. If it does occur, continue to the next character and see if it occurs in the text string in the Source / argument box and stop. Take the characters found thus far in order and place them in the Field. Order in the Field is preserved, while the order of characters in the text string in the Source / argument box or field does not matter.

Toggle Case  Swap upper case for lower case throughout the text.

Trim  Remove leading and trailing separator characters (whitespace, by default) from the Field.

Trim Left  Remove leading separator characters (whitespace, by default) from the Field.
The **Span Including** and **Span Excluding** operators are easier to use than their technical description makes it seem. Both chop up a string at a given cut point and return all characters encountered before the cut point. The difference is in how the operators specify the cut point.

The **Including** version cuts off the string as soon as it finds a character **not** in the set of characters given in the Source / argument box.

The **Excluding** version cuts off the string as soon as it finds a character in the set of characters given in the Source / argument box.

For example, suppose we want to cut a string at the first non-numeric character. We would use **Span Including** and provide the characters `1234567890` in the Source / argument box and each string would be cut as soon as a non-numeric character is encountered. For example, the string `123 Main St` would be cut right after the `123` and the operator would return the value `123`.

Suppose we want to cut a string at the first numeric character encountered. We would use **Span Excluding** and again provide the characters `1234567890` in the Source / argument box and each string would be cut as soon as a numeric character is encountered. For example, the string `Cambridge, MA 02138` would be cut right before the `0` character and the operator would return the value `Cambridge, MA` complete with trailing space character.

There are two **Span** operators because sometimes it is more convenient to specify what you are looking for and sometimes it is more convenient to specify what you do not want. For example, there are fewer numeric characters than non-numerics so if you are looking for non-numerics it is easier to supply a short list of numbers than a very long list of all other characters.

The **Trim** operators remove characters listed in the Tool Properties pane’s list of token separators. By default, these are the “white space” characters consisting of the space character, tab, newline and carriage return. Note that adding any other characters to the separator list in Tool Properties will subject them to removal as well if they occur as leading or trailing characters.

### Integer Operators

- **Add**
  Add Parameter field or value to the Field for each record.

- **Arithmetic Series**
  Fill Field with an arithmetic series from first record to last computed using the value **n** given in the Source / argument box for each step. If **n** = 5, Field will contain 0, 5, 10, 15, 20... series values in records from top to bottom.

- **Binary And with**
  Performs bitwise AND operation on Field and given Parameter value or field, and stores the result in the Field.

- **Binary Not**
  Performs bitwise NOT operation on Field. This is a binary inversion: all 0’s become 1’s and all 1’s become 0’s.

- **Binary Or with**
  Performs bitwise OR operation on Field and given Parameter value or field.

- **Binary Xor with**
  Performs bitwise XOR operation on Field and given Parameter value or field.

- **Clear**
  Delete all values in Field.

- **Copy Day from**
  Examine the date/time in the Parameter field and copy the day number (as the day number in the month) to Field.

- **Copy Day of Week from**
  Examine the date/time in the Parameter field and copy the day number (as the day number in the week) to
Copy Day of Year from
Examine the date/time in the Parameter field and copy the day number (as the day number in the year) to Field.

Copy from
Copy values from the given Parameter field to Field.

Copy Hour from
Examine the date/time in the Parameter field and copy the hour number (as the hour number in a 24 day) to Field.

Copy Leap Year Flag from
Examine a date/time field in the Parameter field, determines whether or not each date value falls on a leap year, and copies the result (0 or 1) into Field, which should be a numeric or Boolean field.

Copy Minute from
Examine the date/time in the Parameter field and copy the minute number (as the minute number in an hour) to Field.

Copy Month from
Examine the date/time in the Parameter field and copy the month number (as the month number in a year) to Field.

Copy Percentage from
Sum values in Parameter field and then for each record take the Parameter field’s value as a percentage of the total and copy into Field.

Copy Record Deviation from
Find the median of all Parameter values and then for each record place in Field the deviation from that median for the particular Parameter value of that record.

Copy Record Variation from
Find the median of all Parameter values and then for each record place in Field the variation from that median for the particular Parameter value of that record.

Copy Running Product from
For each record in the sort order, form a product of Parameter field with the cumulative product of multiplying Parameter field from previous records. Place the result in the current record’s Field.

Copy Running Sub from
For each record in the sort order, subtract Parameter field from the cumulative total of subtracting Parameter field from previous records. Place the result in the current record’s Field.

Copy Running Total from
For each record in the sort order, add Parameter field to the cumulative total of subtracting Parameter field from previous records. Place the result in the current record’s Field.

Copy Second from
Examine the date/time in the Parameter field and copy the second number (as the second number in a minute) to Field.

Copy Week from
Examine the date/time in the Parameter field and copy the week number (as the week number in a 52-week year) to Field.

Copy Year from
Examine the date/time in the Parameter field and copy the year number to Field.

Divide by
Divides Field by the given Parameter value or field. Division by zero results in no change to Field for those records.

Fill with
Fill the Fields of all records with what is in the Parameter. Equivalent to "Copy from" the Parameter value or field.

Fill with Average of
Examine Parameter field values and copy average of
<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Fill with Excess of</td>
<td>Examine Parameter field values and copy excess of these to Field for all records.</td>

<tr>
<td>Fill with Variance of</td>
<td>Examine Parameter field values and copy variance of these to Field for all records.</td>
</tr>
<tr>
<td>Geometric Series</td>
<td>Fill Field with a geometric series from first record to last computed using the value n given in the Source / argument box for each step. If n = 2, Field will contain 1, 2, 4, 8, 16, 32 ...series values in records from top to bottom.</td>
</tr>
<tr>
<td>Logical And with</td>
<td>Places a 0 or a 1 in the Field based on logical AND with the field or value specified in the Source / argument box. Any nonzero value counts as a 1 for the AND operation.</td>
</tr>
<tr>
<td>Logical Not</td>
<td>If the Field contains 0, it is made a 1. If it contains any nonzero value it is made a 0.</td>
</tr>
<tr>
<td>Logical Or with</td>
<td>Places a 0 or a 1 in the Field based on logical OR with the field or value specified in the Source / argument box. Any nonzero value counts as a 1 for the OR operation.</td>
</tr>
<tr>
<td>Logical Xor with</td>
<td>Places a 0 or a 1 in the Field based on logical XOR with the field or value specified in the Source / argument box. Any nonzero value counts as a 1 for the XOR operation.</td>
</tr>
<tr>
<td>Make Absolute</td>
<td>Take absolute value of the Field and place it in the Field.</td>
</tr>
<tr>
<td>Make at Least</td>
<td>Resets all values in the Field which are lower than the field or value specified in the Parameter box to the field or value specified in the Parameter box. A lower bound clipping function controlled by the field or value specified in the Parameter box.</td>
</tr>
<tr>
<td>Make at Most</td>
<td>Resets all values in the Field which are higher than the field or value specified in the Parameter box to the field or value specified in the Parameter box. An upper bound clipping function controlled by the field or value specified in the Parameter box.</td>
</tr>
<tr>
<td>Modulo</td>
<td>Replace the Field with Field modulo value or field given in the Source / argument box.</td>
</tr>
<tr>
<td>Multiply by</td>
<td>Multiplies Field by given field or value in Source / argument box.</td>
</tr>
</tbody>
</table>
Negate  Multiply Field by -1 (switches sign).

Power to  Raise Field value to the power specified by the given Parameter value or field.

Square  Replace Field with square of Field.

Square Root  Replace Field with square root of Field.

Subtract  Subtracts the field or value specified in the Source / argument box from the Field.

Floating Point Operators

Add  Add Parameter field or value to the Field for each record.

Arc Cosine  Replace Field with arc cosine of Field.

Arc CoTangent  Replace Field with arc cotangent of Field.

Arc Sine  Replace Field with arc sine of Field.

Arc Tangent  Replace Field with arc tangent of Field.

Arithmetic Series  Fill Field with an arithmetic series from first record to last computed using the value n given in the Source / argument box for each step. If n = 5, Field will contain 0, 5, 10, 15, 20... series values in records from top to bottom.

Clear  Delete all values in Field.

Copy Day from  Examine the date/time in the Parameter field and copy the day number (as the day number in the month) to Field.

Copy Day of Week from  Examine the date/time in the Parameter field and copy the day number (as the day number in the week) to Field.

Copy Day of Year from  Examine the date/time in the Parameter field and copy the day number (as the day number in the year) to Field.

Copy from  Copy values from the given Parameter field to Field.

Copy Hour from  Examine the date/time in the Parameter field and copy the hour number (as the hour number in a 24 day) to Field.

Copy Leap Year Flag from  Examine a date/time field in the Parameter field, determines whether or not each date value falls on a leap year, and copies the result (0 or 1) into Field, which should be a numeric or Boolean field.

Copy Minute from  Examine the date/time in the Parameter field and copy the minute number (as the minute number in an hour) to Field.

Copy Month from  Examine the date/time in the Parameter field and copy the month number (as the month number in a year) to Field.

Copy Percentage from  Sum values in Parameter field and then for each record take the Parameter field's value as a percentage of the total and copy into Field.

Copy Record Deviation from  Find the median of all Parameter values and then for each record place in Field the deviation from that median for the particular Parameter value of that
Copy Record Variation from
Find the median of all Parameter values and then for each record place in Field the variation from that median for the particular Parameter value of that record.

Copy Running Product from
For each record in the sort order, form a product of Parameter field with the cumulative product of multiplying Parameter field from previous records. Place the result in the current record's Field.

Copy Running Sub from
For each record in the sort order, subtract Parameter field from the cumulative total of subtracting Parameter field from previous records. Place the result in the current record's Field.

Copy Running Total from
For each record in the sort order, add Parameter field to the cumulative total of subtracting Parameter field from previous records. Place the result in the current record's Field.

Copy Second from
Examine the date/time in the Parameter field and copy the second number (as the second number in a minute) to Field.

Copy Week from
Examine the date/time in the Parameter field and copy the week number (as the week number in a 52-week year) to Field.

Copy Year from
Examine the date/time in the Parameter field and copy the year number to Field.

Cosine
Replace Field with cosine of Field.

CoTangent
Replace Field with cotangent of Field.

Decimal Fraction
Replace Field with trailing decimal values of Field. 3.1415 would be replaced by 0.1415.

Divide by
Divides Field by the given Parameter value or field. Division by zero results in no change to Field for those records.

Exponentiate
Raise \( e \) to the power of the Field and place the result in the Field. (A true mathematician’s exponentiation)

Fill with
Fill the Fields of all records with what is in the Parameter. Equivalent to "Copy from" the Parameter value or field.

Fill with Average of
Examine Parameter field values and copy average of these to Field for all records.

Fill with E
Fill with \( e \), that is, 2.7182818285

Fill with Excess of
Examine Parameter field values and copy excess of these to Field for all records.

Fill with Maximum of
Examine Parameter field values and copy maximum of these to Field for all records.

Fill with Median of
Examine Parameter field values and copy median of these to Field for all records.

Fill with Minimum of
Examine Parameter field values and copy minimum of these to Field for all records.

Fill with Pi
Fill with \( \pi \), that is, 3.14159265359

Fill with Random
Fill Field with random numbers.

Fill with Skewness of
Examine Parameter field values and copy skewness of
these to Field for all records.

**Fill with StdDeviation of** Examine Parameter field values and copy standard deviation of these to Field for all records.

**Fill with Sum of** Examine Parameter field values and copy sum of these to Field for all records.

**Fill with Variance of** Examine Parameter field values and copy variance of these to Field for all records.

**Geometric Series** Fill Field with a geometric series from first record to last computed using the value n given in the Source / argument box for each step. If n = 2, Field will contain 1, 2, 4, 8, 16, 32 ...series values in records from top to bottom.

**Invert** Replace Field with (1 / Field). No change if Field contains zero.

**Logarithm (Binary)** Replace the value of the Field with the base 2 logarithm of that value.

**Logarithm (Decimal)** Replace the value of the Field with the base 10 logarithm of that value.

**Logarithm (Natural)** Replace the value of the Field with the natural logarithm of that value.

**Logarithm by** Replace the value of the Field with the logarithm of that value taken to base given in the Parameter field.

**Make Absolute** Take absolute value of the Field and place it in the Field.

**Make at Least** Resets all values in the Field which are lower than the field or value specified in the Parameter box to the field or value specified in the Parameter box. A lower bound clipping function controlled by the field or value specified in the Parameter box.

**Make at Most** Resets all values in the Field which are higher than the field or value specified in the Parameter box to the field or value specified in the Parameter box. An upper bound clipping function controlled by the field or value specified in the Parameter box.

**Modulo** Replace the Field with Field modulo value or field given in the Source / argument box.

**Multiply by** Multiplies Field by given field or value in Source / argument box.

**Negate** Multiply Field by -1 (switches sign).

**Power to** Raise Field value to the power specified by the given Parameter value or field.

**Round** Return the largest integer that is less than or equal to .5 + the value.

**Round Down** Returns the largest integer that is less than or equal to the value.

**Round Up** Returns the smallest integer that is greater than or equal to the value.

**Sine** Replace Field with sine of Field.

**Square** Replace Field with square of Field.

**Square Root** Replace Field with square root of Field.
### Subtract
Subtract the field or value specified in the Source / argument box from the Field.

### Tangent
Replace Field with tangent of Field.

### Date / Time Operators

<table>

<td>Decrement year by one in the date-time field.</td>
</tr>
<tr>
<td>Fill with</td>
<td>Fill the Fields of all records with what is in the Parameter. Equivalent to “Copy from” the Parameter value or field.</td>
</tr>
</tbody>
</table>
Fill with Maximum of Examine Parameter field values and copy maximum of these to Field for all records.

Fill with Median of Examine Parameter field values and copy median of these to Field for all records.

Fill with Minimum of Examine Parameter field values and copy minimum of these to Field for all records.

Increase Day by Increment day by one (with rollover) in the date-time field.

Increase Hour by Increment hour by one (with rollover) in the date-time field.

Increase Minute by Increment minute by one (with rollover) in the date-time field.

Increase Month by Increment month by one (with rollover) in the date-time field.

Increase Second by Increment second by one (with rollover) in the date-time field.

Increase Week by Increment week (with rollover) by one in the date-time field.

Increase Year by Increment year by one in the date-time field.

Make at Least Resets all values in the Field which are lower than the field or value specified in the Parameter box to the field or value specified in the Parameter box. A lower bound clipping function controlled by the field or value specified in the Parameter box.

Make at Most Resets all values in the Field which are higher than the field or value specified in the Parameter box to the field or value specified in the Parameter box. An upper bound clipping function controlled by the field or value specified in the Parameter box.

**Percentage Operators**

**Clear** Delete all values in Field.

**Copy from** Copy values from the given Parameter field to Field.

**Copy Percentage from** Sum values in Parameter field and then for each record take the Parameter field's value as a percentage of the total and copy into Field.

**Fill with** Fill the Fields of all records with what is in the Parameter. Equivalent to "Copy from" the Parameter value or field.

**Fill with Average of** Examine Parameter field values and copy average of these to Field for all records.

**Fill with Maximum of** Examine Parameter field values and copy maximum of these to Field for all records.

**Fill with Median of** Examine Parameter field values and copy median of these to Field for all records.

**Fill with Minimum of** Examine Parameter field values and copy minimum of these to Field for all records.

**Fill with Random** Fill Field with random numbers.
Logical And with Places a 0 or a 1 in the Field based on logical AND with the field or value specified in the Source / argument box. Any nonzero value counts as a 1 for the AND operation.

Logical Not If the Field contains 0, it is made a 1. If it contains any nonzero value it is made a 0.

Logical Or with Places a 0 or a 1 in the Field based on logical OR with the field or value specified in the Source / argument box. Any nonzero value counts as a 1 for the OR operation.

Logical Xor with Places a 0 or a 1 in the Field based on logical XOR with the field or value specified in the Source / argument box. Any nonzero value counts as a 1 for the XOR operation.

Make at Least Resets all values in the Field which are lower than the field or value specified in the Parameter box to the field or value specified in the Parameter box. A lower bound clipping function controlled by the field or value specified in the Parameter box.

Make at Most Resets all values in the Field which are higher than the field or value specified in the Parameter box to the field or value specified in the Parameter box. An upper bound clipping function controlled by the field or value specified in the Parameter box.

URL Operators

Append Appends given text or field to original field.

Clear Clear all values in Field.

Copy Day Name from Examine the date/time in the Parameter field and copy the name of the day to Field using local language settings.

Copy First Token from Copy the first token from Parameter into the Field. If Parameter contains John/Paul/George/Ringo the result would be to copy John into Field.

Copy Month Name from Examine the date/time in the Parameter field and copy the name of the month to Field using local language settings.

Copy URL Object from Copy main part of URL field.

Copy URL Parameters from Copy query parameters, if any, in URL.
Example: "?pg=q&sc=on" from http://www.mydomain.com/cgi-bin/query?pg=q&sc=on

Copy URL Port from Return port, if used, from URL string.
Copy URL Protocol from
Return protocol used by the URL.
Example: "http://" from
http://www.manifold.net

Copy URL Server from
Return the server from the URL. Eg:
"www.manifold.net" from

Decode with
Decrypt Field using a password given in Parameter.

Delete Containing
Clear values in original field that contain the given text or field.

Delete Containing Match
Clear all values that contain a match to the given regular expression pattern.

Delete Ending with
Clear values in original field that end with the given text or field.

Delete Ending with Match
Clear all values that end with a match to the given regular expression pattern.

Delete First Token
Delete the first token in the Field together with the separator (if any) following it. If applied to John/Paul/George/Ringo the result would be Paul/George/Ringo.

Delete Last Token
Delete the last token in the Field together with the separator (if any) preceding it. If applied to John/Paul/George/Ringo the result would be John/Paul/George.

Delete Left
Delete the first n characters of the original field, where n is a number specified by the given numeric field or value.

Delete Matching
Clear all values that match the given regular expression pattern.

Delete Right
Delete the last n characters of the original field, where n is a number specified by the given numeric field or value.

Delete Sounding Like
Clear all values that sound like the given word. Requires a lot of faith in the Soundex algorithm. A better idea is to use a viewbot to select all that sound like the given word and then take a look at the selection before deleting.

Delete Starting with
Clear values in original field that start with the given text or field.

Delete Starting with Match
Clear all values that start with a match to the given regular expression pattern.

Delete Starting with Token
Clear all values that start with the given token.

Encode with
Encrypt Field using a password given in Parameter. Caution: don't "Encode" a field twice by accident!

Fill with
Fill the Fields of all records with what is in the Parameter. Equivalent to "Copy from" the Parameter value or field.

Fill with Maximum of
Find the "maximum" value that occurs in Parameter field using lexicographic arithmetic and copy it to the Field.

Fill with Median of
Find the "median" value that occurs in Parameter field using lexicographic arithmetic and copy it to the Field.

*Transform - Using Tokens and Text Strings*
Transform - Using Tokens and Text Strings
This topic explains the use of Tokens with text operators.

A token is one or more characters that is found in a text field between token separator characters. Any character may be specified as a token separator character in the Tool Properties pane. By default, a variety of brackets and other punctuation marks are listed as token separators. For example, the semicolon (;) character is listed as a token separator by default. If you don't like the default list of token separators, you can specify your own separators by entering them into the Separate tokens with box in the Tool Properties pane.

Using the default token separator characters, the string John;Paul;George;Ringo would contain the tokens "John", "Paul", "George", and "Ringo". If this string occurred in a field in the value box, the text operator Copy First Token to would copy the string John into the subject field.

Suppose we have a table where dates are stored as text strings in the form 09/21/98 and we wish to extract separate month, day and year fields. Or, perhaps we have a table that stores text strings in the US format of month/day/year and we wish to convert to European format of day/month/year. Or, perhaps we wish to extract the year field so we can prepend a "20" to year dates such as "00" and "01". All of these cases can be managed using a slash (/) character as a token separator. In this case, the string 09/21/98 would consist of three tokens, "09", "21" and "98". (Note that if the data were stored as a Microsoft Access Date field, we could use Copy Day To and similar Commander operators to extract the date, year, etc.)

Token separators may be combined. Order is not significant. A token is parsed as one or more characters between any two (or preceding or following at the beginning and end of the string) characters listed as a token separator in the Options dialog. Extra token separators are ignored when they occur together.

So, if / and * are listed as token separators, /John*/Paul*/George*Ringo is still parsed as the Fab Four tokens. Constructions such as 30°42'13.0" can be parsed as three separate tokens if the *, ', and " characters are listed as token separators.

Caution: If we wish to parse as a single token numeric values that are written as strings using a decimal point, we must make sure to remove the period, ., from the list of token separators if we have added it to the list as a token separator. Otherwise, text strings such as "3.1415" will get parsed as two tokens, "3" and "1415"

Tip: how to extract the "nth" token? Repeatedly use the Move First Token To command n times to get to the nth token. For example, suppose we have a field called location that contains values in the form 30°42'13.0" and we wish to extract this information into three separate fields called degrees, minutes, and seconds. We would perform the following commands, where the Target box is in blue, the operator is in black and the source / argument box is in violet.

location Move first token to degrees
location Move first token to minutes
location Move first token to seconds

Tip: Don't be intimidated by the use of tokens. It's a lot easier than it appears from the above. Just dig in and try a few examples. Also, don't hesitate to change the characters listed in the Tool Properties pane as token separators. One often wishes to use only a single character as a token separator. This takes but a moment to change to suit any need.

See the Extract Last Names using Tokens example for a simple step-by-step procedure using tokens.
Transform - Span Excluding / Including

These functions in the Transform Toolbar for Tables are similar to the programming functions of the same name. They are simple to use even though they often seem too complex to learn. These examples show the Target box contents in blue, the operator in black and the Source / argument box contents in violet.

Span Excluding keeps going on until it finds something that is supposed to be excluded and then it stops. Span Including keeps going on as long as it keeps finding things that are supposed to be included. If it finds something not in the included list, it stops. A simple example that uses these functions to extract numbers from a text list of latitudes and longitudes will help us understand how these functions work.

Suppose we have columns of latitude and longitude coordinates written as text strings where each coordinate has a redundant "N" "S" "E" or "W" plus some commentary after the actual coordinate number. In the latitude field, a text field in this table, we encounter coordinates written as:

-45.8908S (verified 1982)

We’d like to strip out the trailing text and leave just the numbers:

latitude span excluding NSEW

results in "-45.8908" for the above value. The span excluding operator kept on going until it found something to be excluded (in this case, the S character) and then it stopped. So far, so good.

Now, suppose we realize we have some records of the form:

-45.8908 (verified 1982)

…where the N, S, E, or W were forgotten; therefore, the previous example does not always work. We would like to get any leading combination of numbers and stop as soon as we encounter any other character, even a space:

latitude span including +-.1234567890

…does the trick. In this case, the span including operator will keep on going so long as it keeps finding characters in the included list (plus and minus signs, a decimal point, and digits). As soon as it hits anything else it stops.
Queries

Queries

Queries are components that contain statements written in the database language SQL. Opening a query by double clicking on it will open the query in an editing window to show the SQL statement it contains.

Clicking on the query to highlight it in the project pane and pressing the Run button will execute the query and will display the results in the opened window. If there are any errors in the query text (such as typographical errors or SQL syntax errors) the query text will be opened in a query window and the first error located will be highlighted.

Queries are usually used to create tables that contain records and fields from other tables in the project. The SQL statement specifies what the table should contain and how the contents should be displayed. The simplest form of query chooses columns and records from one table and displays them.

Queries are easy to create. Use File - Create - Query to create a new query and then edit it by right clicking on it and choosing Open. Enter the SQL statement desired and close the query. To make it easier for us to write queries, Manifold will automatically color different parts of the query text in different colors.

Whenever the query is run it will execute the SQL statement and will display in the resultant table window whatever table results from the SQL statement. The resultant table may be used like any other.

SQL is an industry standard database query language used to fetch records from tables and to present those records with the fields desired. The result of an SQL query is what appears to be a new table. SQL may also be used to create new tables by combining existing tables, and may even be used to alter the structure of the database and the data it contains.

Note: For very simple, one line queries with drawings an alternative to using queries is to use the Query toolbar.

To create a new query:

1. Select File - Create Query command within main menu, or
2. Press the Create button in the project pane toolbar and select Query, or
3. Right click within the project pane or on any component and select Create - Query.
4. Open the query for editing as described below.
5. Write the SQL statement desired. Changes are made directly to the query. Make a copy of the query if you wish to be able to abandon the changes.
6. Close the query window when done. Run the query as described below.

To edit a query:

1. Select the query component in the project pane and press the Open button on the project pane toolbar, or
2. Right click the component and select Open, or
3. Double click the component.
4. Make any changes to the SQL text contained in the query.

To execute (run) a query:

1. Select the query component in the project pane and press the Run button on the project pane toolbar, or
2. Right click the component and select Run, or
3. Open the query for editing and select Query - Run from main menu.

To export a query as a table:
1. Select the query component in the project pane and press the Run button on the project pane toolbar, or
2. Right click the component and select Run, or
3. Open the query for editing and select Query - Run from main menu.
4. Choose File - Export - Table to export as a table.

Example

Let's begin by importing the Orders table from the sample Nwind.mdb database.

<table>
<thead>
<tr>
<th>Ship Name</th>
<th>Ship Address</th>
<th>Ship City</th>
<th>Ship Country</th>
<th>Freight</th>
</tr>
</thead>
<tbody>
<tr>
<td>Around the Horn</td>
<td>120 Hanover Sq.</td>
<td>London</td>
<td>UK</td>
<td>4.45</td>

<td>Genève</td>
<td>Switzerland</td>
<td>50.87</td>
</tr>
<tr>
<td>PROSELLA-Restaurant</td>
<td>5ª Ave. Los Polos Gr</td>
<td>Caracas</td>
<td>Venezuela</td>
<td>17.67</td>
</tr>
<tr>
<td>Piccolo un mőrd</td>
<td>Gesweig 14</td>
<td>Salzburg</td>
<td>Austria</td>
<td>22.1</td>
</tr>
<tr>
<td>Filies hermanet</td>
<td>184 chemin de Titte</td>
<td>France</td>
<td>113.01</td>
<td></td>
</tr>
</tbody>
</table>

The Orders table has many fields related to orders in the sample database. We will create a table that shows the country names for all orders where the freight is greater than 50.

Using File - Create - Query we insert a new query into the project and then open it for editing by double clicking it in the project. We will write a simple SQL query:

```
Select [Ship Country] from Orders where [Freight] > 50;
```

SQL is not case sensitive (except for string literals and string operations), nor does SQL care if we write our statements in one line or in multiple lines or if we use indents. Extra parentheses are fine as well. We could write our queries with the terms all jammed together in one line or we can write nice, neat, understandable SQL statements like the above. It is always wise to establish a regular style and stick to it to enhance readability of SQL both for our colleagues as well as for future review by us.

Manifold query windows will automatically color different parts of an SQL query with differently colored text. This helps avoid typographical errors. If we would like to change the colors used by Manifold to color query syntax, the Tools - Options - Colors page includes entries for Query Comment, Query Keyword, Query Number, Query Operator, Query String and Query Text colors. The Tools - Options - Fonts page restricts the choices for the Query font to fixed size fonts.
The query appears in the project pane using the standard Microsoft icon for queries (these are also called "views" in Access). If we select the query in the Project pane and click the Run button in the toolbar, the query opens as a table:

The table created by the query works just like a regular table. For example, if we right click onto the Ship Country column head and choose Sort Ascending from the context menu we can sort the table by this column:

We can also use many other table window commands such as the Best Fit commands.
SQL is a straightforward, easy-to-use query language.

```
SELECT [Ship Name], [Ship Country], [Freight]
FROM Orders
WHERE [Freight] > 50;
```

If we would like to see additional fields in our table we can add them to the query as shown above.

The result of running the new query is a table with three fields instead of just one.

**Types of Queries**

There are two main types of queries: **select** queries and **action** queries:

- **Select** queries show results in tables and always begin with the SQL word **select**. Select queries choose data from one or more tables and display it in tabular form. Select queries do not change any data in the tables.

- **Action** queries do not display data but rather perform a task when they are run. Action queries change data in existing tables by appending, updating or deleting records. Action queries can also create new tables. Action queries start with words other than **select**. For example, an update query starts with the word **Update**.

See the Simple Queries topic for an introduction to simple select queries that display data from one table.

See the Queries Using Multiple Tables topic for instructions on creating queries that combine fields from multiple tables.

See the Action Queries topic for information on queries other than select queries.

**Dot Nomenclature**

"Dot" nomenclature allows us to refer to exactly a desired field within a given table even when other tables in our project might use the same field name in a different way. Dot nomenclature is simply the table name followed by a period "." and then the field name:

```
Customers.ContactName
```
The above refers to the **ContactName** field in the **Customers** table. If we are writing simple queries that involve only one table we need not use dot nomenclature. We could simply write **ContactName** as in the examples above. However, if we are working with more than one table we can always use dot nomenclature to clear up any ambiguities about which field is intended.

**Autocompletion**

Manifold will offer to autocomplete SQL functions and other parts of the query, popping up lists of key words and other useful items, to help guide us in writing the query. See the Autocompletion in Queries topic.

**Names in Brackets**

Some database management systems (including Manifold tables) allow field names and table names to contain the space character and other non-alphanumeric characters. Such field names should be enclosed in `[ ]` square brackets when written in queries. Simple field names that do not contain spaces or other unusual characters need not be enclosed in brackets.

To preserve maximum capability to export data to a wide variety of database systems we suggest the use of field names that do not contain spaces or other unusual characters.

Dot nomenclature and names in brackets can be combined. For example, one could write

```sql
Select * from [Mexico Table]
where [Mexico Table].BUSES_1991 > 3000;
```

**Case Sensitivity**

SQL itself is not case-sensitive, but string literals and string operations are. Hence, comparing a pair of string values which only differ by case for equality will return false. If you want to compare string values ignoring their case, use the `UCase` function.

**Selection and SQL**

Because many SQL queries begin with the word **Select** it is tempting to think of them as adding items to the selection. Although this is "selection" in the database sense of the word, the actual records and the objects with which they are associated may or may not be selected in the Manifold sense of the word depending on the setting of the **Automatically select query records** option in the Tools - Options - Miscellaneous dialog.

The default setting of this option is to automatically select records reported by a query. This makes it easy to use a query to select objects in a drawing. If automatic selection of query records is not desired, uncheck the option. If the option is not checked, records resulting from a query will simply be displayed in a table. We can then select them as desired. For example, we could choose **Edit - Select All** to select all the records in that table.

For reference information on SQL see the SQL Reference Guide information beginning with the SQL in Manifold System topic.

**VBScript Style Operators and Functions**

Manifold SQL supports use of numerous VBScript operators and functions. For example, `LikeX` is similar to the standard SQL `Like` operator but uses VBScript style syntax to match regular expressions.

The `RegExp` function returns values based on regular expressions. It transforms strings in a manner similar to the Manifold **Edit - Replace** dialog with the **Regular Expressions** checkbox turned on, so that:

```sql
RegExp("abc", "b", "d") returns "adc",
RegExp("abc", "[a-b]", "d") returns "ddc",
RegExp("abc", "[a-b]", "") returns "c",
RegExp("ab c", "([a-z]*) ([a-z]*)", "$1+$2") returns "ab+rc".
```
RegExp("ab c", "([a-z]*) ([a-z]*)", "$2 $1") returns "c ab",

For more on VBScript style operators and functions see the Expressions topic in the SQL Reference Guide.

**Manifold SQL and ANSI Syntax Option**

Manifold’s SQL is designed to be compatible with Microsoft SQL as implemented in the Microsoft "Jet" database engine. Manifold SQL is intended to be a superset of Jet SQL with features supporting ANSI SQL as well. SQL syntax as documented within the Microsoft Jet SQL Reference for Access 2000 is a practical approach to Manifold SQL.

Manifold SQL has also been extended with special functions to use the spatial and geocoding capabilities of Manifold. Note that the geocoding extensions to SQL will be available only if either the Manifold US street address geocoding database is installed or if Microsoft MapPoint has been installed. See the Spatial Extensions and Geocoding Extensions and Raster Extensions topics for a list of extensions to SQL in Manifold that allow creation of SQL queries that make spatial comparisons, work with rasters or employ the geocoding engine for work with street addresses.

In addition to being Microsoft Jet-like, Manifold’s SQL engine may be switched into an alternate mode where it parses SQL queries using pure ANSI syntax. To do so, open the query and in the View - Properties dialog check the **Use ANSI-compatible syntax** box. It is also possible to automatically set the **Use ANSI-compatible syntax** option for all new queries by checking the **Make new queries ANSI-compatible** option in the Tools - Options dialog.

When the ANSI option is turned off, line comments start after an apostrophe (‘) or double dashes (--) and always start after line comments. The names of tables and columns can be enclosed in square brackets ([ ]) or backward apostrophes (`). Strings are enclosed in quotes (") and times are enclosed in quotes (") or hashes (#).

When the ANSI option is turned on, line comments start after double dashes (--) and always start after line comments. The names of tables and columns can be enclosed in square brackets ([ ]) or quotes ("), or backward apostrophes (`), or apostrophes (‘) and times are enclosed in apostrophes (‘) or hashes (#).

Clearly, the safest course given that users might change the settings is to use double dashes (--) to mark line comments and to enclose the names of tables and columns in square brackets ([ ]) and to enclose times with hashes (#). The main difference between having the ANSI option off or on is that with it off strings are enclosed in quotes (") and with the ANSI option on strings are enclosed in apostrophes (‘).

**Lookup Values and CStr and CAST**

Invoking CStr on a lookup value or using CAST to convert the value to a string returns the descriptive name of the lookup value.

**Example**

We have a table T with a lookup column Region with values East and West. We want to select all records with the value of Region being East. We can do this with the following query:

```sql
SELECT * FROM [T] WHERE CStr([Region]) = "East";
```

**Example**

We have a drawing D and we want to select all areas it contains. We can do this with the following query:

```sql
SELECT * FROM [D] WHERE CAST([Type (I)] AS TEXT) = "Area";
```

**Use cache Option**

In the View - Properties dialog for a query the **Use cache** option allows us to control the caching behavior of queries.
The **Use cache** option applies to table queries, such as those using SELECT and TRANSFORM. When this option is turned on, the query may cache the resulting table between invocations provided its text and parameters have not changed. This is obviously good for performance when lots of data is involved in the query.

When the **Use cache** option is turned off, the query forcefully re-computes itself (re-computing any dependent queries and refreshing any linked tables) each time it is run from the project pane or from the query window. By default, the option is turned off.

The default setting of the **Use cache** option may be specified in the Tools - Options - Miscellaneous dialog via the **Make new queries cached** option.

**Queries and Linked Components**

In addition to using queries as dynamically refreshed tables, one can also import or link queries as drawings, images or surfaces to create linked components. See the Linked Drawings topic as well as the Queries and Images or Surfaces topic for details.

**Queries and Virtual Tables for Images and Surfaces**

Queries may use data from images or surfaces by using **virtual tables** for these components. See the Virtual Tables for Images and Surfaces topic for details.

**Tech Tip**

We may simultaneously open a query for editing with **Open** in one window and also run it in another window with the **Run** button. Any changes to the query's SQL statement made in the editing window will take effect in the opened viewing window when we next press **Run**. Note that for the **Run** button to work the query component must be highlighted in the project pane.

Suppose we create a query using data from **Mexico Table**, the table associated with our sample map of Mexican provinces. We can open the query in an editing window. We can also press the **Run** button to execute the query and open the results in a table window. The screen shot above shows the editing window, the table window and the project pane. (Windows have been resized to very small size to fit into the screen shot).
We can change the 3000 value to 4000 in the SQL statement and then press the Run button. The table window will be updated with the new results of the query.

If we change the 4000 to 5000 we can press the Run button again to update the table once more. Note that there is no need to "save" the SQL statement in the editing window. Changes to the query in the editing window take effect whenever the Run button is pressed.

As a convenience for users, if a query is open at the same time as an editable query window and also as a table window reporting the results of the query being run, the Windows dialog will append the postfix (Table) to the latter. For example, if we have a query called MyQuery and it is open both as an editable query window and also as a table window reporting the results of running the query, the Windows dialog will show two windows open, one called MyQuery and the other called MyQuery (Table).

**Keyboard Shortcuts for Editing Queries**

In addition to the usual Windows keyboard shortcuts query windows support key combinations for doing advanced syntax-aware editing tasks:

- **CTRL-J** Display a list of auto-complete suggestions for the context word.
- **CTRL-K** Comment selected text.
- **CTRL-SHIFT-K** Uncomment selected text.
Queries

CTRL-M Convert selected text to lower case.
CTRL-SHIFT-M Convert selected text to upper case.
CTRL-Y Multi-level Redo.
CTRL-Z Multi-level Undo.
CTRL-] Check the character near the cursor and, if it is a bracket character, jump to the matching bracket.
CTRL-SHIFT-] Check the character near the cursor and, if it is a bracket character select the text between the bracket and the matching bracket.
CTRL-Space Auto-complete the context word.

Recognized bracket combinations are { and }, [ and ], { and }, ' and ', " and " and # and # (used to delimit dates in queries).

Query windows are unusual in that they support multi-level Undo / Redo. One can CTRL-Z (Undo) backwards through many changes and CTRL-Y (Redo) forwards to redo many Undo operations.

Formatting Columns

Queries also use the Formatting Columns capabilities of table windows, inheriting the format style used for the column in the table. Styles should be chosen to provide clarity of results.

Users are sometimes surprised to see numbers they expect to be values like 1.1 appear in a query or other table as 1.0999942779541, even if a floating point type is used. That is a result of the fundamental architecture of computers combined with the choice of format style used.

Floating-point values have finite precision. Some values, such as 1.2, or 0.25 can be represented precisely, but most can not. For example, neither 12.6 nor 13.7 can be represented precisely. To see what really hides behind a value shown as 12.6, set the format style of the relevant column to 12.34 and increase the number of decimal digits to 10. Try the same for 13.7.

If we subtract one approximation from another, as in the case of an SQL query, we get an approximation of the result so that an expected result such as 1.1 may appear as 1.0999942779541.

The default format style uses a Microsoft Windows API which makes some approximations, such as 12.6000..., look round but leaves others unaffected. There is some logic behind that API, but that logic is obviously not applicable to all cases. To provide fine control over desired appearance is one reason why Manifold allows setting the format style and the number of decimal digits explicitly.

Notes

See the Query Templates and Sample Queries example topics for samples of queries.

For very simple, one line queries with drawings an alternative to using queries is to use the Query toolbar.

The idea of relational databases originated in a 1969 IBM research report written by Dr. E.F. "Ted" Codd, who invented the relational model of databases and introduced it to the world. SQL originated as SEQUEL (for "Structured English Query Language") in 1974 at the IBM San Jose Research Laboratory in a project led by Donald Chamberlin.

Just about everyone in computing thinks that "SQL" is an acronym for "Structured Query Language." That’s not true, despite the historical origin of the language, as the ANSI standard defining SQL officially names it “Database Language SQL.” Experts will also point out that SQL is not structured, it is used for more purposes than just asking about things (the conventional meaning of the English word “query”) and it is technically not a “language” in the Turing sense of the word.
According to ANSI, “SQL” should be pronounced by saying the letters as in “ess cue ell.” However, many people prefer to pronounce the term as the English word “sequel,” especially when referring to Microsoft’s SQL Server DBMS product since “sequel server” is more alliterative and easier to say than “ess cue ell server.” It is very common to use both pronunciations, even in the same sentence, as in “This ess-cue-ell works in Sequel Server but not in Oracle.”

When running SQL within Manifold queries, one is using the Manifold SQL engine. When executing SQL within the Database Console one is using whatever SQL is the native SQL of the external database system. One should be aware that SQL implementations in various databases systems can contain bugs. If an SQL bug occurs within the Database Console, the bug should be tracked down with the vendor of the external database system being used.

Queries made with query components as well as queries made with the Query toolbar execute within Manifold on the local machine and thus must fetch the content of involved tables from their respective data sources. This frees the user from the hassles of different dialects of SQL as supported by different drivers, allows querying data sources that do not support any SQL at all and allows using spatial, geocoding and other extensions implemented within Manifold.

To make a query execute on a database server using that server’s own SQL, create a view on that server and link that view to the Manifold project as you would link a table.

Queries made within the Database Console run within the database server.

Autocompletion in Queries

When editing queries, Manifold will offer to autocomplete SQL statements, clauses and operators as well as table names and columns, popping up lists of key words and other useful items, depending on the context, to help guide us in writing the query. Autocompletion provides several key benefits:

- Increased editing speed.
- Fewer typographical errors.
- Consistent capitalization style
- Quick reference to component, table and column names in the project.
- Quick reference to SQL keywords, statements, clauses, functions and operators.

The default behavior is to pop up a list of possible completions when a candidate word is started or when a left bracket, [ character, is entered to signify the possible desire to use a table or column name. A list of completion candidates will pop up if the Automatically list completion suggestions when editing queries box in Tools - Options - Miscellaneous has been checked.

Pressing the keyboard down arrow moves the focus to the list. Pressing Enter, tab, or typing a bracket character inserts the selected suggestion into the query.

In addition, pressing CTRL-space after beginning a candidate word will have Manifold automatically complete the word if an unambiguous match is found in SQL key words.

These functions may be manually invoked by use the SQL autocompletion commands in the Edit - Advanced menu of commands available when a query is edited:

- **Complete Word**
  Appears for queries. Complete the word automatically if an unambiguous choice is possible. If no unambiguous choice is possible, pop up a list of choices (the same as Complete Word with List). Usually invoked with the standard Microsoft CTRL-space shortcut.

- **Complete Word with List**
  Appears for queries. Pop up a list of possible completions. Not usually used, since checking (the default) the Automatically list completion suggestions when editing queries box in Tools - Options - Miscellaneous causes the list to pop up automatically.

We can invoke the above manually with a CTRL-space and CTRL-J keyboard shortcuts.

To choose an autocompletion item presented to us we can double-click with the mouse or press the tab key if a choice is unambiguous. Manifold provides different pathways to autocompletion so that we can select whichever method is the fastest and most convenient at the time.

**Example**

Let's write a simple query using the Mexico sample drawing and table. This example assumes the Automatically list completion suggestions when editing queries box in Tools - Options - Miscellaneous is checked (the default setting). The query we will write is a single line of SQL:

```
SELECT [Place_name] FROM [Mexico Table] WHERE [POBL_1990] > 1000000;
```

Autocompletion will help us write the above query without the tedium of having to manually write out all the column and table names manually. Autocompletion also spares us much trouble caused by typographic errors that often creep into manually-entered text.

We begin by creating a new query and then double-clicking the new query open in a query window.
We enter the character $S$ (beginning the first character in the \texttt{Select} statement) and immediately the system pops open a menu of choices for autocompletion, scrolled down to the items that begin with $S$.

One way to autocomplete the \texttt{Select} statement is to double click the \texttt{SELECT} entry with the mouse.
This will immediately add the remaining characters in the `SELECT` statement to the query. Let us continue the query to specify what field we want to select.

We do this by entering the `[` left bracket character. The system immediately pops open a list of table names and column names available in the project. We double click the `Place_name` table to have it autocompleted.

The system automatically adds characters to complete the name of the column. About now the novice SQL programmer begins to realize that autocompletion is one of those wonderful things in life that once tasted cannot be done without.

There is a potentially faster way of invoking autocompletion than double-clicking with the mouse, as will be seen as we continue the query by building a `FROM` clause.
As we enter the F character to begin the FROM clause, the system pops up a menu of options that begin with F. Note that none of them is yet highlighted.

As we continue and enter the R character the system highlights FROM since that is the only match that begins with FR. At this point we can hit the tab character (a typical Windows shortcut for accepting an autocompletion choice)....
...and the system will complete the FROM statement for us.

It is true that entering a sequence of an F character and an R character followed by the tab character is not much of a time saver for an accomplished touch-typist who could just as rapidly bang out FROM using all four characters; however, in the case of more complex constructions, such as long field names, using autocompletion can be a great time saver as well as a way of guarding against typographic errors.

We can see the above effect by continuing the example.

If we begin entering a column name by entering M the system will jump to those columns that begin with M. We could double-click onto a column to choose it for autocompletion, or we could continue entering characters to get a highlighted match to an unambiguous autocompletion choice.
When we enter `[Mexico T` we get a highlighted match to the `Mexico Table` column, at which point we can press the `tab` key to autocomplete it.

Again, it's true that an accomplished touch-typist could enter the above text almost as rapidly as autocompleting it; however, by using autocompletion we guarantee the field name does not contain a typographic error because if it did a highlighted match for autocompletion would not have occurred. Saving just a single typographic error in a query can save us as much time in debugging as entering hundreds of characters.

Another advantage to autocompletion is consistent use of case. Because autocompletion uses the same capitalization style regardless of whether initial characters were uppercase or lowercase, autocompletion is also a handy way of adhering to a consistent capitalization scheme without having to pay too much attention to using the `SHIFT` key.
Queries

For example, suppose we continue the query by entering `WHERE` and then press the `tab` key for an autocompletion.

```
SELECT [Place_name] FROM [Mexico Table] WHERE
```

The system will enter a `WHERE` clause using all uppercase letters.

```
SELECT [Place_name] FROM [Mexico Table] WHERE [POB1_1990] > 100000;
```

We can finish the query by manually entering the remaining text.

**Options**

As mentioned in the beginning of the example, the above example assumes the **Automatically list completion suggestions when editing queries** box in Tools - Options - Miscellaneous is checked (the default setting). This option causes a list of choices to automatically appear whenever a SQL key word is begun or a `[` left bracket indicates the beginning of a table name or column name.

It is not to everyone’s taste to have a list of autocompletion choices appear automatically. If we don’t like the pop up lists, we can disable them by unchecking the option in Tools - Options. With the option turned off at any time we can cause a list to appear (if one is possible) by pressing `CTRL-J`.

For example, if the option is turned off and we enter...

```
SELECT [Place_name]
```
...and we would like to be reminded of what might come next we can always press CTRL-J and a list of SQL statements, clauses and operators will appear.

Note that regardless of whether the above option is turned on or off at any time when beginning an SQL key word we can have it completed for us with a CTRL-space if we have entered enough characters to unambiguously select a possible completion choice.

Queries
Simple Queries
**Simple Queries**

This topic provides an introduction to writing simple queries using SQL. For very simple, one line queries with drawings an alternative to using SQL queries is to use the Query toolbar.

Simple queries will display data from a single table. They use elementary SQL using the SELECT statement written as follows:

```
SELECT <fields> FROM <table> WHERE <condition>
```

A simple example using the **Customers** table from the **Nwind.mdb** sample database would be:

```
SELECT [Contact Name], [Phone] FROM [Customers]
WHERE [Country] = "France"
```

If we’ve imported the **Customers** table into our project and place the above SQL statement into a query, when we open the query we will see a simple table with two columns:

<table>
<thead>
<tr>
<th>Contact Name</th>
<th>Phone</th>
</tr>
</thead>
<tbody>
<tr>
<td>Daniel Torini</td>
<td>30.59.64.10</td>
</tr>
<tr>
<td>Frédérique Citeaux</td>
<td>68.60.15.31</td>
</tr>
<tr>
<td>Martine Rancé</td>
<td>23.16.10.16</td>
</tr>
<tr>
<td>Janine Labrune</td>
<td>40.67.86.98</td>
</tr>
<tr>
<td>Arnette Roulet</td>
<td>61.77.61.10</td>
</tr>
<tr>
<td>Laurence Leibhan</td>
<td>91.24.45.40</td>
</tr>
<tr>
<td>Paal Hvorrsh</td>
<td>26.47.16.10</td>
</tr>
</tbody>
</table>

SQL is not case sensitive except inside text strings used within quotes in criteria. We can use parentheses to group criteria within criteria to keep our statements legible, and we use tabs and spaces, multiple lines and indents as desired to keep things clear.

**Templates**

```
SELECT <fields>
FROM <tables>
WHERE <condition>
GROUP BY <fields>
HAVING <criteria>
ORDER BY <expression>;
```

The Query Templates example topic provides a list of templates like the above. These are intended to guide creation of frequently occurring types of queries by providing a template for the SQL statement to be used. Replace the generic items in angle < > brackets with the specific items you wish to use.

The above template shows the basic options in simple queries. Choices except the **Select** and **From** constructs are optional. Click on the links above to jump to the applicable Help topic for more information.

**Autocompletion**

Manifold will offer to autocomplete SQL functions and other parts of the query, popping up lists of key words and other useful items, to help guide us in writing the query. See the Autocompletion in Queries topic.

**Tech Tip: SQL and Strings**
SQL is case insensitive for SQL itself but is case sensitive when evaluating string values. Suppose, for example, we have a query such as

\[
\text{SELECT } f \text{ FROM table WHERE } f = "13AF";
\]

This query will return no results if the value in \( f \) is \texttt{13aF}, because "13aF" is not the same as "13AF".

To normalize case, use the Transform toolbar Make Lower Case or Make Upper Case operators to force all values in the column to upper case or lower case. Alternatively, use a modified SELECT statement:

\[
\text{SELECT } f \text{ FROM table WHERE UCase(f)="13AF"};
\]

When comparing strings, SQL is sensitive to leading or trailing whitespace. "13AF  " does not equal "13AF". To remove leading / trailing whitespace use the Transform toolbar Trim Left, Trim Right or Trim operators to eliminate leading, trailing or both leading and trailing whitespace. Alternatively, use a modified SELECT statement:

\[
\text{SELECT } f \text{ FROM t WHERE Trim(f)="13AF"};
\]

How can we create strings with special characters in them? Use the \texttt{CHR} function. For example, to create a string that includes a quote character we can use

\[
"ab" + \text{Chr}(34) + "cd"
\]

which results in a string with an \texttt{ab"cd} value.

Queries Using Multiple Tables

Queries can incorporate fields from two different tables. There are several methods for doing so depending on the structure of the tables and their contents.

This is the easiest situation is when the two tables have a key field in common. We can then combine them by using an inner join between the tables. This is also called an equi-join in some database management systems.

```
SELECT [Customers].[Company Name], [Orders].[Employee ID]
FROM [Customers] INNER JOIN [Orders]
ON [Customers].[Customer ID] = [Orders].[Customer ID]
```

The inner join operation combines two tables (in the above case, the Customers table and the Orders table) using a key field they have in common. The example shown above will create a table that takes the Company Name field from the Customers table and shows it with the Employee ID field from the Orders table. It will create a table for all records where there are both customers and orders.

We can also create a similar query that will show all customer records in the results even if there are no orders for some customers. We might also want to run the query in a way that includes all records in the orders table even if there are no customers for some orders. This should not occur (a well-run business should not be recording orders for which there are no customers), but it is a way of checking for errors. To do this, we use an "outer join" which is phrased as either a left join or a right join.

```
SELECT [Customers].[Company Name], [Orders].[Employee ID]
FROM [Customers] LEFT JOIN [Orders]
ON [Customers].[Customer ID] = [Orders].[Customer ID]
```

The left join operation will include all of the records from the left-hand table mentioned, the Customers table in the example above, even if there are no matching values to records in the right hand table (the Orders table in the example above).

```
SELECT [Customers].[Company Name], [Orders].[Employee ID]
FROM [Customers] RIGHT JOIN [Orders]
ON [Customers].[Customer ID] = [Orders].[Customer ID]
```

The right join operation will include all of the records from the right-hand table mentioned, the Orders table in the example above, even if there are no matching values to records in the left hand table (the Customers table in the example above).

**Simplified Syntax for Inner Joins**

Inner joins can be created by default in Manifold using a simplified syntax such as the following:

```
SELECT [Customers].[Company Name], [Orders].[Employee ID]
FROM [Customers], [Orders]
WHERE [Customers].[Customer ID] = [Orders].[Customer ID]
```

This simplified syntax replaces the inner join and on words with a comma in the list of tables involved and a simple where clause. Many SQL systems can use the above syntax. Access uses the inner join syntax because the "inner join" construct is used as a hint to the Jet database engine within Access to build temporary indices that will be used to optimize the query. Manifold SQL optimizes both inner join and where constructs so the above simplified syntax works just as fast as using inner join.

SQL can also be used to combine fields from more than two tables, and even from multiple tables that do not have a key field in common. However, such SQL topics are beyond the introductory level of this help documentation. For advanced SQL discussion we suggest readings in one of the many good books oriented to SQL in a Microsoft Windows environment.

**The Identity Command**
Right clicking on a column head in a table created by a query pops open a context menu from which we can choose the **Identity** command. The **Identity** command allows us to select the ID column to be used in tables that have more than one identity column.

Suppose we have two drawings, one of cities and one of states, called **Cities** and **States**. The following query...

```sql
SELECT * FROM Cities, States
WHERE Contains(States.ID, Cities.ID);
```

...will generate a table with two identity columns: **States.ID** and **Cities.ID**.

Suppose the query generates a record containing a **New York** city and a state of **New York**. Let's also suppose that **New York** city is selected and the state of **New York** is not. The selection state of the record that is linked to both of these objects is determined by the active identity column. The record will appear selected if the active identity column is set to **Cities.ID** and unselected if the active identity column is set to **States.ID**.

The active identity column also specifies how selection in the table selects objects in the associated drawings. If the **Cities.ID** column is made the active identity column then selecting a record in the table will select the corresponding object in the **Cities** drawing. If the **States.ID** column is made the active identity column, then selecting a record in the table will select the corresponding object in the **States** drawing.

**Note**

When removing components contributing to a content of a query Manifold tries to preserve the query output if a query table is open. Suppose we select data from two tables in a query and the resulting query table shows some columns from the first table and some columns from the second table. If we delete the first table while the query is open, the cells of the resulting table that belong to the first table will become empty but the cells that belong to the second table will stay populated. Removing all components contributing to the content of a query will close the query table.

- SELECT Statement
- CROSS JOIN Operator
- OUTER (LEFT, RIGHT, FULL) JOIN Operators
Calculations in Queries

Queries can automatically perform calculations to create new columns from existing fields. The general syntax is

```
SELECT <expression> [AS <name>] FROM <table>;
```

For example,

```
SELECT [Unit Price] * [Quantity] * (1 - [Discount]*100)/100
AS [Total Price] FROM [Order Details]
```

Would create a table with one column called Total Price. The value for each record in Price would come from multiplying the Unit Price, Quantity and normalized Discount fields in the Orders table. (Note that using square brackets for field names is optional except for Unit Price, which has a space in the field name.)

We can use multiple field expressions in the Select construct's field list by separating each with a comma:

```
SELECT [Unit Price] * (1 - [Discount]*100)/100
AS [Discounted Price],
[Unit Price] * [Quantity] * (1 - [Discount]*100)/100
AS [Total Price] FROM [Order Details]
```

This creates two columns called Discounted Price and Total Price. Note that queries are insensitive to extra white space or line breaks so that we can add extra line breaks in the above to make it fit within the narrow margins of this document and still be reasonably legible.

Operators

Manifold queries can utilize numerous operators and expressions. These include arithmetic, comparison and logical operators. See the Expressions topic.

Examples

```
SELECT ([First Name] & " " & [Last Name]) AS [Full Name]
Creates a column called Full Name that contains the contents of the First Name field plus a space plus the Last Name field contents.

SELECT (City & ", " & State & " " & Zip) AS Address
Creates a column called Address that contains the contents of the City field plus a comma and a space plus the State field, a space and the Zip field contents.

SELECT (Mid(Phone),2,3) AS [Area Code]
Create a column called [Area Code] that contains the second, third and fourth characters of the Phone field. If phone numbers are in the US form of (800)556-5919 this yields the area code. The Mid function's parameters ask it to report the three characters beginning with the second character. [Only works if we are sure all phone numbers are in the above form!]

SELECT [Freight] * 1.1 AS [Freight Charged]
Create a Freight Charged column that contains 1.1 times the value of the Freight column.

SELECT [Quantity] * [Unit Price] AS [Amount]
Create an Amount column that multiplies Quantity by Unit Price for each record.

SELECT DateDiff("d", [Required Date], [Shipped Date]) AS [Lead Time]
Creates a Lead Time column by subtracting the Shipped Date value from the Required Date value. Note that use of parentheses is optional but that it helps legibility.

1375
SELECT [Units in Stock] + [Units on Order] AS [Total Stock]

Show a Total Stock column that adds the Units in Stock and Units on Order fields.

SELECT DateDiff("d", [Order Date], [Shipped Date]) AS [Lag Time]

Show a Lag Time column that uses the DateDiff function to compute the number of days between the order and shipping dates.

SELECT DatePart("yyyy", [Hire Date]) AS [Year Hired]

Create a column showing the year hired by using the DatePart function to find the year from the Hire Date field.

SELECT Statement
Expressions
Action Queries

Action queries are queries that make changes to many records at once. They are used to delete records, to update records (that is, to change values in them), to create new tables, to delete tables and to launch queries that accept a user-supplied parameter. Action queries are just like any other SQL query in that they use SQL and are written within a Manifold query component. They are given the special name "action" to highlight their activity in changing the tables or interacting with the user by virtue of the SQL commands they use.

Examples

Using the Nwind.mdb sample database:

```
DELETE FROM [Order Details] WHERE [Discount] = 0;
```
Delete records for non-discounted orders.

```
DROP TABLE [Categories];
```
Delete the Categories table (square brackets are not necessary).

```
PARAMETERS Threshold INTEGER;
SELECT * FROM [Order Details] WHERE Quantity > Threshold;
```
Select orders whose quantity exceeds a number entered by the user.

```
SELECT DISTINCT [City] INTO [Locations] FROM [Customers];
```
Select all cities from Customers into the new table (Locations). The use of the DISTINCT quantifier suppresses duplicates.

```
UPDATE [Order Details] SET [Unit Price] = [Unit Price]*0.95 WHERE Quantity >= 30;
```
Lower prices (by 5%) on items whose quantity is too high.

Notes

Running an action query reports the number of affected records in the History pane.

See Also

Parameter Queries for an example of writing and launching a parameter query.

SQL in Manifold System
ALTER TABLE Statement
CREATE TABLE Statement
CREATE VIEW Statement
DELETE Statement
DROP TABLE Statement
DROP VIEW Statement
INSERT INTO Statement
SELECT INTO Statement
UPDATE Statement
Parameter Queries

Queries using PARAMETERS can ask for user specified parameters when the query is run. Parameter variables are declared in the first line of the query using a declaration in the form:

```
PARAMETERS name type;
```

Where `name` is a legal variable name (no spaces or special characters) and `type` is a valid data type such as TEXT, INTEGER, etc. Thereafter, the parameter variable can be used in the query as a variable.

The project pane will report the number of parameters in a query when the query is highlighted in the project pane.

Example

This example uses the Order Details table from the Nwind.mdb sample database. Import this table from the database.

Use File - Create - Query to create a query and then enter the above text.

Press the Run button in the project pane to execute the query.

When we do so, the Query Parameters dialog launches to allow us to enter values for those parameters used in the query. The query we've written is a simple query that has only one user supplied parameter called Threshold so only this parameter appears in the dialog.

The first row in the list of query parameters (if there is more than one) will be highlighted. To enter a value, double click into the Value cell for that parameter, enter the desired value and then press Enter.
We've entered the value 10. Press OK to continue with the query.

Queries using more than one parameter can be constructed. List multiple parameters separated with commas, for example:

PARAMETERS [Beginning Date] DateTime, [Ending Date] DateTime;

When more than one parameter has been used the Query Parameters dialog will show each parameter. To specify the values desired for each parameter, double click into the Value cell for each parameter and enter the value desired.

Tech tip: a keyboard shortcut to double clicking into a Value cell is to use the down and up keyboard arrows to highlight the desired row in the dialog and then press the F2 key to begin editing the value.

PARAMETERS Declaration
Selecting Objects with Queries

This topic explains how to select objects in drawings (or in drawing layers in maps) using queries. Queries can be used to select objects either automatically or manually using mouse-based selection commands within the query table.

Queries are written using SQL, which usually begins with the SELECT command. This meaning of "selection" is the traditional database meaning of picking out records and columns from database tables to construct a new table. It is a different meaning than the Manifold use of the word "selection" to mean choosing objects in drawings or pixels in images or otherwise choosing items in other components.

The normal use of queries is to generate a table display showing the results of the query. If the query includes the ID field in its results, query tables can automatically select the drawing objects corresponding to each row in the query table based upon the setting of the Automatically select query records option in the Tools - Options - Miscellaneous dialog. When this option is checked (the default setting) queries will automatically select objects in the drawing.

That is, with this option on querying a drawing will automatically deselect any selected objects and then select all objects returned by the query. This is equivalent to making a selection using Replace mode. When a query includes more than one drawing, all previously selected objects in all of the drawings will first be deselected and then objects from the query will be selected in the first drawing for which an ID column is found in the query.

If the Automatically select query records option is not checked then running a query will generate a tabular display of the query results, but the objects in that query will not automatically be selected. We can then use such a query-generated table to manually select objects in the drawing with interactive mouse commands much as we could use a drawing's table to select objects in the drawing.

Use the manual option if queries will be used to make incremental, interactive selections, for example using Add or Subtract selection modes with mouse selection within the query window to add the query's results to a previous selection or to subtract the query's results from a previous selection.

Query Selection in Drawings

There are three cases of queries to consider:

- Queries using one drawing that result in a single ID column in the query table.
- Queries using two or more drawings that result in multiple ID columns in the query table.
- Queries joining columns from different tables.

Queries using One Drawing

If the Automatically select query records option is checked, queries that reference one drawing may be used to select objects in that drawing if they include the ID field in the query. If the automatic option is not checked, the query table can be used for interactive selection using mouse commands (clicking on records) just as selection operates with the drawing's table.

```sql
SELECT * FROM [Mexico_eg Drawing]
WHERE [Place_name] LIKE "BAJA%";
```

The above query, for example, will create a table from the example mexico_eg.mif drawing that finds all Mexican provinces with "BAJA" in their name. If the Automatically select query records option is checked the query will also select all objects that have "BAJA" in their name.

If the Automatically select query records option is not checked the query table will display but no objects will be selected. If desired we can select all of the objects in the query table with mouse selection commands. For example, we could click on the first record in the query table and SHIFT click on the last record in the query table to select all of the items in the query.

We can use either a drawing or the drawing's table in a query to exactly the same effect. For example, the above query could have been written...
```
SELECT * FROM [Mexico_eg Table]
WHERE [Place_name] LIKE "BAJA%";
```

...with exactly the same effect.

Objects are not selected by queries in Manifold unless the ID system field is selected by the query. The ID field is required either for automatic selection or for manual selection using mouse commands. For example, if we have a drawing of provinces that each has a name, the SQL fragment ...

```
SELECT Name from [Provinces Table] WHERE...
```

... will create a table, but it will not select the objects associated with the records that appear in that table. In contrast, the fragment...

```
SELECT ID, Name from [Provinces Table] WHERE...
```

... will select the objects as well as creating the table.

**Queries using Two Drawings**

Queries that reference two drawings may be used to select objects in either drawing using the Identity command.

Suppose, for example, that we have created a map with a drawing of points, called Points, as a layer above the Mexican boundaries map, which we have renamed Mexico for brevity.

```
SELECT * from Mexico, Points
WHERE Contains(Mexico.ID, Points.ID);
```

The above query selects records in both Mexico and Points for those cases where provinces in Mexico contain some of the points. To change which drawing's records are displayed in the query, choose the Identity command in the column context.

If the Automatically select query records option is checked, the query will select objects from the drawing (in this case Mexico) for which the first ID column appears.

Suppose we have two drawings, one called Points that contains points and one called Areas that contains areas. We select some areas in the Areas drawing and now we would like to use a query to select all points in the Points drawing that are inside the selected areas:

```
SELECT * FROM [Points], [Areas]
```
WHERE [Areas].[Selection (I)]
AND Contains([Areas].[ID],[Points].[ID]);

Note the use of the Selection (I) intrinsic field to use only selected areas in the query.

Queries Joining Columns from Different Tables

In current editions of Manifold, queries that join columns from tables not associated with drawings cannot be used to select objects in drawings. For example, a query formed with "Union D1, D2, T3" where D1 and D2 are drawings and T3 is a table could not be used to select objects in the drawings.

Selection Modes and Selection from Queries

Selection modes do not affect automatic selection when the Automatically select query records option is checked. Automatic selection always operates in Replace mode.

The selection mode set affects selection only within the query window using interactive mouse commands.

For example, if we have Select Replace set (the default, seen above) any selections we make in the query window will replace the entire selection in the query window. This will change the selection in the referenced drawing window only to the extent that the objects in the drawing are represented in the query window.

Suppose that in the example seen above we have previously selected the province of Oaxaca in the southern part of Mexico.

We can then run the following query to find all provinces in Mexico that contain one of the points in the Points layer.

```
SELECT DISTINCT Mexico.ID, Mexico.Place_name from Mexico, Points
WHERE Contains(Mexico.ID, Points.ID)
```

We can run this query by pressing the Run button in the project pane toolbar.
The result will be a table listing the IDs and names of each province (seen with Identity set to the Mexico drawing).

<table>
<thead>
<tr>
<th>ID</th>
<th>Place_name</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>SAN LUIS POTOSI</td>
</tr>
<tr>
<td>2</td>
<td>ZACATECAS</td>
</tr>
<tr>
<td>3</td>
<td>DURANGO</td>
</tr>
<tr>
<td>5</td>
<td>SINALOA</td>
</tr>
<tr>
<td>7</td>
<td>NUEVO LEON</td>
</tr>
<tr>
<td>11</td>
<td>COAHUILA</td>
</tr>
<tr>
<td>12</td>
<td>CHIHUAHUA</td>
</tr>
<tr>
<td>30</td>
<td>NAYARIT</td>
</tr>
</tbody>
</table>

With the focus on the query table window we can select all the records in the query table by pressing CTRL-A or by choosing Edit - Select All.

The result seen in the map is that all of the objects in the query table are selected. However, even though the selection mode is set to Select Replace the province of Oaxaca is still selected.
Next, we can click on the record handle for the Durango province to select it. Because the selection mode is Select Replace, selecting Durango deselects the other records in the query table.

We can see in the map that the province of Durango is selected while the other provinces in the query table are no longer selected.

Finally, with the focus on the query table window we can choose Edit - Select Inverse to invert the selection so that all records except Durango are selected.
In the map window we can see that Durango province has been deselected and all of the other provinces in the query table have been selected. As before, Oaxaca province is still selected.

**Lookup Values and CStr and CAST**

Invoking `CStr` on a lookup value or using `CAST` to convert the value to a string returns the descriptive name of the lookup value.

**Example**

We have a table `T` with a lookup column Region with values East and West. We want to select all records with the value of Region being East. We can do this with the following query:

```sql
SELECT * FROM [T] WHERE CStr([Region]) = "East";
```

**Example**

We have a drawing `D` and we want to select all areas it contains. We can do this with the following query:

```sql
SELECT * FROM [D] WHERE CAST([Type (I)] AS TEXT) = "Area";
```

Geocoding Extensions  
Geometry in Tables
Queries and Geoms

**Geoms** are drawing metrics stored in tables from which linked drawings may be created. See the Linked Drawings and the Geometry in Tables topics for an introduction to geom data.

The numerous Spatial Extensions in Manifold SQL allow using SQL as a very powerful and flexible way of manipulating drawing objects when data for object metrics is stored as a geom in a table. In this conceptual model, all object data is stored as geoms in tables (or converted to geoms on the fly from an existing drawing) and whenever a drawing is desired it is created on the fly as a linked drawing.

In this model SQL becomes the user interface for manipulating data that is geographic or geometric in nature. Although it may seem retrograde to move away from a WYSIWYG, point and click visual interface into an SQL interface, for certain analyses or manipulations of data SQL offers a tool of formidable compactness and power that can be a better approach. This is especially true when automating procedures that are ill-suited for a lengthy series of point-and-click visual operations.

This topic provides a miscellaneous collection of notes and examples using spatial SQL with geoms to illustrate the wide-ranging power of spatial SQL and geoms.

### Create a Triangulation

Triangulate all points in drawing D and output triangulation lines:

```sql
SELECT TriangulationLines(AllCoords([Geom (I)])) FROM [D] WHERE IsPoint([ID])
```

### Using the SPLIT BY Clause

The SPLIT BY clause allows us to split tables using the content of one or more columns.

The SPLIT BY clause has the reverse effect of the GROUP BY clause: the GROUP BY clause collapses groups of records into single records, and the SPLIT BY clause explodes single records into groups of records. Unlike the GROUP BY clause, the SPLIT BY clause does not require the use of aggregate functions.

Consider a hypothetical table with columns called **ID** (an integer field) and **List** (a text field). The values in the **ID** column are used to uniquely identify each record. The values in the **List** column contain a list of names separated by commas. Let us say we want to transform this table so that each original record is replaced with one or more records with individual names in the **List** field corresponding to the same **ID**.

For a conceptual example, if we had a table...

<table>
<thead>
<tr>
<th>ID</th>
<th>List</th>
</tr>
</thead>
<tbody>
<tr>
<td>37</td>
<td>Orange, Blue, Red</td>
</tr>
<tr>
<td>38</td>
<td>Yellow, Green</td>
</tr>
<tr>
<td>39</td>
<td>Purple</td>
</tr>
</tbody>
</table>

...we would like to transform it into...

<table>
<thead>
<tr>
<th>ID</th>
<th>List</th>
</tr>
</thead>
<tbody>
<tr>
<td>37</td>
<td>Orange</td>
</tr>
<tr>
<td>37</td>
<td>Blue</td>
</tr>
<tr>
<td>37</td>
<td>Red</td>
</tr>
<tr>
<td>38</td>
<td>Yellow</td>
</tr>
</tbody>
</table>
We can use the SPLIT BY clause to accomplish the above. The above is a conceptual example only to illustrate how a group or list of items is split by a given field, the ID field. In actual practice, the SPLIT BY clause is used to split tables by one or more geometry columns. For example, we could use the SPLIT BY clause to split a table of lines by branches.

A split function is used to control how the SPLIT BY clause splits data. Currently, the SPLIT BY clause supports the following split functions:

- Branches: Splits geoms by branches
- Islands: Splits area geoms by islands
- Coords: Splits geoms by coords (inflection points).

### SPLIT BY Examples

The following query outputs each branch of each object in drawing D as a separate geom:

```
SELECT [ID], [P] FROM [D] SPLIT BY Branches(Geom([ID])) AS [P];
```

The following query creates a convex hull of each area in drawing D and outputs its coords (inflection points). Linking this query as a drawing will produce a point object at each coord of each created convex hull:

```
SELECT [ID], [P] FROM [D] WHERE IsArea([ID]) SPLIT BY Coords(ConvexHull(Geom([ID]))) AS [P];
```

The following query creates a Voronoi diagram for all points in drawing D and outputs the Voronoi areas for each point:

```
SELECT [P] FROM (SELECT Voronoi(AllCoords(Geom([ID]))) AS [V] FROM [D] WHERE IsPoint([ID])) SPLIT BY Branches([V]) AS [P];
```

The following query creates a Voronoi diagram for all points in drawing D and outputs the Voronoi areas for each point whose ID exceeds 5:

```
SELECT [ID], [P] FROM (SELECT [P] FROM (SELECT Voronoi(AllCoords(Geom([ID]))) AS [V] FROM [D] WHERE IsPoint([ID])) SPLIT BY Branches([V]) AS [P]) INNER JOIN [D] ON Contains([P], [ID]) WHERE IsPoint([ID]) AND [ID] > 5;
```

### The CoordSys and AssignCoordSys Functions

The CoordSys query function loads a coordinate system from a component or a preset with use as follows:

- `CoordSys("Latitude / Longitude")` loads a coordinate system from the Latitude / Longitude preset.
- `CoordSys("D" AS COMPONENT)` loads a coordinate system from a component named “D”.
- `CoordSys([D])` loads a coordinate system from a preset whose name resides in a column named “D”.
- `CoordSys([D] AS COMPONENT)` loads a coordinate system from a component the name of which resides in a column named “D”.

The AssignCoordSys query function assigns a coordinate system to a geom.

The following query selects each object in drawing D and interprets its coordinates as Latitude / Longitude coordinates.
SELECT AssignCoordSys(Geom([ID]), CoordSys("Latitude / Longitude")) FROM [D];

The Project Function

The Project query function projects a geom to a specified coordinate system.

The following query selects each object in drawing \textit{D} and projects it to the coordinate system used in drawing \textit{E}:

SELECT Project(Geom([ID]), CoordSys("E" AS COMPONENT)) FROM [D];

Height Functions and Surfaces

The Height, HeightMax, HeightMin, and HeightSum query functions return the average, maximum, minimum, and summed height of pixels in given surface covered by a geometry object.

The following query selects all points in drawing \textit{D} along with the heights at their respective locations in surface \textit{S}:

SELECT [ID], Height([S], Geom([ID])) FROM [D];

The following query selects all areas in drawing \textit{D} for which the maximum height in \textit{S} exceeds 1000:

SELECT [ID] FROM [D] WHERE HeightMax([S], Geom([ID])) > 1000;

The HeightSum function is used to compute cumulative figures such as population in a given region or to compute the volume of a surface (the HeightSum value multiplied by the size of a pixel).

Creating New Points

The NewPoint and NewPointLatLon query functions create point geoms in either the default (Orthographic) or Latitude / Longitude coordinate systems.

The following query uses the \textit{UTMX} and \textit{UTMY} columns in table \textit{T} to create points in the UTM Zone 17N coordinate systems:

SELECT AssignCoordSys(NewPoint([UTMX], [UTMY]), CoordSys("Universal Transverse Mercator - Zone 17 (N)")) FROM [T];

The following query selects all areas in drawing \textit{D} that contain the Latitude / Longitude location 89W 32N:

SELECT [ID] FROM [D] WHERE Contains(Geom([ID]), NewPointLatLon(-89, 32));

Linear Referencing

The LinePoint query function creates a point on a line geom at a given distance from the start of the line. The LinePart query function creates a new line constituting that part of a line geom between a given pair of distance limits.

Distances continue between branches: If a line contains two branches with lengths of 5 and 6, the first branch contains distances from 0 to 5 and the second branch contains distances from 5 to 11. Obviously, it is easy to get confused when using linear referencing with multi-branched lines so it make sense to split multi-branched objects into single-branched lines before using linear referencing.

Unless we specify a unit parameter, all distances are measured in native drawing units.
**Linear Referencing Example**

Let us say we have a drawing $D$ and a table $T$ which contains records in the form: $ID$, $F$, $T$, where $ID$ is the ID of a line in $D$, $F$ is a "from" distance on that line, and $T$ is a "to" distance on that line.

The following query traverses all records in $T$ and extracts those parts of lines it specifies:

```
SELECT LinePart([T].[ID], [F], [T]) FROM [T] INNER JOIN [D] ON [D].[ID] = [T].[ID];
```

The following query traverses all records in $T$ and extracts all "to" points it specifies:

```
SELECT LinePoint([T].[ID], [F]) FROM [T] INNER JOIN [D] ON [D].[ID] = [T].[ID];
```

**Queries and Coordinate Systems**

When queries are used to create objects in linked drawings the objects in those drawings will be based upon the coordinate system in use in whatever source drawings or geoms are used in the query. The units used to compute, say, a buffer will be the local units used in the projection.

Suppose we have a drawing containing point objects that is called $Points$. Consider a query like the following:

```
SELECT Buffer(Geom([ID]), 1000, "mi") FROM [Points];
```

Suppose a linked drawing is created from this query. The buffer objects the query creates may or may not appear to be circles depending upon the coordinate system (projection) used in the $Points$ drawing. The query will create buffer areas such that the outline of each area is the same distance, 1000 miles, from the central point for each area. However, this may or may not be shaped like a circle depending on the projection used.

If the $Points$ drawing contains one point and the projection for the $Points$ drawing is the Orthographic or similar azimuthal projection centered exactly on that one point then the result will be a true geographic circle. However, if the projection is otherwise what will appear on the screen will be a circular area (because in the drawing's local coordinate system each location on the boundary of the buffer will be equidistant from the point) but it will not actually draw a geographic circle on Earth.

For illustrations of this effect and the difference between drawing a circle upon a projected map and creating a geographic circle, see the Adding Shapes topic.

Queries and Images or Surfaces
Queries and Images or Surfaces

Queries may be written using the virtual tables of images or surfaces. Such queries can extract data from images or surfaces or they can manipulate the data in images or surfaces. See the Virtual Tables for Images and Surfaces topic for a list of columns in a virtual table and other details on virtual tables.

Queries can refer to the virtual table of an image or a surface by using the name of the image or surface. For example, the following query displays the total number of selected pixels in an image named **Bronze**:

```
SELECT Count(*) FROM [Bronze] WHERE [Selection (I)];
```

The following query displays the total number of selected pixels in a surface named **Foothills**, the heights of which do not exceed 100:

```
SELECT Count(*) FROM [Foothills] WHERE [Selection (I)] AND [Height (I)] <= 100;
```

**Example**

Consider the sample **bronze** image in which a rectangular region of pixels has been selected.

We can write a query, called **Bronze Query**, which selects selected pixels in the image.

```
SELECT * FROM [Bronze] WHERE [Selection (I)];
```

The above query uses the **Selection (I)** intrinsic field of the virtual table to select all fields for all pixels that are selected.

If desired, we can now create a linked image using that query. We choose File - Link - Image and in the Files of type box in the Link dialog we choose This Project().
In the Link Data dialog we choose the query we created. The rest of the fields use default values since we know the query has been created from an image using SELECT * so that all the required columns are generated by the query.

The result of the image linking operation is that a new component, a linked image, appears in the project pane.

If we open the linked image we see that it consists of the pixels that were selected in the image which is the subject of the query from which the linked image was created.
Suppose we change the selection in the **Bronze** image.

If we click on the linked image and do a **View - Refresh Data** command then the linked image will automatically change to show the current results of the query. Note that, since images must be rectangular in extent, any additional pixels required to create a rectangular image will be invisible.

**Example**

Consider a portion of the example Montara Mountain surface on the Manifold CD.
We can create a query that selects all pixels where the height of the surface is greater than or equal to 1000.

We shall call the query **Montara Query**. We can then create a linked surface based upon that query.

To do so, we choose **File - Link - Surface** and in the Data Source dialog we choose **This Project**. In the resulting **Link Surface** dialog, seen above, we choose the **Montara Query** query and use default settings otherwise.
The result is that a linked surface appears in the project pane. Note that the linked surface has a terrain associated with it just as would any other surface.

If we open the linked surface, we can see it contains those pixels in the original surface that are at a height of 1000 or greater. Note that the new surface is not colored with any palette. We can use the **View - Display Options** command to color it as we see fit. If we would like to duplicate the coloring used in the original Montara surface, we can open the Montara surface, choose **View - Display Options** and then use **Save to File** to save the exact palette being used to an .XML file.

We can then open the linked surface, choose **View - Display Options** and use **Load from File** to load the palette desired from the .XML file to which it was saved.

**Projections and the OPTIONS Clause**

By default, queries using virtual tables for images or selections do not save projection information. The image and surface created in the above examples will be created in a default Orthogonal projection that is not georeferenced. To save projection information, we can use the OPTIONS clause with the **CoordSys** query function. The OPTIONS clause allows a declaration of options for query execution and usage. At the present time, the only option for this clause is the **CoordSys** query function.

**Note:** The OPTIONS clause must be the first clause in the query, since it potentially specifies the operation of all the rest of the query.

Consider the following two queries operating on a surface named **Surface**:

```
SELECT * FROM [Surface] WHERE [Height (I)] > 100;

...and...

OPTIONS CoordSys("Surface" AS COMPONENT);
SELECT * FROM [Surface] WHERE [Height (I)] > 100;
```
Both queries select all pixels with a height greater than 100. However, linking a surface from the first query will create a surface in the default Orthographic projection, since pixels do not carry coordinate system data, but linking a surface from the second query will create a surface using the coordinate system (that is, the projection) of the original surface.

The OPTIONS clause works for drawings, too.

**Example**

We have a large surface and we would like to create a query that grabs only a portion of that surface within a given latitude and longitude range. We will then create a linked surface based on the query. The result will be a surface that is only a portion of the larger surface. We will use an OPTIONS clause in the query to make sure the resulting linked surface is correctly georegistered using the same projection as the original surface. This is a common technique for Internet Map Server (IMS) applications.

We begin with a surface showing dropout rates from high school in the US (blue represents lower dropout rates, red shows higher dropout rates). This is the same surface created in the Displaying Data in a Gradient Map example. We have colored the background black and have turned on a graticule showing latitude and longitude lines every five degrees.

We write a query called Surface Query that selects pixels between -85 and -80 degrees longitude and between 35 and 40 degrees latitude. The OPTIONS clause will ensure that linked surface created from the query will use the same projection as the original surface.
If we create a linked surface from the query we see that only that portion of the surface within the desired latitude and longitude ranges is in the linked surface. [The illustration seen above was created by using View - Display Console - Save to File from the original surface to save the palette, and then View - Display Console - Load from File in the linked surface to load the saved palette. This assures that both surfaces are colored the same way.]

For use in an application like an IMS website, we would probably rewrite the query used in this example as a parameter query as seen above. This would allow users to specify the minimum and maximum longitude and latitude range to get the desired portion of the surface.

To see the effect of parameter queries when working interactively with Manifold at the PC console (that is, not using IMS) we will have to manually refresh the linked component using the following procedure:

Create a parameter query. Launch the query using the ! button and supply values for the parameters. Next, link a surface from the query. The surface will use the data computed with the parameters that were supplied. Launch the query one more time and supply new values for the parameters. Refresh the surface by invoking View - Refresh Data. The surface will then use data computed with the new parameters.

**Example**

Spatial SQL can include functions for dynamic geometry that can be used to create linked drawings, that is, linked drawings that are created from spatial SQL queries. These can even be created from queries using an image's or a surface's virtual table.

Suppose we start with the surface from the previous example, with part of the surface selected as seen above.
We can write a query, called **Selection Points**, that creates a point for each selected pixel in the surface. The OPTIONS clause at the beginning of the query assures that any linked drawing created from this query will have the same coordinate system as the surface and thus will be correctly georegistered.

Using **File - Link - Drawing** with **This Project** in the Data Source dialog, we can create a linked drawing. The **Link Drawing** dialog is completed as seen above.

**Link Drawing**

- **Data source:** This Project
- **Type:** Table with geometry column
- **Source:** Selection Points
- **Columns:**
  - Column
  - Height (')
- **Geometry:** Column
- **Geometry type:** Geometry
- **Version:** [None]

The result is a linked drawing that consists of a mass of points arranged in the shape of the selected region of the surface.
The drawing is read-only, because it is created based on a query. If we want to use this drawing in subsequent operations and we would like it to be writable, we can make a writeable copy of it by right clicking on the linked drawing in the project pane and choosing Duplicate from the context menu. That will create a copy of the drawing as a separate, ordinary drawing.

Alternatively, we could right click on the linked drawing in the project pane and choose unlink to convert it from a linked drawing into a regular drawing. Choosing unlink sever all connections with the query.

Relink and Unlink

If a connection is lost between a linked image or surface and its originating data, the Image - Relink or Surface - Relink command allows us to restore the connection. If we would like to convert a linked image or surface into a regular image, the Image - Unlink or Surface - Unlink command will sever all connections to the originating source and will convert it into a regular image or surface.

Updates

Suppose we create a linked image or surface from a query or table. If the data changes we must use View - Refresh Data to update the linked image or surface. Simply closing and opening the component is not enough to refresh it.

Refreshing a component linked from a table or query is always done manually or via a script. One of the reasons for this is that the table or query providing data for the linked component may be external to Manifold. For example, it may reside in a remote database managed by SQL Server or Oracle. In such cases, depending upon the nature of the connection to that database, it could be very computationally expensive to determine when the remote data has been updated and thus a change in the linked component is required. Some queries can also be very expensive to run in terms of processor bandwidth and user interface pauses.

For these reasons, Manifold caches linked components so that the system is not loaded running unnecessary queries or continuously making computationally expensive determinations that no changes have occurred.

Units of Measure in Linked Surfaces

A limitation of Manifold's linked surfaces mechanism is that File - Link - Surface dialog expects heights to be represented in meters. If a linked surface is generated using a data set in which heights are expressed in feet or some other unit, then the hill shading effect will be overly dark.

A workaround for this limitation is to convert heights to meters if they are in some other unit. This may easily be done within the spatial query from which the linked surface is generated. For example, the Montara Mountain on the Manifold CD expresses heights in feet. To use heights in meters, we could write the following query:

```sql
OPTIONS CoordSys("Montara" AS COMPONENT);
SELECT [Height (I)]*0.3048 AS Z, [X (I)], [Y (I)] FROM Montara;
```

We could then use Z as the height in the Height box in the Link Data dialog.

Checking for Invisible Pixels

When writing a query that uses an image's or a surface's virtual table, it is usually wise to add a check for invisible pixels. Images or surfaces may have large regions of invisible pixels, and it usually does not make sense to return via a query many pixels that cannot be seen. We can easily accomplish this using the Invisible (I) field. For example, the Montara Mountain on the Manifold CD expresses heights in feet. To use heights in meters, we could write the following query:

```sql
OPTIONS CoordSys("Montara" AS COMPONENT);
SELECT [Height (I)]*0.3048 AS Z, [X (I)], [Y (I)] FROM Montara;
```

We could then use Z as the height in the Height box in the Link Data dialog.
Queries

* FROM [Surface]
WHERE
  ([Longitude (I)] >= MinLon AND [Longitude (I)] <= MaxLon) AND
  ([Latitude (I)] >= MinLat AND [Latitude (I)] <= MaxLat) AND
  NOT [Invisible (I)];

To illustrate that different indentation styles are possible the query text above uses a different style of indenting than the other examples in this topic. Manifold SQL is very tolerant of “white space” characters such as tabs, extra spaces or returns so that we can arrange our text using whatever style we think is most comprehensible.

Examples of UPDATE Queries

Because some fields of an image’s or surface’s virtual table are writeable (see the Virtual Tables for Images and Surfaces topic for a list of writeable fields), we can use UPDATE queries to change an image or surface.

Make all pixels with a value in the alpha channel greater than 200 invisible:

UPDATE [Image] SET [Invisible (I)] = True
WHERE [Alpha (I)] > 200;

Make all selected pixels red:

UPDATE [Image] SET [Color (I)] = RGB(255, 0, 0)
WHERE [Selection (I)];

Raise heights of all selected pixels by 10:

UPDATE [Surface] SET [Height (I)] = [Height (I)] + 10
WHERE [Selection (I)];

Select all pixels with heights between 10 and 30:

UPDATE [Surface] SET [Selection (I)] = True
WHERE [Height (I)] BETWEEN 10 AND 30;

Select all pixels with heights between 10 and 30 degrees and deselect all other pixels:

UPDATE [Surface] SET [Selection (I)] =
  ([Height (I)] BETWEEN 10 AND 30);

Examples of Analysis done with Queries

Queries may be used to perform analysis on images and surfaces as the following examples illustrate.

Determine the number of pixels falling into a given height range:

SELECT Count(*) FROM [Montara]
WHERE [Height (I)] BETWEEN 1000 AND 1200;

Determine the number of pixels falling into a given intensity range:

SELECT Count(*) FROM [Montara]
WHERE Intensity([Color (I)]) BETWEEN 240 AND 255;

Create a table of all heights along with their relative frequencies:

```
SELECT
  Sum(Iif([Height (I)] <= 499, 1, 0)) / Count(*),
  Sum(Iif([Height (I)] BETWEEN 500 AND 999, 1, 0)) / Count(*),
  Sum(Iif([Height (I)] BETWEEN 1000 AND 1499, 1, 0)) / Count(*),
  Sum(Iif([Height (I)] >= 1500, 1, 0)) / Count(*)
INTO [Percentages] FROM [Montara];
```

**Tech Tip**

Consider the linked drawing created from a surface in an example above, which contains a mass of points arranged in the shape of the selected region of the surface. How might we use those points to create an area object in the same shape?

This is a surprisingly complex task due to the ambiguities involved in determining where "holes" or "islands" should be placed in the resultant area object. It's an easy thing for the human eye to see in cases of such dense point placement, but in regions where points might be very sparsely placed it could be difficult even for the human eye to decide where an area should begin or end.

For an automated process, we can create buffers or rectangular areas or a convex hull about the points to approximate the region covered with an area object. The following queries provide some example approaches.

**Buffers (slowest, area slightly increased):**

```
SELECT
  UnionAll(Buffer(AssignCoordSys(
    NewPoint([X (I)], [Y (I)]),
    CoordSys("Montara" AS COMPONENT)), 10, "m"))
FROM [Montara] WHERE [Height (I)] > 1600;
```

**Rectangles (slightly faster than buffers, area slightly increased):**

```
SELECT
  UnionAll(BoundingBox(Buffer(AssignCoordSys(
    NewPoint([X (I)], [Y (I)]),
    CoordSys("Montara" AS COMPONENT)), 10, "m")))
FROM [Montara] WHERE [Height (I)] > 1600;
```

**Convex hull (fastest, but probably least "accurate"):**

```
SELECT
  ConvexHull(AllCoords(AssignCoordSys(
    NewPoint([X (I)], [Y (I)]),
    CoordSys("Montara" AS COMPONENT))))
FROM [Montara] WHERE [Height (I)] > 1600;
```

**Notes**

Many of the above techniques (such as using a spatial query to select by latitude and longitude) can be used with images, surfaces or, with slight modifications, drawings.

Geocoding

Geocoding is the process of finding the correct geographic position for a record in a table and then adding latitude and longitude values for each record in a table. Before continuing with this topic, please first read the About Geocoding topic.

There are two main types of geocoding:

- **Street Address Geocoding** uses the values of address fields such as street, city, state or province, and postal code to estimate the location for that record. Street address geocoding requires a specialized database that gives the position of various address ranges for different streets. As a practical matter, address information is rare and expensive outside of the United States, although the auxiliary use of MapPoint for Canada, Mexico and eleven countries in Europe provides a low cost option in those regions. Even within the United States, because of the highly irregular nature of addresses in the US and the poor quality of most address databases, street address geocoding provides at best an approximation of where a given address is truly located. See the Street Address Geocoding topic for more information.

- **Spatial Geocoding** matches the values of records in a database table with field values in the table of an available drawing. The spatial layout and locations of the drawing objects are used to determine locations for records that match object data fields. In Manifold marketing documents this capability is at times referred to as “generic geocoding.” Spatial geocoding has the advantage of allowing spatial matches to any available drawing. See the Spatial Geocoding with Match topic for information on spatial geocoding with Manifold.

Requirements

**Spatial geocoding** using **Match** does not require purchase of any options, but it does require a drawing to which matches can be made. For example, if we would like to geocode a table by Chilean postal codes then we will need a drawing showing centroids of Chilean postal codes that **Match** can use for the geocoding process.

Street Address Geocoding has two requirements:

- We must acquire and install a license for the optional Manifold Geocoding Tools package. The **Geocoding Tools** package is a built-in part of Manifold **Universal Edition**, but it is an optional extension to other Manifold System editions.

- We must have access to one or more of the geocoding data sources that can be used by the internal Manifold geocoding engine. Once enabled by installation of the **Geocoding Tools** package, Manifold can use a variety of geocoding data sources, including the Manifold Geocoding Database for US streets provided as a free download on the **manifold.net** site, MapPoint North American or European editions, user-provided geocoding data extensions or Manifold Geocoding Servers accessed through the web. The geocoding data source in use must be appropriate to the geographic region of interest. For example, if we have the US street geocoding database provided as a free download on the **manifold.net** site, that will allow us to geocode street addresses in the US but not in Europe.

- Spatial Geocoding with Match
Geocoding Tools

The Geocoding Tools package is an optional extension to Manifold System that provides street address geocoding capability as well as access to the Manifold Geocoding Database data provided as a free download on the manifold.net site for both US street address geocoding as well as the easy creation of drawings showing US streets. The Geocoding Tools package also requires access to one or more of the geocoding data sources that are required for street address geocoding.

If you do not have the optional Geocoding Tools package you will not be able to use street address geocoding functions within Manifold (regardless of the data source used) or take advantage of the street address geocoding data provided as a free download on the manifold.net site for the United States. If you do not also have at least one geocoding data source appropriate to the geographic region of interest (regardless of whether you have installed the Geocoding Tools package), you will not be able to use street address geocoding functions. If you plan on using the Manifold Geocoding Database see the Geocoding Data Sources topic for instructions on installing the database provided as a free download on the manifold.net site.

Very important: the Geocoding Tools package will not be operational until you install at least one geocoding data source. You must install at least one geocoding data source.

The Geocoding Tools extension adds functionality in several areas:

- Street address geocoding within the United States using the Manifold Geocoding Database provided as a free download on the manifold.net site.
- Street address geocoding within North America or Europe using the appropriate edition of Microsoft’s MapPoint product as a data source.
- Street address geocoding anywhere in the world using user-provided geocoding data extensions in either range or points of interest formats.
- Street address geocoding using web-based Manifold geocoding servers to provide geocoding services.
- Easy import of drawings showing US streets from the Manifold Geocoding Database provided as a free download on the manifold.net site as set forth in the Import Drawing - Geocoding Database topic.
- Geocoding Extensions may be used within SQL to allow use of street address geocoding functions within SQL queries.
- Programming objects such as the Geocoder object may be used from scripts or other programs or from within IMS applications.
- Street addresses and ZIP codes may be used in the Edit - Go To dialog.

If you do not have the optional Geocoding Tools package enabled you will not have the above capabilities enabled within Manifold System. This documentation describes these commands but they will not be enabled if you do not have the Geocoding Tools package enabled.

Installing Geocoding Tools

The Geocoding Tools package is built into your Manifold System installation and becomes enabled for use when activated. Activate it by providing a Geocoding Tools serial number and Activation key that turn on Geocoding Tools functionality. The process of activating the Geocoding Tools extension is very similar to that used to activate Manifold System. See the Activation Keys and Serial Numbers topic and the Installing and Activating a Manifold Extension topic for details.

Some Manifold product options, such as Universal Edition or Ultimate Edition, use a single serial number and Activation key to enable permanent installation of both Manifold System as well as extensions. If you have activated Universal Edition or Ultimate Edition you do not need to individually turn on Business Tools or Geocoding Tools or Surface Tools. Activating Universal Edition or Ultimate Edition will also automatically turn on all three extensions.

Turning on Geocoding Tools

If you have licensed Universal Edition, you do not need to turn on Geocoding Tools. The Geocoding Tools extension is automatically enabled with a Universal Edition serial number.

If you have not licensed Universal Edition and you wish to add Geocoding Tools functionality to your installation, begin by acquiring a Geocoding Tools license from manifold.net, which will provide you with a Geocoding Tools serial number.

2. Launch Manifold System. Close any projects that may be open.

3. Choose Help - Activate Extension

4. Enter the Geocoding Tools serial number. Enter it exactly as it was issued to you by manifold.net. Do not change upper case to lower case. Do not replace hyphens with space characters or make any other changes to the serial number. If desired, you may also enter an Activation key for the serial number as well. Press Accept.

5. Manifold will then exit. When re-launched, the Geocoding Tools package will be enabled.

6. Using the serial number alone the Geocoding Tools package may be run for 30 days from the date the serial number was issued. After that, an Activation Key must be fetched and provided to the Help - Activate Extension dialog together with the serial number. Once an Activation Key and a serial number have been provided to the Help - Activate Extension dialog the extension will be permanently installed. Don't forget to login as Administrator when permanently activating the Geocoding Tools extension.

7. Install a geocoding data source - You must have at least one geocoding data source installed to operate the Geocoding Tools package. Most US users will download and install the Manifold Geocoding Database provided as a free download on the manifold.net site

---

**Status of Extensions**

The Help - About dialog shows all extensions that have been installed. If a serial number only has been used to install an extension, the number of days left before an Activation key is also required will be shown.

Manifold Geocoding Servers
Street Address Geocoding

Street address geocoding is the process of determining an estimated latitude and longitude position for the location of a street address, such as "1600 Pennsylvania Avenue NW, Washington, DC 20500." Manifold includes a sophisticated street address geocoding engine, but it must be enabled through the installation of Geocoding Tools and supported by access to an appropriate geocoding data source. Before continuing with this topic, please first read the About Geocoding topic.

Street Address Geocoding within Manifold is mostly used in two situations:

- Adding a latitude and longitude location to each record in a table of addresses. The table then becomes a geocoded table and can easily be copied and pasted as a drawing. Geocoding the street addresses allows us to see where they are located as points in a drawing.
- Using a street address within interactive commands such as the GoTo command. In that case the street address is "geocoded on the fly" to determine the latitude and longitude location to be used by the command.

In addition to the above uses, Manifold street address geocoding facilities are also used within SQL queries and are used by programmers via the Manifold API.

Required Geocoding Tools

Manifold's street address geocoding capability becomes operational only when the optional Manifold Geocoding Tools package is installed. If you do not have the optional Geocoding Tools package, you will not be able to use street address geocoding functions within Manifold (regardless of the data source used) or take advantage of the Manifold Geocoding Database provided as a free download on the manifold.net site for the United States.

Note that Manifold Universal Edition automatically installs the Geocoding Tools package. If you are using Universal Edition, you do not need to perform an extra Geocoding Tools installation as it has already been installed.

Required Geocoding Data Sources

In addition to installation of Geocoding Tools, the Manifold installation must have access to a geocoding data source. Once enabled by installation of the Geocoding Tools package, Manifold can use a variety of geocoding data sources, including the Manifold Geocoding Database for US streets provided as a free download on the manifold.net site, MapPoint North American or European editions, user-provided geocoding data extensions or Manifold Geocoding Servers accessed through the web.

Without a geocoding data source such as the US streets Manifold geocoding database or MapPoint, Manifold's street address geocoding commands cannot function. The Manifold Geocoding Database supports US street address geocoding only. The Microsoft MapPoint North American edition product will allow street address geocoding in the US and Canada, while the European edition of MapPoint will allow street address geocoding in eleven European countries. User-supplied geocoding extensions can cover whatever region the user desires. Web-based servers vary greatly in the regions they cover. See the Geocoding Data Sources topic for information on these sources as well as information on installing the Manifold Geocoding Database provided as a free download on the manifold.net site.

Limitations of Street Address Geocoding

Unless a special type of geocoding data source is used that provides data in "points of interest" format, the latitude and longitude location created for a given address by Manifold is only an estimate. In all cases, the accuracy of either the estimate or a putatively-precise location made possible by points of interest data sources will be determined by the accuracy and detail of the geocoding data source used. As the famous saying has it, "Garbage in, garbage out."

If the data source in use does not include a particular street or does not include information on the address of interest, that address cannot be located. At times addresses in use in the US and other countries will vary considerably from the usual pattern to the degree they cannot be easily cited within a data source.

For these and other technical reasons, street address geocoding normally cannot find latitude and longitude locations for all street addresses submitted and the locations which are found will at best be estimates and not exact locations. Street address geocoding using high quality geocoding data sources in urban areas that feature
regular address patterns on streets will often result in high hit rates, with over 90% of addresses routinely being located and geocoded to within a few dozen meters of their actual locations. Street address geocoding done in rural areas with irregular address patterns can have abysmally poor hit rates and accuracy unless the geocoding data source is a user-supplied geocoding data extension using points of interest format.

Requirements for Records to be Geocoded

Manifold can geocode an entire table containing street address records, a process often called "batch street address geocoding" in GIS nomenclature. Records that are to be geocoded must have the following characteristics:

- **Standard fields** - Each record must include four standard text columns containing street address, city, state and ZIP code. Using Standardize, it is usually possible to fill in missing ZIP codes based on street address, city and state information. The Country field by default uses the United States; however, when geocoding outside of the United States using MapPoint the Country field should be used to specify the country for that address.

- **Well-formed addresses** - Address fields cannot contain multi-line values or special characters such as newlines.

- **Complete street addresses** - Street address fields should contain the true name of the street. For example, if an address is located on "Johnston Road" the street name should not just be something like "265 Johnston" but should include the full "265 Johnston Road" or include a standard abbreviation for "Road".

- **No extensions** - The column containing the street address must contain the street address only without any additional address information such as apartment number or other embellishments (such additional information can be kept in a separate field).

- **Text columns** - Columns used for geocoding must be text columns, not numeric columns. Note that many postal codes, such as ZIP codes, have leading "0" characters (with ZIP codes such as "02138") that are significant and will be preserved if a text column is used and lost if a numeric column is used.

- **International addresses** - See the Geocoding with MapPoint topic for additional requirements and limitations when geocoding Canadian or European street addresses using MapPoint.

When geocoding addresses, most effort will be expended on cleaning addresses and converting those that are in non-standard form into standard form. This is accomplished with the Standardize command. Once addresses have been standardized, we can use the Geocode command to geocode them.

The Manifold Geocoding Database or some other geocoding data source must be installed on for either of these commands to function. If a usable geocoding data source has not been installed, neither of these two commands will be enabled.

The Standardize and Geocode dialogs are related in how they use the geocoding database and both dialogs use the same Unmatched Records dialog to allow manual adjustments to records that cannot be automatically standardized or geocoded. The Standardize dialog uses the geocoding database to look up valid zip codes, city names, street names and address ranges. It can use that information to identify errors in records and to offer alternatives. The Geocode dialog uses presumably valid address information to determine, if possible, the latitude and longitude location of a specific address.

To geocode a table of street addresses:

1. Open the table of addresses. If the addresses are not known to be absolutely clean and well formed we should first run Table - Address - Standardize to eliminate common problems.
2. Choose Table - Address - Geocode. Specify the fields that are to be used for the standard geocoding fields of Address, City, State and Zip. Specify which fields are to contain the created latitude and longitude values or let Manifold create new columns for these values. Press OK.
3. Any records that cannot be automatically located in the geocoding database will be presented in the Unmatched Records dialog. This dialog will allow us to edit the record to make corrections. It will present a menu of nearest matches, if any, from which we can quickly choose a desired match.

After geocoding the table will contain latitude and longitude columns that will contain the latitude and longitude location of each record.

Standardize
The **Standardize** command is used to convert addresses from non-standard forms into the standard form expected by the Manifold geocoder. It has several functions:

- **Extract Address, City, State and Zip fields** - Given one or more address fields that contain a mix of street address, city, state and Zip code information, the command will attempt to parse the data and (usually) extract information into four newly-created standard **Address**, **City**, **State** and **Zip** fields. The command can normally extract the main street address from a single address field. For example, if we have a single database field called "Street Address" that contains a string such as "408 Queen Street Suite 35, Causeway Bay, Kansas" Manifold can parse the string to obtain "408 Queen Street" for the **Address** field.

- **Find missing Zip codes** - If a Zip code is not present the command can usually find the missing Zip code or present possible matches for approval.

- **Normalize address nomenclature** - If the **Normalize addresses** box is checked the command will convert address nomenclature into standardized abbreviations, such as "Rd" for "Road," and will convert state names into official postal abbreviations. The command will also correct elementary errors in case, such as converting "1208 Hennessy ROad" to "1208 Hennessy Rd".

- **Check for unknown locations** - The command will automatically check for impossible combinations of streets, towns and zip codes, including unknown town names, street names and other clearly inaccurate address data.

The **Standardize** command will process a table and then raise the **Unmatched Records** dialog to allow editing and selection of proposed matches the system thinks are close to what is intended.

### Standardize Addresses Dialog Controls

<table>
<thead>

</table>
records designated Address, City, State and Zip fields.

Fail on Options

any error Does not process record unless it is a perfect match in all fields. Equivalent to setting an "unknown building" error.

unknown street name, possible misspelling Matches to Zip and City and does not process record unless the street name is an exact match.

unknown street name, no similar names Matches to Zip and City, and attempts to match to similar street names if an exact match to the street name cannot be found. Uses “Soundex” and similar algorithms to attempt to find the right street in case of a street name misspelling. This is the default setting.

unknown zip Do not process record if the zip code cannot be found.

critical error Stop processing only on problems with an incomplete geocoding database or on hardware failure.

Status Values

When reporting the status of a record's processing in a Status field the following values are used, listed in order of increasing severity:

ok No errors in processing record.

unknown building The geocoder was able to locate the zip code and the street name, but the street does not appear to contain an address of the given number.

unknown street name, possible misspelling The geocoder was able to locate the zip code but not the street name; however, the zip code does contain some streets with names similar to the street name.

unknown street name, no similar names The geocoder was able to locate the zip code but not the street name. The zip code does contain any streets with names similar to the street name.

unknown zip code The geocoder could not locate the zip code.

critical error The geocoder could not function due to an incomplete geocoding database, a problem accessing the database or a hardware failure.

Search Priority

The biggest difficulties encountered when standardizing addresses arise from errors in the address. Addresses may be incomplete, missing zip codes, for example, or they may incorporate typographical or other errors that result in erroneous zip codes, city names, street names and building numbers. At times, cities may be called by local names that are different than those officially recorded by the US government. For example, a small town located North of Boston is called "Manchester," "Manchester-by-the-Sea" and "Manchester by the Sea".

Manifold helps deal with such errors by prioritizing searches for standardization and geocoding using the following order of precedence:

- Search by zip code and then search by street name and building number.
- If the zip code and street can be located but there is no address range on the street that allows the given building number the system will return the data found and will generate a unknown building error.
• If the zip code can be located but no such street name can be found within that zip code, the system tries to locate streets with similar names. Variations will be scanned for different prefixes (for example, "East" or "West" in combination with the street name), different types ("Road," "Street," "Drive," "Lane," etc.), typical abbreviations and possible misspellings. Finally, the system will search for street names that sound like the one given. If similar street names can be found, the system will return the data found and will generate an unknown street name, possible misspelling error.

• If the zip code cannot be found or if there are no streets with similar names found, the system tries to located street names (first, by exact matches and then approximate matches) in a wider geographic area, first within the city name given and then within the state name given. It then returns the data found and generates either an unknown street name, no similar names error or unknown zip error depending on whether the search started with a valid zip code or not.

The setting used for the Fail on parameter allow Manifold to accept failed address matches up to a given level of severity. For example, the default setting of unknown street name, no similar names for the Fail on parameter will allow Manifold to automatically accept records for which an unknown building or an unknown street name, possible misspelling error would be reported.

**Geocode**

The Geocode command takes an address in standard form, finds it in the Manifold Geocoding Database and then produces latitude and longitude values for the location of the address. Addresses to be geocoded must include the four standard Address, City, State and Zip fields.

Records that cannot be located within the error level specified by the Fail on parameter will be reported in an Unmatched Records dialog to allow editing and selection of proposed matches the system determines may be the correct locations. If a particular address cannot be located on a street, the system will report "Building not found" and will offer a match to the address. Choosing that match will choose a location for the address that is at the midpoint of the street segment for the street of that name.

Records that cannot be geocoded at all, even after manual intervention, will have zero values for latitude and longitude. When the table is copied and pasted as a drawing these records will be ignored if the Skip zero latitude / longitude records option is checked (the default setting) in the Paste As Drawing dialog.

If an address cannot be found in the available street address ranges for a specific street the command will choose a point near the middle of the street segment.

**Geocode Addresses Dialog Controls**

- **generate ... using** Specify the columns to be used for Longitude and Latitude, Status and Match type fields, and which columns in the table should be used for the standardized Address, City, State, and Zip fields.

- **Longitude** Table column to be used for the longitude of geocoded record. Contains 0 if the record was not geocoded. Use [New Column] to automatically create a new column called Longitude.

- **Latitude** Table column to be used for the latitude of geocoded record. Contains 0 if the record was not geocoded. Use [New Column] to automatically create a new column called Latitude.

- **Status** If desired, add a column that reports the status of a particular record after processing. [None] does not report status, [New Column] will add a new column to the table called Status.

- **Match type** If desired, add a column that reports the geocoding match type of a particular record after processing. [None] does not report match type, [New Column] will add a new column to the table called Match type.

- **Fail on** Criterion to be used to declare a particular record to be unmatched.
Offset Locations by
Offset the location for each geocoded record by the given number of units from the street line, to the left or right side of the street based on whether the address was found in the left or right range.

Skip completed records
Do not process records that already have values in the designated Address, City, State and Zip fields.

Fail on Options

any error
Does not process record unless it is a perfect match in all fields. Equivalent to setting an "unknown building" error.

unknown street name, possible misspelling
Matches to Zip and City and does not process record unless the street name is an exact match.

unknown street name, no similar names
Matches to Zip and City, and attempts to match to similar street names if an exact match to the street name cannot be found. Uses "Soundex" and similar algorithms to attempt to find the right street in case of a street name misspelling. This is the default setting.

unknown zip
Do not process record if the zip code cannot be found.

critical error
Stop processing only on problems with an incomplete geocoding database or on hardware failure.

Match type Values

When reporting the status of a record's processing in a Match Type field the following values are used, listed in order from most precise to least precise:

building
The zip code, street name and building number were used to identify a location at the building's number.

street
The zip code and acceptable street name were found but not the building's number so the location has been placed at the center of the bounding box for the street.

zip
Only a zip code was used so the location has been placed at the center of the bounding box for the zip code.

city
Only the city name was used so the location has been placed at the center of the bounding box for the zip code.

(empty string)
The record could not be geocoded and values of 0 have been written into both Latitude and Longitude.

Selections

Both the Standardize and the Geocode commands are auto-scoped: if a selection is present in the table they will operate only on the selected records.

Example
Suppose we have a table like that above, which contains two text fields: a Name field and a Street Address field. The table lists a few sushi restaurants near the USGS facility in Menlo Park, California. To geocode this table we must first standardize the addresses it contains using the Standardize command by choosing Table - Address - Standardize.

The Standardize Addresses dialog allows us to designate which fields will be used as sources to generate the five standard Address, City, State, Zip and Country fields and which existing fields, if desired, will host the four standard fields. We choose Street Address as the source for the new fields and [New Column] for each new field to be generated, so that a new column is created for each. Note: We will have to explicitly choose [New Column] for the Address column, since Manifold will by default the Street Address column into that field since it has "Address" in the name of the field and Manifold will guess that we might want to use it.
The result is that five new columns, Address, City, State, Zip and Country, have been created in the table and the relevant parts for each record have been extracted from the Street Address column and placed in the new columns.

Let's hide the Street Address column to reduce the size of the illustrations. We also hide the Country field since we don't need an explicit reminder that these locations are in the United States. That makes the table smaller but the Address and City fields look ugly all in capital letters. We can convert them to title case by using the Make Title Case operator in the transform toolbar for the Address and City columns.
That's better. Manifold will happily geocode whether or not columns contain all upper case letters so the above step is not necessary. But using title case makes the table more legible to humans so that's what we prefer to use. The table above is now in standard form so we can geocode it using Table - Address - Geocode.

The Geocode Addresses dialog allows us to choose which columns will be used for the four standard fields used by the Manifold geocoder. Even though the Country column is not visible, Manifold knows it is still in the table and can use it. Even if we did not have an explicit Country column Manifold would know to use the default country set in the Tools - Options dialog. We can also choose which columns will receive the generated latitude and longitude locations.

The Offset locations by checkbox will automatically position geocoded points to the left or right side of a street based on which side of the street that address falls on (according to the geocoding database). The distance and units boxes allow us to choose how far from the street centerline the geocoded points will be offset. The default offset is 50 feet.

The Skip completed records checkbox tells the dialog to ignore records that already contain data in the target fields.

If all records can be matched by the geocoder the result will be the addition of two new columns to the table called Latitude and Longitude that contain the latitude and longitude locations for each address. The table is now a geocoded table and can be copied and pasted as a drawing.
If we copy the table and paste it as a drawing, we can drag and drop the drawing into a map created from a drawing of roads in the Menlo Park and Palo Alto area. The points have been formatted as bright green dots.

**The Unmatched Records Dialog**

The Unmatched Records dialog is used with both the Standardize and the Geocode commands. In both cases, records that cannot be correctly standardized or geocoded are presented one by one within the Unmatched Records dialog to allow users to deal with each record on a case-by-case basis.

The dialog presents the address record being processed in editable boxes for Address, City, State and Zip fields. A list of possible alternatives found in the geocoding database is presented in a Found pane. We can edit the fields manually or, if we see a match that we like in the Found pane we can click on it to highlight the match and load it into the edit boxes in the dialog. Pressing Accept will save the values from the edit boxes into the record in the table, including the latitude and longitude in the case of the Geocode command.

If desired (say in the case of an obvious typographical error in the name of a street) we can edit the values in the Address, City, State and Zip edit boxes and then press Look Up to direct the system to check the new values against the geocoding database to see if they can be located. If the location is found we can press Accept to accept the geocoding for the edited address and to write the edited address values back into the table for that record. If we would like to go back to the previous set of values, before editing, we can press the Previous button.

If we would like to skip this record and continue with other unmatched records, we press the Skip button.

**Unmatched Record Dialog Controls**

- **Record**  Current record as it has been read from the table. A read-only edit box that can be used with Copy.
- **Address**  Address value now in use.
- **City**  City value now in use.
- **State**  State value now in use.
- **Zip**  Zip value now in use.
- **(result)**  Result of last Look Up operation.
- **Found pane**  A list of possible matches found in the geocoding database. Clicking on one of the matches will load it into the edit boxes. Double-clicking on one of the matches will load it and immediately Accept it as well and move on to the next record.
- **Accept**  Accept the current values in the edit boxes. Click on one of the choices in the Found pane and then choose Accept. This updates the table with specified values, replacing the current values of the record.
- **Look Up**  Look up the current address in the edit boxes in the geocoding database. When used with Standardize, this checks the possible validity of the address. When used
with Geocode, this looks up the location of the address.

**Previous**  Reload the previous values for this address into the edit box. Enabled if the address has been edited, either by choosing a possible match in the Found pane or by manually editing the address.

**Skip** Skips this record and continue with other unmatched records.

**Close** Skips this and all remaining unmatched records. Note that any Accept commands that have been issued for any unmatched records before a Close command will have already updated the table. Close is not the same as a Cancel of all changes made in this session with the Unmatched Records dialog.

The **Unmatched Records** dialog has keyboard accelerators for the Accept, Look Up, Previous, Skip and Close commands bound to ALT E, L, P, K and O keys. Pressing ALT-E is the same as clicking Accept. Using keyboard accelerators can help deal with very long lists of unmatched records.

### Skipping Unmatched Records when Creating Drawings

The results of the Geocode command are latitude and longitude values for each record that was successfully geocoded. Unmatched records that were skipped will have 0 values for their latitudes and longitudes. When copying a table that contains unmatched records and pasting it as a drawing, make sure the Skip zero latitude / longitude records checkbox is checked in the Paste As Drawing dialog. This will make sure that the unmatched records having 0 values for their latitudes and longitudes are not pasted as a cluster of points off the coast of Africa.

### Geocoding SQL Extensions

Manifold SQL includes geocoding extensions that operate with Manifold’s geocoding engine to perform spatial operations based upon an address string or zip code. Geocoding extensions will not work unless the US streets geocoding database is correctly installed. Geocoding extensions will not work with Manifold IMS unless the US streets geocoding database is installed within the Manifold application installation folder (normally, C:\Program Files\Manifold System). Therefore, the US streets geocoding database should be installed in the Manifold application installation folder on machines on which Manifold IMS operates.

**Boolean CloseToAddress** (Number ID, String Address, Number Distance, [String Unit])

Given an object ID, an address string, a distance and an optional distance unit determine if the object lies within the specified distance of the address.

**Boolean CloseToZip** (Number ID, String Zip, Number Distance, [String Unit])

Given an object ID, a ZIP code string, a distance and an optional distance unit determine if the object lies within the specified distance of the zip code centroid.

**Number DistanceToAddress** (Number ID, String Address, [String Unit])

Given an object ID, an address string, and an optional distance unit computes the distance between the object and the address.

**Number DistanceToZip** (Number ID, String Zip, [String Unit])

Given an object ID, a ZIP code string, and an optional distance unit computes the distance between the object and the zip code centroid.

### Notes on usage:
If an object is a line or an area the object's centroid is used for distance calculations.

If an address string produces more than one match, the system automatically selects the closest of the building-level matches (possibly with an "unknown street name, possible misspelling" error).

If an address string produces no building-level matches, `CloseToAddress` returns `False` and `DistanceToAddress` returns `-1`.

If the optional distance unit is omitted, the system will use the native measurement unit of the drawing or meters if the drawing is not projected.

Distances are great circle distances computed over a WGS84 ellipsoid and are accurate to 1 meter.

The geocoding functions cache returned geocoding data between subsequent calls.

Functions can be used from IMS as long as the geocoding database is located within the Manifold application installation folder (usually `C:\Program Files\Manifold System`).

### Geocoding Function Examples

```sql
SELECT * FROM Dealers
WHERE CloseToAddress(ID, "330 Lytton Ave, Palo Alto, CA, 94301", 10, "mi")
```

```sql
SELECT * FROM Dealers
WHERE DistanceToAddress(ID, "330 Lytton Ave, Palo Alto, CA, 94301", "mi") <= 10
```

```sql
SELECT * FROM Dealers
WHERE CloseToZip(ID, "94301", 10, "mi")
```

```sql
SELECT * FROM Dealers
WHERE DistanceToZip(ID, "94301", "mi") <= 10
```

All four examples have a similar function. The first query selects all objects in `Dealers` that are within 10 miles of the given address using the `CloseToAddress` function, while the second example performs the same task using the `DistanceToAddress` function. The third and fourth examples perform the same functions using the 94301 ZIP code.

To keep the user interface simple and to avoid the complication of dealing with possible user errors when entering address information into forms, many web applications with IMS will use the `CloseToZip` or `DistanceToZip` functions since these require the user to merely enter the ZIP code correctly. For many applications, such as locating a dealer, finding the closest objects to the ZIP centroid provides acceptable accuracy.

See the Units topic for a list of unit abbreviations that may be used to specify optional distance units.

### GoTo Extensions

When the US street address Manifold Geocoding Database is installed, the Edit - GoTo command will allow a GoTo to an Address or to a Zip code within the US. The address may be a full street address, or it may be a partial address, such as "Atlanta" or "Atlanta, GA" or "GA." Manifold includes a gazetteer of large city names so that "Atlanta" will find the large city in Georgia and not one of the various small towns of that name throughout the US. City names will take priority over states when spelled out, so that "Washington" will find the capital city of the US and not the state. To find the state, use "WA."

### Accuracy

The accuracy of the Manifold geocoder depends almost entirely upon the accuracy of the US streets geocoding database it uses. The Manifold Geocoding Database uses address data extracted from the US Bureau of the Census TIGER/Line data set. Although TIGER/Line is the federal standard for address accuracy used to support the Constitutional requirement of a census that counts every citizen, even this mammoth data set does not accurately capture all possible addresses in the US. Although TIGER/Line is updated every few years using a network of many Census Bureau field offices it does not capture address exceptions nor does it provide a satisfying level of geospatial accuracy in rural areas.

A further limitation of TIGER/Line is that due to constant churning of zip codes by the US Postal Service it is possible (although very rare) that a zip code for a valid geographic location might not be matched. A more
frequent problem is the appearance of zip codes within address records that are abstract zip codes (such as those assigned to some ships in the US Navy) that do not correspond to a geographical location within the United States.

If a street address cannot be found within the Manifold Geocoding Database, resulting in an unmatched record with no options presented, the user has several choices to deal with the unmatched address:

- Accept a zip code only match, if the zip code exists.
- Ignore the address.
- Manually create a point for the address in a drawing, if local knowledge is available.
- Use a geocoding system from another vendor to locate the address, and manually add latitude and longitude values to the geocoded table for that address record.

When using the geocoder for demographic or marketing studies it is usually safe to ignore unmatched addresses because addresses that can not be found in TIGER/Line are usually randomly dispersed. After all, if within a sample of 10,000 addresses one can obtain 90% geocoding without any effort to identify unmatched records the 9,000 data points thus obtained will normally be highly representative of the characteristics of the overall data set. For some applications, of course, achieving a match for every record may be a sufficiently important objective to merit a significant amount of time working with the Unmatched Records dialog or manual geocoding or use of a different geocoder.

Troubleshooting

If the geocoder does not work, check the following:

- Either the Manifold Geocoding Database or MapPoint or some other geocoding data source has been installed.
- All state files required are present (that is, required files have not been removed after installation).
- The Geocoding Database folder in the Tools - Options - File Locations correctly specifies the folder used to install the geocoding database. By default, this location is C:\Program Files\Manifold System\GCDB.
- If Manifold has been installed in a different folder than the default and if geocoding functions do not work within IMS, check that the geocoding database has been installed within the main Manifold installation folder, such as in the default path above.
- Are all columns used for addresses text columns?
- If MapPoint has also been installed, make sure the Use MapPoint … option has been checked.

If an address cannot be located, check the following:

- The address is correct. Nowhere is the ancient maxim of computing, "Garbage in, garbage out" more correct than in street address geocoding.
- The address does not contain secondary address information, such as "Apartment 20" co-mingled with the primary street address field.
- The address is a real street address and is not a virtual address, such as a Post Office box address (which, of course, can only be geocoded to a zip code).
- Try manually breaking up a single line address into street, city, state and zip fields.
- If the zip code cannot be found, check the zip code against the US Postal Service's website to make sure it is a valid zip code.
- If MapPoint has also been installed, make sure the Use MapPoint as… option has been checked in the Tools - Options - Geocoding dialog.

Geocoding Data Extensions
Geocoding Data Sources

The Geocoding Tools package is an optional extension to Manifold System that provides street address geocoding capability as well as access to the Manifold Geocoding Database data provided on the Manifold downloads site for both US street address geocoding as well as the easy creation of drawings showing US streets. The Geocoding Tools package also requires access to one or more geocoding data sources that are appropriate for the geographic region of interest.

Very important: the Geocoding Tools package will not be operational until you install at least one geocoding data source. You must install at least one geocoding data source.

A geocoding data source is a data source that provides the internal Manifold geocoding engine information about the location of street addresses. The geocoding engine can consult the data source to get information that helps the geocoding engine estimate the location of a particular street address. Once enabled by the installation of the Geocoding Tools package, Manifold can utilize the following geocoding data sources:

- The Manifold Geocoding Database provided for free download on the manifold.net site. It provides data for streets in the United States extracted from the US Bureau of the Census TIGER database. The Manifold Geocoding Database is fast, but is not as complete as the internal databases within Microsoft's MapPoint product. It is limited to the US only. The Manifold Geocoding Database is provided at no charge on the manifold.net site, so it is usually the first geocoding data source employed by new users in the US and more often than not the only geocoding data source users in the US ever need employ.
- Microsoft's MapPoint product in North American or European editions, which provide data either for North America or for selected countries in Europe. When MapPoint is installed on the same computer as Manifold System, the Manifold geocoder can reach into MapPoint's internal database to use it as a geocoding data source. MapPoint has one of the very best geocoding databases in the GIS industry, but it is significantly slower than using the Manifold Geocoding Database. Although MapPoint must be purchased, the combination of Manifold together with MapPoint is by far the least expensive way of doing street address geocoding for Canada and Mexico or for the countries supported by the MapPoint European edition.
- User-provided geocoding data extensions in either address range or points of interest formats. User-provided data sources must be used outside of the US or of the coverage provided by MapPoint. Even within the US or Europe, user-provided data sources are often used when exact precision is required since only "points of interest" formats can provide exact address precision.
- Web-based Manifold geocoding servers that provide geocoding services. Any such data source must fulfill the requirements of the Manifold Geocoding Server interface, but web services vary widely in their speed, accuracy and cost. Web services do have the potential advantage of greater timeliness, as it is possible to update a centralized data source more rapidly than, say, MapPoint editions may be updated. Visit the manifold.net web site for information on free geocoding server modules that may be downloaded.

Any combination of the above geocoding data sources may be used. This topic briefly surveys the above geocoding data sources and discusses the Manifold Geocoding Database in greater detail. See the specific Help topics for each of the other geocoding data sources for greater details.

A Geocoding Data Source Strategy

Users operating in the United States will normally use the Manifold geocoding database by default, since it is free. Users desiring slightly greater "hit" rates will also install MapPoint so MapPoint can be consulted if an address cannot be found in the Manifold geocoding database (the default setting).

Users in Canada or in the countries supported by MapPoint European edition don't really have much choice but to use MapPoint as a geocoding data source as this is generally far less expensive and easier to do than to try to acquire geocoding databases from other vendors and to convert such databases into the format required for user-provided geocoding data extensions.

Users outside the above areas cannot engage in street address geocoding unless they provide their own geocoding data extensions. That can be a difficult and expensive proposition. However, using Manifold on a notebook computer together with a portable GPS receiver, two employees in a vehicle (one to steer the vehicle and one to operate the notebook computer) can acquire addresses in points of interest format very rapidly. Many hundreds of streets can be done in a week and thousands of streets in well under a month by two people in a single vehicle. Once acquired, such data can be very valuable, the value of the data far exceeding the cost of acquiring it.
Web-based geocoding servers are so varied as to defy characterization. They range from very slow to very fast, from free to very costly, from very timely to remarkably obsolete. The Manifold Geocoding Server interface allows users to write modules that enable use of a very wide range of web-based geocoding servers.

**Precision**

Most users in the US doing street address geocoding with Manifold will use the Manifold US streets geocoding database provided as a free download on the manifold.net site. This database is based on the US government's official address database published in the TIGER/Line data set and allows the Manifold geocoder to find estimated positions for street addresses in the United States. It works best in urban and suburban areas where street addresses follow reasonably regular patterns.

**Very Important:** The Manifold Geocoding Database does not capture all possible street addresses nor can it guarantee the exact location of any address. Therefore, it must **not** be used for applications, such as 911 or other emergency response applications, which require every address to be exactly located. Note that the Manifold System End User License Agreement (EULA) specifically excludes uses, such as emergency response, that require fail-safe performance.

Nonetheless, the Manifold geocoder working together with the Manifold Geocoding Database is a good choice for many GIS tasks, such as demographic or marketing studies, that require geocoding of a reasonably high percentage of addresses. For such uses the Manifold Geocoding Database is highly effective and a spectacularly good value.

If Microsoft MapPoint is installed, the MapPoint database provides slightly greater accuracy in the United States, finding a few percentage points more addresses in large geocoding projects than is possible using the Manifold Geocoding Database. The MapPoint geocoder uses a variety of data sources in addition to government data to provide slightly better address recognition than is possible with government data only.

Some users prefer to use a Geocoding Data Server like the open source geocoding server module for Microsoft's Virtual Earth geocoding server. That has the advantage of frequently updated data in Virtual Earth, but it is slower since it has to go through Internet to geocode each address.

User-provided geocoding data extensions are normally used to provide custom information on street addresses not found within the Manifold Geocoding Database or MapPoint. For example, users may have specific address information licensed from commercial sources that provide more recent data than the TIGER data used in Manifold's geocoding database product or user may have custom address information for countries not covered by either Manifold or MapPoint.

**Installing the Manifold Geocoding Database**

Street address geocoding functionality within Manifold requires installation of an appropriate data source. If US street address geocoding is intended, we can use the Manifold Geocoding Database provided as a free download on the manifold.net site as our data source. If the database is not installed on the computer system and no other geocoding data source is provided, Manifold's street address geocoding commands and functions will not be available. The full US streets Manifold geocoding database requires approximately 950 MB of free space on disk.

**Installing the Manifold US geocoding database:**

1. Download the Manifold Geocoding Database zip file from the product downloads page in the manifold.net website. This is a **very large** file, over 800 MB in size. If your Internet connection is not totally reliable it might get damaged in transit. If it does not unzip correctly, download it again until it does. Unzip the zip file.
2. In Windows Explorer, drill down into the unzipped files to find the GCDB.msi installation program and double click on the GCDB.msi installation program to launch it. **Note:** If Windows Explorer has been set to hide extensions for well-known file types, this file may be listed in Windows Explorer as GCDB without the .msi extension. **Warning:** The geocoding installation .msi file is a huge file. Microsoft Windows Installer wants to check each .msi file before installing it so there may be a **very long** period of apparent inactivity while the Installer checks the GCDB.msi file, perhaps even tens of minutes on a slow machine. This is normal: just let the installation process continue to run and all will be well.
3. The installer will offer to install the geocoding database into a default folder, C:\Program Files\Manifold System\GCDB, within the default installation folder for Manifold System. If you have installed Manifold System in a different location on your hard disk it is strongly recommended that you update the file locations for geocoding in any IMS config.txt file so that geocoding capabilities will be available within Manifold IMS.
4. Launch Manifold. In the **Tools - Options - File Locations** pane, specify the folder used to install the geocoding database for the **Geocoding Database** folder and press **OK**. This step may be skipped if the default location for installation is used.

The **states.dat** file must always be available on your hard disk. The geocoding database is organized by US states with a file for each state. Each state file ends in a .dat extension and is named using the state postal abbreviation. For example, the geocoding database files for California and New York are **ca.dat** and **ny.dat** respectively.

The **GCDB.msi** installer will install geocoding database files for all US states. However, only those state files for which addresses will be geocoded need be located on the hard disk. Files for states that will not be used may be removed to free up disk space. For example, if we will be geocoding street addresses only in the state of California and no other state, we may delete all files from the **GCDB** folder on hard disk except the **states.dat** file and the **ca.dat** file.

**Tech Tip:** Don’t delete any of the files. In an era of hard disks of virtually limitless size, there’s little point in trying to save a few megabytes by deleting state files and at the same time much risk of inconvenience should those state files be needed at some future date.

To uninstall the US geocoding database and entirely remove all files, we may use the Windows Control Panel **Add / Remove Programs** applet. Removing the geocoding database will render all geocoding functions inoperative.

**Geocoding Data Extensions**

User extensions to street address geocoding data may be provided in the form of a Manifold .map project file that contain tables with columns using predefined names and types. The project file must be placed in the folder cited in the **Tools - Options - File Locations** pane for **Geocoding Extensions** and the **Use geocoding extensions** checkbox must be checked in the **Tools - Options - Geocoding** pane.

User geocoding extensions are always considered first when processing data. Next, either the Manifold Geocoding Database or MapPoint geocoding data are consider depending on whether MapPoint is set to be used before or after the Manifold geocoding database as specified in the **Tools - Options - Geocoding** dialog.

See the Geocoding Data Extensions topic for details on user-supplied extensions.

Geocoding with MapPoint

Microsoft's MapPoint product is a high quality "atlas" mapping program that is popular for many consumer applications. MapPoint also has the ability to geocode street addresses within the region covered by the edition of MapPoint in use. The European edition of MapPoint can geocode street addresses in eleven European countries (Austria, Belgium, Denmark, France, Germany, Italy, Luxembourg, the Netherlands, Spain, Switzerland and United Kingdom).

If the Manifold Geocoding Tools package is installed, Manifold System can use MapPoint as a geocoding data source to enable the Manifold geocoding engine to provide street address geocoding capabilities. See the Geocoding Tools topic for information on the capabilities provided by the Geocoding Tools package. If the Geocoding Tools package is not installed, the capabilities provided by this topic will not be available.

If a recent edition of Microsoft MapPoint (from 2002 onward) is installed on the same computer as Manifold System, Manifold can use the database within MapPoint to provide a geocoding data source for Manifold. MapPoint can be used as an adjunct to the Manifold Geocoding Database or it can be used as a replacement for the Manifold Geocoding Database. See the Geocoding Data Sources topic.

Most geocoding functions, including geocoding extensions in SQL, programming and use within IMS will work (IMS usage will require correct configuration of user permissions - see below). However, note that functions with MapPoint will be limited to those that use a full street address.

Although the Manifold Geocoding Database enables geocoding down to the centroid of the lowest resolvable entity (state, city, zip code) if a full street address is not available, MapPoint cannot geocode to, say, the centroid of a postal code if no more detailed street address is known. In general, MapPoint will not return the centroid of a postal code. It will return the location of a valid street address, and will "jump" to the location of a postal code in the MapPoint user interface when used interactively. However, MapPoint will not return the location of a postal code when it is called programmatically as is the case when it is used as a data source for Manifold.

Because MapPoint is much less expensive than buying proprietary geocoding data sets for Canada or European countries, using MapPoint as a geocoding data source is the least expensive way of getting Canadian or European street address geocoding within a true GIS like Manifold. Since both the North American and European editions of MapPoint may be simultaneously installed, Manifold users who have both editions installed can simultaneously geocode street addresses in the US, Canada and in the European countries supported by MapPoint.

MapPoint may also be used as the default geocoder for US street addresses and MapPoint may be used as a geocoding data source for Manifold even if the Manifold Geocoding Database is not installed. Although MapPoint does cost more than the Manifold Geocoding Database, which is provided for free download on the manifold.net web site, it provides more extensive and more up-to-date street address matching capability for US street addresses. The downside of using MapPoint is that geocoding will run slower because accessing information within MapPoint as a geocoding data source is slower than using the Manifold Geocoding Database.

Installation and Use

Using MapPoint as a geocoder is easy: simply install the edition(s) of MapPoint desired, and then in the Tools - Options - Geocoding dialog check the Use MapPoint ... option and in the same dialog choose whether MapPoint is to have priority over the Manifold geocoding database. Most users with large geocoding tasks in the US will give the Manifold geocoding data priority (the default setting) so that geocoding can run as fast as possible with only those addresses not found in the Manifold geocoding database subjected to the slower MapPoint data lookup.

With MapPoint installed and used as the geocoder, the geocoding process works just as it would when using a Manifold street address data product or when using your own geocoding data extensions. Standardization works the same as well, with any auxiliary information returned by MapPoint in the process of standardizing an address being appended to the appropriate column.

When using MapPoint for geocoding, country names are specified as follows:

- If a single field is used for addresses the various parts of the address (street address, city, etc.) must be separated by commas. The MapPoint address parser in general cannot extract address parts (street address, city, state, zip/postal code or country) from a single field unless they are separated by commas.
- If separate fields are used, then the **State** field must contain the state/province name and the **Country** field should contain the country name.
To geocode Canadian or European Addresses using MapPoint

1. Install the required edition(s) of MapPoint.
2. Launch Manifold and in Tools - Options - Miscellaneous check the Use MapPoint ... option. Check the Give MapPoint priority... box if MapPoint is to be the primary (or only) geocoder and uncheck that box if the Manifold geocoder is to be used as the primary geocoder.
3. If geocoding addresses outside of the United States, include the country name in a Country field. Alternately, if only one country will be used, specify the default country name in the Tools - Options - Geocoding dialog.
4. Follow the instructions in the Street Address Geocoding topic. All Manifold geocoding functions will operate correctly using MapPoint as the geocoder.

Examples

Suppose we would like to geocode the street addresses of some hotels in Vancouver, Canada.

### Single Field Addresses

<table>
<thead>
<tr>
<th>Addresses</th>
</tr>
</thead>
<tbody>
<tr>
<td>645 Howe St, Vancouver, BC, Y6C2Y9, Canada</td>
</tr>
<tr>
<td>1128 West Hastings Street, Vancouver, BC, V6B4R5, Canada</td>
</tr>
<tr>
<td>1277 Robson St, Vancouver, BC, V6E1C4, Canada</td>
</tr>
<tr>
<td>845 Burrard St, Vancouver, BC, V6Z2K6, Canada</td>
</tr>
<tr>
<td>567 Hornby St, Vancouver, BC, V6C2E8, Canada</td>
</tr>
<tr>
<td>322 Davie St, Vancouver, BC, Y6B5Z6, Canada</td>
</tr>
</tbody>
</table>

If our table contains the addresses in a single field, we must take care to separate the different parts of the address using commas. Before a single-field address can be used with MapPoint it must be split into multiple fields using Standardize.

### Multiple Field Addresses

<table>
<thead>
<tr>
<th>Address</th>
<th>City</th>
<th>State</th>
<th>Zip</th>
</tr>
</thead>
<tbody>
<tr>
<td>645 Howe St</td>
<td>Vancouver</td>
<td>BC, Canada</td>
<td>Y6C2Y9</td>
</tr>
<tr>
<td>1128 West Hastings Street</td>
<td>Vancouver</td>
<td>BC, Canada</td>
<td>V6B4R5</td>
</tr>
<tr>
<td>1277 Robson St</td>
<td>Vancouver</td>
<td>BC, Canada</td>
<td>V6E1C4</td>
</tr>
<tr>
<td>845 Burrard St</td>
<td>Vancouver</td>
<td>BC, Canada</td>
<td>V6Z2K6</td>
</tr>
<tr>
<td>567 Hornby St</td>
<td>Vancouver</td>
<td>BC, Canada</td>
<td>V6C2E8</td>
</tr>
<tr>
<td>322 Davie St</td>
<td>Vancouver</td>
<td>BC, Canada</td>
<td>Y6B5Z6</td>
</tr>
</tbody>
</table>

If our table contains the addresses as multiple fields, we must make sure that the field to be used as the State field includes the province and country separated with a comma. Standardize will automatically split single field addresses into multiple field addresses that correctly have the province (if used) and country in the State field.
Running the geocoder will add **Latitude** and **Longitude** columns and values to the table.

### Multiple Field Addresses

<table>
<thead>
<tr>
<th>Address</th>
<th>City</th>
<th>State</th>
<th>Zip</th>
</tr>
</thead>
<tbody>
<tr>
<td>645 Howe St</td>
<td>Vancouver</td>
<td>Canada</td>
<td>V6C2Y9</td>
</tr>
<tr>
<td>1228 West Hastings Street</td>
<td>Vancouver</td>
<td>Canada</td>
<td>V6B4R5</td>
</tr>
<tr>
<td>1277 Robson St</td>
<td>Vancouver</td>
<td>Canada</td>
<td>V6E1C4</td>
</tr>
<tr>
<td>845 Burrard St</td>
<td>Vancouver</td>
<td>Canada</td>
<td>V6Z2K6</td>
</tr>
<tr>
<td>567 Hornby St</td>
<td>Vancouver</td>
<td>Canada</td>
<td>V6C2E8</td>
</tr>
<tr>
<td>322 Davie St</td>
<td>Vancouver</td>
<td>Canada</td>
<td>V6E5Z6</td>
</tr>
</tbody>
</table>

Note that MapPoint can almost always find a street address even if the province is not included in the **State** field. However, the country name must always be included in the **State** field so MapPoint knows which country to use.

### Postal or ZIP Codes

The **Standardize** command will extract address, city, state and postal/ZIP fields from an address given in a single field. It also works when MapPoint is used as a geocoder except that MapPoint will not extract and return the postal or ZIP code from a single address field. Therefore, when converting a single-field address to a multiple field address using **Standardize** the postal/ZIP code field will be blank.

For this reason, if postal codes are required to geocode street addresses in a given area and MapPoint is the geocoder, use addresses in multiple field form. Note that usually having a street address and a city is usually enough for geocoding purposes since in most cases the postal/ZIP code is redundant if the city name and name of the street are known. In cases where the postal/ZIP code is required and addresses are in single field form, it us usually easy to use the transform toolbar token operators to manually extract postal/Zip codes from a single field address into a separate Zip field.

When using geocoding functions in SQL, the **LocateZipLat** and **LocateZipLon** functions only work for US zip codes, something to keep in mind when using MapPoint European edition in Europe.

### MapPoint Versions

The Microsoft product meant by "MapPoint" in this topic is the packaged consumer application that installs on the local computer, and not the .NET service offered by Microsoft. The MapPoint geocoding facilities used by Manifold System require a reasonably current edition of MapPoint from 2002 onward and will not work with earlier MapPoint editions.

The European edition of MapPoint 2004 has enhanced support for additional European countries. Following is a list of countries covered by European editions of MapPoint 2004 and MapPoint 2002 for street address geocoding:

- Austria (partially covered by both 2004 and 2002).
- Belgium (fully covered by 2004, partially covered by 2002).
- Denmark (fully covered by 2004, partially covered by 2002).
- Finland (partially covered by 2004, not covered by 2002).
- France (partially covered by both 2004 and 2002).
- Germany (fully covered by both 2004 and 2002).
- Italy (partially covered by both 2004 and 2002).
- Norway (partially covered by 2004, not covered by 2002).
- Portugal (partially covered by 2004, not covered by 2002).
- Spain (partially covered by both 2004 and 2002).
- Sweden (fully covered by 2004, not covered by 2002).
- Switzerland (fully covered by 2004, partially covered by 2002).
- United Kingdom (partially covered by both 2004 and 2002).

MapPoint 2004 also covers Czech Republic and Ireland, but only in that those countries can be used during routing. They cannot be used for street address geocoding.

Expectations are that MapPoint editions will continue to be compatible with the interface used by Manifold to access MapPoint as a geocoding data source.

**MapPoint and IMS**

MapPoint geocoding will normally not work from IMS unless we map anonymous Internet connections to a user account that has more enhanced permissions than the default Internet access `IUSR_xxx` account.

**To enhance permissions for the Internet access account:**

1. Create a regular user account with default permissions that is a member of the `Users` group.
2. Open Control Panel - Administrative Tools - Internet Information Services (or the equivalent dialog in your version of Windows).
3. Right click the folder that contains the published website, select Properties, switch to Directory Security and click Edit under Anonymous access and authentication control.
4. Set the user account used for anonymous access to the account created in step 1 above.

About Geocoding
Geocoding
Street Address Geocoding
Geocoding Data Sources
Geocoding Data Extensions
Geocoding Data Extensions

If the Manifold Geocoding Tools package is installed, Manifold System can use various geocoding data sources to enable the Manifold geocoding engine to provide street address geocoding capabilities. See the Geocoding Tools topic for information on the capabilities provided by the Geocoding Tools package. If the Geocoding Tools package is not installed, the capabilities provided by this topic will not be available.

Users may customize geocoding operation by providing their own data to be used as a geocoding data source. Such additional, customized data are referred to as geocoding data extensions because most frequently such user-provided data is intended as an adjunct to existing geocoding data sources, perhaps providing corrections or a limited amount of more recent data. However, even though such data is referred to as extensions, Manifold can use user-provided data without any other geocoding data source required.

Users provide geocoding data extensions in the form of one or more Manifold .map project files that contain tables with columns using predefined names and types. The project files must be placed in the folder cited in the Tools - Options - File Locations pane for Geocoding Extensions and the Use geocoding extensions checkbox must be checked in the Tools - Options - Geocoding pane.

User geocoding extensions are always considered first when processing data. Next, either the Manifold geocoding database or MapPoint geocoding data are considered depending on whether MapPoint is set to be the primary or the fallback geocoding engine.

Geocoding data extensions are used mainly in two forms:

- First, they may be used to provide addresses for specific points of interest that exist at a specific latitude or longitude (such as the address and location of a hotel or restaurant). This format is easier to understand and implement.
- Second, they may be used to provide ranges of addresses such as the ranges of address that may occur on a given street segment so that any address and location within the range may be interpolated.

The format for data extensions allows for both types of uses.

Tables used for geocoding data extensions may be local within the project, they may be linked from external DBMS providers or, if Enterprise Edition is in use, they may be shared from an Enterprise server.

Format

Each .map file must have a table named Geocoding Data. The table must have one or more address columns using specific names (Address, City, Country, From Number, Number, State, Street, To Number, Zip) and location columns that give latitude and longitude locations. The location columns may be either latitude and longitude columns (Latitude, Longitude) that specify a single location or they may be range columns (From Latitude, From Longitude, To Latitude, To Longitude) that specify a range of locations.

Address columns except Number columns (Number columns include Number, From Number and To Number) must be text. Number columns may be text or numeric, and latitude and longitude columns must be numeric. Latitude and longitude coordinates are assumed to be in WGS 84.

Range latitude and longitude columns (From Latitude, From Longitude, To Latitude, To Longitude) are always used in conjunction with range Number columns (From Number, To Number) to geocode street segments. The Street and Number columns are used as a substitute for the Address column if there is no Address column. If there is an Address column, the Street and Number columns are ignored.

Examples

Suppose we would like to create a user-supplied geocoding data extension that contained points of interest. For each point of interest such as a hotel or restaurant we have a record that contains a specific address and latitude / longitude location.

We would create a table called Geocoding Data and make sure that it contains the following fields and field types:
- State - Text (ANSI, variable-length)
- City - Text (ANSI, variable-length)
- Address - Text (ANSI, variable-length)
- Latitude - Latitude
- Longitude - Longitude

In the above table each record represents a specific address at a specific location. When a given address is geocoded the exact latitude and longitude will be reported. If an address can not found in the table then no geocoded latitude and longitude will be reported.

Suppose we would like to create a geocoding data extension table for ranges of addresses. We could create a table called **Geocoding Data** and make sure that it contains the following fields and field types:

- State - Text (ANSI, variable-length)
- City - Text (ANSI, variable-length)
- Street - Text (ANSI, variable-length)
- From Number - Integer (32-bit)
- To Number - Integer (32-bit)
- From Latitude - Latitude
- From Longitude - Longitude
- To Latitude - Latitude
- To Longitude - Longitude

In the above table each record represents a street segment that extends from a **From** latitude and longitude location to a **To** latitude and longitude location. The street segment contains addresses numbered from the **From** number to a **To** number. For example, a street segment may contain addresses from 100 to 200 on a **Street** called Western Avenue. An address located at 150 Western Avenue will be located at the middle of the straight line drawn from the **From** latitude and longitude location to the **To** latitude and longitude location.

The **From Number** used in a street segment may be greater than the **To Number**. More than one record can overlap for the same **Street** name with **From Number** and **To Number** address range so long as the overlapping number ranges are all odd or all even. The geocoding engine can exploit an all odd or all even number range to assign an odd or even street address number to the correct segment.

Consider a situation where a street segment has a **From Number** of 10 and a **To Number** of 31. This is a typical situation where a building number between 10 and 31 with that same street name will be geocoded within that segment.
If desired, the same street can be represented by more than one street segment where the ranges overlap numerically but the segments are distinguished by having all odd or all even number ranges. In the above illustration the same portion of the street is represented using three segments. There are two segments that use all even numbers for the From Number and To Number values (10 to 20 on one segment and 24 to 30 on the other segment). There is one segment that uses all odd numbers (11 and 31) for the From Number and To Number values.

The illustrations above show the position of street segments as lines for conceptual clarity, but .map files used for geocoding data extensions need not contain any drawings. All they need contain are one or more tables that have either point locations (as in the case of points of interest) or ranges of locations.

When matching a building number (street address number) against street segments for that street name, if the building number is even the geocoding engine will first try to find a segment into which the number falls where the number ranges are both even. If the building number is odd the engine will try to find a segment into which the number falls where the number ranges are both odd. For example, given three segments for Main Street with From / To Number ranges of 10 to 20, 24 to 30, and 11 to 31, the geocoding engine will match 18 Main Street to the first segment and 25 Main Street to the third segment.

If the geocoding engine cannot find any all odd or all even segments into which the street number falls, it will try to find a segment with a mixed odd/even From / To range (like the first illustration above) into which the number falls.

Note that the above table organization makes two assumptions:

- There is no distinction between the left or right sides of the street in address ranges. Therefore, left and right offsets should not be used when geocoding using user-supplied geocoding data extensions. In some cases, left and right side addressing can be accomplished if the left or right sides of the street are exclusively odd or even numbers. In such cases, use two segments for the same part of the street with one segment being odd numbers and the other segment being even numbers. These segments may be offset from the centerline, as in the second illustration above, to create the effect of a left or right offset.
- Each street segment geocoded is a straight line. A highly curved street should therefore be segmented into straight line segments that approximate the curves of the street with address ranges and latitude / longitude location ranges assigned for each segment.

In many cases, when creating custom geocoding data it may be easier to simply use points of interest organization and assign a specific location to each address that actually exists in the area of interest. Using the GPS Console or other GPS software it is remarkably fast and easy to collect street address locations even for very large numbers of addresses. Points of interest organization is also usually much more accurate than street segment ranges when creating custom geocoding data extensions for rural areas.

**Tech Tip**

Keep in mind that Manifold may lock the .map files used for geocoding data extensions or may cache their content; therefore, any modifications made to such files will only be visible in sessions of Manifold launched after any such modifications.

Street Address Geocoding
Geocoding Data Sources
Geocoding with MapPoint
Manifold Geocoding Servers
Manifold Geocoding Servers

The Manifold street address geocoding engine can geocode addresses using generic geocoding data sources. A generic geocoding data source is a .NET object that supports the Manifold Geocoding Server (MGS) interface. When such a .NET object is correctly written and made available within a Manifold installation, it is called a Manifold Geocoding Server, that is, it is a geocoding server that conforms to the interface which allows it to be used by Manifold System.

Although geocoding servers are often web-based geocoding services, there is no reason why the MGS interface could not be used to provide access by Manifold to a local application, such as some third-party commercial geocoding software. Part of the magic of .NET and the MGS interface is that they can be used to connect different applications which otherwise could not interoperate.

Required Geocoding Tools

Manifold's street address geocoding capability becomes operational only when the optional Manifold Geocoding Tools package is installed. If you do not have the optional Geocoding Tools package, you will not be able to use the geocoding servers capability discussed in this topic.

Note that Manifold Universal Edition automatically installs the Geocoding Tools package. If you are using Universal Edition, you do not need to perform an extra Geocoding Tools installation as it has already been installed.

Enabling a Manifold Geocoding Server

When a .NET module for a Manifold Geocoding Server has been correctly written and made available to Manifold, it will appear in the Tools - Options Geocoding page. The pane captioned Use the following Manifold Geocoding Servers will show a list of available geocoding servers with checkboxes to turn them on or off. Check the box of a geocoding server to turn it on.

By default, Manifold will have one Manifold Geocoding Servers listed, for Oracle geocoding with Oracle Spatial. This geocoding server requires installation of Oracle Spatial geocoding capability. It is provided as a "built-in" capability of Manifold to assure compatibility with Oracle Spatial DBMS products.

Earlier editions of Manifold also had two additional Manifold Geocoding Servers listed but these have since been moved out into optional downloads:

- The free Geocoder.us web-based service.
- Microsoft Virtual Earth geocoding using the Virtual Earth service.

Because web-based geocoding servers often change, a geocoding server built into Manifold cannot be maintained without a new release of Manifold. Therefore, the geocoding servers for Geocoder.us and for Virtual Earth have been moved into free modules that can be downloaded from the manifold.net web site. Drill down through the Product Downloads page to find these.

The .NET module for the Oracle geocoding servers is automatically installed when Manifold System is installed. To get the geocoding servers for Geocoder.us and Microsoft Virtual Earth, download the zip file containing them from the manifold.net web site and unzip them to get the .dll files that make up the geocoding server modules. A geocoding server module is simply a .dll file. Place the .dll files for the geocoding servers into your Manifold System installation folder. When you restart Manifold they will be automatically incorporated into Manifold.

The default Manifold System installation folder is C:\Program Files\Manifold System. If you are operating a 64-bit Manifold installation in 64-bit Windows or a 32-bit Manifold installation in a 64-bit Windows system there will also be a second Manifold System installation folder at C:\Program Files (x86)\Manifold System. In that case, the .dll files for image server modules should be placed in both the C:\Program Files\Manifold System and also in the C:\Program Files (x86)\Manifold System installation folders.

When Manifold launches, none of the installed geocoding server modules are checked by default: if we would like to use a particular geocoding server we must launch the Tools - Options dialog, click on the Geocoding page and then check the box for the desired geocoding server.

Example: Using the Geocoder.us Geocoding Server
Consider the table of sushi restaurants from the About Geocoding topic.

<table>
<thead>
<tr>
<th>Sushi Restaurants *</th>
</tr>
</thead>
<tbody>
<tr>
<td>Name</td>
</tr>
<tr>
<td>Sushi Ya</td>
</tr>
<tr>
<td>Miyaki</td>
</tr>
<tr>
<td>Higashi West</td>
</tr>
<tr>
<td>Naoko Sushi</td>
</tr>
<tr>
<td>Tengu Sushi</td>
</tr>
<tr>
<td>Minokichi</td>
</tr>
<tr>
<td>Le Poisson Japonais</td>
</tr>
<tr>
<td>Jidai-Ya</td>
</tr>
<tr>
<td>Akasaka</td>
</tr>
<tr>
<td>Mikasa</td>
</tr>
<tr>
<td>Toshi's Sushiya</td>
</tr>
</tbody>
</table>

We can geocode this table using the Geocoder.us geocoding server as follows:

In the Tools - Options dialog's Geocoding page we check the box for the Geocoder.us geocoding server and we uncheck all other boxes, such as the Use Manifold Geocoding Database box, for other geocoding data sources. We do this for the sake of this example to guarantee that any geocoding will be done only via the Geocoder.us geocoding server.

Next, with the table open we launch the Table - Address - Geocode dialog and geocode the table as we normally would. The process is remarkably slow, but eventually it does indeed geocode all of the records.

Advantages and Disadvantages of Geocoding Servers

This simple example shows some of the advantages and disadvantages of using a geocoding server. On the plus side, this particular geocoding server is free. Because it is based upon a centralized web database, it has the potential to use a geocoding database that is timelier than a geocoding database that is resident on your hard disk. It is possible to update a database on a web server continuously, while downloading files can take time. Therefore, a web-based geocoding service has the potential to incorporate changes in street addresses, such as the inclusion of new streets in rapidly growing regions, more rapidly than geocoding data sources distributed as files.

This advantage may at times result in a geocoding server returning a different location than a location determined using the Manifold Geocoding Database or other geocoding data sources. In the above example, the latitude and
longitude locations obtained using the Geocoder.us geocoding server were identical to those obtained using the Manifold Geocoding Database. That's not surprising, because both the Manifold Geocoding Database and Geocoder.us use the same underlying TIGER/Line 2004 data. However, it could well be that a geocoding server using a different database would yield different locations.

This example also raises some typical limitations of web-based geocoding services. First, although it is theoretically possible to keep the service’s database more up to date than a downloaded distribution of geocoding data, in actual practice few organizations have the resources to do more than simply recycle TIGER data. As of this writing, the free Geocoder.us web service uses the same TIGER/Line 2004 database used in the Manifold Geocoding Database so it will not be able to find any addresses not found in the Manifold Geocoding Database nor will it be able to plot any found addresses more accurately than the Manifold Geocoding Database.

Second, the free service is very slow. Using the Manifold Geocoding Database to geocode eleven records takes no time at all: the records are geocoded virtually as soon as we finish clicking the OK button in the Geocode dialog. In contrast, using the Geocoder.us server requires over two minutes for eleven records. Such a slow pace means that over four hours will be required to geocode a mere 1,000 records. As a practical matter, this speed limitation will prevent the use of the free Geocoder.us service in commercial applications, no doubt the intention, as a free demo service is not usually considered a substitute for faster, paid commercial services.

Third, the quality and performance of a web service can vary greatly between free versions, if such are offered, and paid versions of the same service. Some paid versions are very expensive compared to simply using the Manifold Geocoding Database or using MapPoint as a supplementary geocoding data source. Many commercial geocoding web services will offer a free version that is slower than the paid service or which is limited to some smaller number of records. Such limitations can cause frustration or time wasted on attempted troubleshooting if users are not aware of those limitations. If users understand the limitations of free services, such services can be an effective way of testing the range or accuracy of a given geocoding server against a sample set of data before purchasing a paid service.

Finally, geocoding web services can apply all sorts of restrictions to their use and not all sites do a good job of setting forth the terms and conditions of use. Some web sites attempt to specify limitations using language that is not drafted by legal professionals who are expert in such matters, or (at times a worse situation) using language drafted by legal professionals who may understand the law perfectly well but who are clueless about technology. Either way, the result can be language that is ambiguous, is nonsense or is self-contradictory within the context of the technology being used. That can force users into a guessing game as to what uses are allowed or not allowed. In all fairness, this is not a problem just with geocoding web services but seems to be a generic problem in many web sites.

The Geocoder.us web site as of the present writing appears to limit free access to "non-commercial" purposes. That is an easy restriction to observe for Manifold users since the free Geocoder.us service is too slow for commercial use, whatever is meant by that term. Even if it was faster, because the data behind Geocoder.us is the same as the data in the Manifold Geocoding Database (provided for free download on the manifold.net web site) and the Manifold Geocoding Database may be used for commercial purposes, there is no reason why anyone would choose to use Geocoder.us instead of the Manifold Geocoding Database. That is especially true given that using the Manifold Geocoding Database as a geocoding data source works immensely faster than using Geocoder.us.

Nonetheless, because Geocoder.us is a good idea and deserves publicity, it was selected as an example for implementation of a Manifold Geocoding Server. Users who experiment with the free Geocoder.us service will be more likely to sign up for paid service, which most likely will be faster. In addition, open source experimentation like that involved in people cobbling up their own examples of geocoding servers using the MGS interface is the sort of thing that helps new web sites like Geocoder.us get traction and expand their user base.

Continued user interest in this area will help web-based geocoding servers get better and better. We expect that in the future such servers will emerge to provide geocoding services, perhaps for a fee, in areas outside of the United States or to provide specialized geocoding services such as rapidly updated or especially accurate geocoding data sources using points of interest data. We hope the examples published by manifold.net will help such activities to flourish.

The Manifold Geocoding Server Interface

See the Geocoding Server Interface topic for a description of the interface. Programmers should also visit the manifold.net website for any supplemental documentation or example implementations, if any are made available in the future. Source code is normally provided for any free geocoding server modules available for download on the manifold.net web site.

Troubleshooting
In case of difficult using a geocoding server, the first things to check are:

- Has the Manifold Geocoding Tools package been installed? Manifold has no street address geocoding capability if the Geocoding Tools package has not been installed.
- Has the desired geocoding server checkbox been checked in the Tools - Options - Geocoding dialog? Geocoding servers are not enabled by default and must be enabled by checking their checkbox.
- If the geocoding server is a web service, does the computer have Internet access? If you can't launch a browser to visit that geocoding server's web site (they almost always have some web page advertising the service) then Manifold will not be able to connect over the web to the service, either.
- Does this geocoding server require special configuration? Some geocoding servers may utilize services that require specification of user logins, passwords, account numbers or other information within some configuration file or through other means.

Manifold Geocoding Servers are not enabled by default for several reasons. The most important is that they are usually web-based services and web connections may not be available in all circumstances on machines where Manifold is installed.

Since geocoding servers are usually services on remote machines and the availability or manner of operation of such services is beyond the control of the user, it may be necessary to check if a particular service is still available before enabling it in Manifold or to configure some accessory files, perhaps to specify some special login name and password for a paid service, before the geocoding server may be used. Contact your provider of the geocoding server module being used for any such configuration information.

In the particular case of the Geocoder.us service for which an MGS module is provided as an example, although the service was available for free and worked fine at the time of publication of this release of Manifold, there is no guarantee that it will continue to be available to users at no charge or in the same manner. Web site URLs change frequently, so users should be alert to the possibility that a geocoding web service may have changed and is no longer available as a particular geocoding server module.

If you encounter trouble while using a third party Manifold Geocoding Server module that is said to enable a particular geocoding service, consider the possibility that the web service has changed and that a modified MGS module might now be required. Contact the author of the module being used and see if an updated module has been made available.

Street Address Geocoding
Spatial Geocoding with Match

The Table - Match command provides spatial geocoding within Manifold System. See the Geocoding topic for a general discussion of geocoding and the difference between address geocoding and spatial geocoding.

Match can be used to geocode tables by matching locations to drawings of postal codes, provinces, regions, counties or other geographic entities. Such drawings/maps are much more frequently available in international settings than are detailed data sets necessary for address geocoding. In addition, Match can be used to spatially geocode tables of all types using drawings as a guide. For example a table of well drilling information can be geocoded using a drawing of well locations as a guide.

Controls

**Match** - Choose a drawing to which the table should be spatially matched.

**Move to Top** - Move the highlighted field to the top of the field list. This gives it the highest priority in matching.

**Move Up** - Move the highlighted field up one position in the field list.

**Move Down** - Move the highlighted field down one position in the field list.

**Move to Bottom** - Move the highlighted field to the bottom of the field list. This gives it the lowest priority in matching.

**Use Case** - Consider upper or lower case when matching text values in fields. When pressed, "nAme" will not match "Name" or "name".

**Use Side Whitespace** - Consider space characters occurring before or after text strings. If pressed, " 89701" will not match " 89701" (with two spaces before the 8).

**Use Interior Whitespace** - Consider space characters occurring within text strings. If pressed, "8 9 7 0 1" will not match "89 701".

**Match All** - If pressed, requires a match to all fields.

**Column / Match To Pane** - Choose fields that must be matched to guide a spatial match.

**X** - Field name to save longitude / x data. Suggested name: "Longitude".

**Y** - Field name to save latitude / y data. Suggested name: "Latitude".

**Latitude / Longitude coordinates** - Write location in decimal degrees latitude and longitude.

**Match** is easy to use. If we have a database table that has one field in common with a drawing, we can use the drawing to geocode the table.

To spatially geocode a table using Match:

1. Open the table.
2. Choose Table - Match - Drawing
3. In the Match Drawing dialog choose the name of the drawing to serve as a spatial guide.
4. Choose the fields in the table that are to be matched to fields in the drawing.
5. Check boxes as desired for matching text values.
6. In the X and Y boxes specify a name to use for the longitude field and latitude field.
7. Verify the Latitude / Longitude coordinates box is checked and press OK.

Each record in the table will be compared to all objects in the drawing for the specified fields. If the record matches field values for an object in the drawing the latitude and longitude of that object's centroid will be written into the record's latitude and longitude fields.

If only one field is specified, the records in the table will be geocoded by matching objects against that single field. If two or more fields are specified, Manifold will try to match against all fields.

Multiple fields are used for sub-matches to resolve duplicates. For example, if we are geocoding a table that has a city name and a country name for each record there may be multiple cities of the same name in different countries (for example, a "Paris" in France as well as a "Paris" in the United States). If both the city name and the country name are specified (with the city name field listed above the country name field in the Match dialog), then Match will first match all city names and then match by country names to resolve city name duplicates.

Example

We have a ZIPs drawing that shows zip code areas using Census Bureau ZCTAs. We also have a Customers table that has a zip code field for each customer. The zip code field is a text column. We want to geocode the table so that each record acquires latitude and longitude values to position it at the zip code centroid for that customer.

The drawing used is called ZIPs. The ZIPs drawing shows Census Bureau Zip Code Tabulation Areas (ZCTAs) in the San Francisco Bay region. ZCTAs are standardized areas that approximate the coverage of particular zip codes. The drawing was created by selecting ZCTA's near the Bay from a drawing of all ZCTAs in California, copying them and then pasting them to their own drawing. The areas have been colored using the Color dialog for no reason other than to avoid a bland, default look.
If we click open the ZIPs drawing's table we see that for each area in the drawing we have one field, a ZIPCODE field that gives the ZIP code for each area. (For our international readers, "ZIP" codes are postal codes in the US.)

<table>
<thead>
<tr>
<th>Name</th>
<th>Zip</th>
</tr>
</thead>
<tbody>
<tr>
<td>Laurence Leibman</td>
<td>94060</td>
</tr>
<tr>
<td>Elizabeth Lincoln</td>
<td>94070</td>
</tr>
<tr>
<td>Victoria Ashworth</td>
<td>94063</td>
</tr>
<tr>
<td>Patrick Simpson</td>
<td>94062</td>
</tr>
<tr>
<td>Francisco Chang</td>
<td>94303</td>
</tr>
<tr>
<td>Yang Wang</td>
<td>94025</td>
</tr>
<tr>
<td>Pedro Afonso</td>
<td>94061</td>
</tr>
<tr>
<td>Elizabeth Brown</td>
<td>94027</td>
</tr>
</tbody>
</table>

If we click open our Customers table we see it has only two fields, a Name field giving the name of the customer and a Zip field giving the customer's zip code. Of course, a real "customers" table would likely have many more fields than just these two. This example shows only two fields to keep the illustrations as simple as possible.

To spatially geocode the table by matching it to the ZIPs drawing we choose Table - Match. This launches the Match Drawing dialog.

In the dialog we choose ZIPs as the drawing to match. To match using the Zip field we double-click into the Match To column for the Zip field and choose ZIPCODE in the list box that appears. Press ENTER to accept the ZIPCODE choice.
The Customers table does not yet have any fields in it that store the longitude and latitude value. We now tell Manifold what to name the fields that will be created. In the X box we enter Longitude and in the Y box we enter Latitude. Manifold will use these names for the X coordinate (the longitude) and for the Y coordinate (the latitude) values. We could name these fields whatever we choose but it is wise to name them "Longitude" and "Latitude" so that the table’s column names are self-documenting.

The ZIPs drawing is not a projected drawing so automatically the coordinates taken from it are degree-based latitude and longitude coordinates. If the drawing being used for the match was a projected drawing, the Latitude / Longitude coordinates checkbox would be enabled and would be checked by default.

Checking this box when using projected drawings will geocode the table records using degree-based latitude and longitude coordinates. Unchecking this box when matching to a projected drawing will geocode the table’s records using whatever native coordinate system is used in the projected map. For example, if one matches to a drawing projected into UTM coordinates and unchecks the Latitude / Longitude coordinates box the coordinates written into the table will be UTM coordinates. This is a rarely used option designed for expert usage.

The result seen in the table is that the Customers table now has two new columns called Longitude and Latitude. For each record these columns contain the precise location of the zip code centroid for the zip code area shown in the ZIPs drawing that has the same ZIPCODE value as the ZIP value for that record. In the illustration we’ve formatted the columns so that only four digits appear after the decimal point (see Formatting Columns).

If we like, we can create a drawing from our newly geocoded table. To do so, in the project pane we Copy the table and then Paste As a drawing.
In the Paste As Drawing dialog that appears we choose the Name and the Zip fields and choose the Longitude and Latitude fields to be used as our X and Y fields. These fields will be loaded into the X and Y boxes by default since Manifold knows that table columns called "Longitude" and "Latitude" quite likely contain the desired values. This also illustrates the wisdom of using these names in the Match Drawing dialog.

The result of the Paste As operation is to create a new drawing in the project called Customers 2 by default (since we already have one component, the table, called Customers Manifold will call the next component created by pasting it "Customers 2").

We can drag and drop the new Customers 2 drawing into a map that also shows the ZIPs drawing. This drawing shows us the points at which each customer record in the table was geocoded. We can use this map to discuss three important aspects of geocoding using Match.

First, note that locations taken from the ZIPs drawing objects appear at the centroids of those objects. With unusual, bow-shaped areas (such as those at the bottom center of the map) the centroid of an area will often be located outside of the area.

Second, if we have more than one customer at the same zip code there will be more than one point created at exactly the same location. If we wish to disperse these points slightly we can use a script or other method to disperse them or to create displays that show the density of customers at different locations.
Third, if the drawing used to geocode the table has more than one object with the same target value, only the first such object encountered will be used to assign a location to the record. For example, suppose we had more than one area in the ZIPs drawing with the same ZIP code. Any record with that ZIP code would take its location from the first such area encountered (by Object ID order). This is not an issue with full five digit zip code areas like ZCTAs (in which every five digit numeric code is guaranteed to be unique), but it can be an issue when geocoding to other entities.

For example, suppose we use Match to geocode records to a drawing of US Counties. Most such drawings have many counties that consist of several area objects; for example, in the case of coastal counties that have a mainland area as well as several other areas showing coastal islands that are part of the county. Each such area object will usually have the county name, FIPS code and other fields with the same value. If we matched a table of records to such a county drawing the centroids will be taken from the first object with the given matching field value. If we are matching using FIPS code the first object with a particular FIPS code could easily turn out to be a coastal island for some counties. In that case, the point for the matched record would appear at the island and not on the "main body" of the county area where we intuitively might prefer to see it.

That may well not matter in some cases. Match is often used in tasks where the objective is not exact spatial positioning but rather to see a representative spatial distribution where one's customers (or other records) are located. In the example above, for instance, it may well be that we don't really care so much exactly where the customer is located but rather just wish to know if our customer base is located mostly in the South Bay or in the North Bay. If the latter interest is our objective we really won't care whether or not a particular record is geocoded to an "island" bit of an area instead of the "main" area.

However, if we really do care whether or not our table is geocoded to an "island" bit of an area, we can take a moment to clean up the drawing being used to guide the Match so that it contains only one area for each value used to geocode. In the case of a counties drawing where some counties consist of multiple areas we have many ways of undertaking such a clean up.

For example, we could use the Union transform operator to create a single area from all areas having the same FIPS code. Another approach might be to use the Area (I) intrinsic field within a query to find all areas smaller than a given size (the islands, presumably) and to move them to a separate drawing. In that case they could still appear in maps for visual fidelity but would not participate in analytic operations such as Match using the drawing.

**Tech Tips**

When working with ZIP codes or postal codes make sure to use text columns for the zip code or postal code. Many postal codes, such as ZIP codes, have leading "0" characters (with ZIP codes such as "02138") that are significant and will be preserved if a text column is used and lost if a numeric column is used.

If we have the Manifold Geocoding Data option installed we can use Street Address Geocoding to geocode a table of ZIP codes. In that case, there is no need to use Match.

Zip Codes are Not Areas

**Street Address Geocoding**
Decision Support System

The Manifold Decision Support System (DSS) provides a way to select records using flexible criteria. DSS results are reported as percentage values from 0 to 100 percent within a Rank Column in a table. We use the Add Rank Column Dialog to add rank columns by specifying DSS criteria and a DSS query they should use.

Instead of using fixed criteria such as “greater than 50” in a query, DSS can handle a situation where the criterion might be more than 50 most of the time but sometimes a value near 50 is also acceptable. The science of using flexible criteria is generally referred to as “fuzzy” logic. See the Introduction to Decision Support topic for more information on fuzzy logic.

Decision Support describes objectives for each data field using criteria. Criteria are curves that show which values for the data field are more desired and which are less desired. One or more criteria may then be used in a ranking query to find records that are a good fit to the combined requirements of all the criteria used. The results will be reported using a rank number, a percentage from 0 to 100 percent that appears within a Rank Column in the table. Records that fit the query well will be ranked at or near 100 percent. Records that fit the query less well will be ranked at increasingly lower percentages.

Records may then be organized by clicking on the Rank Column heading to sort the table in order of DSS ranking.

To select records using Decision Support:

1. Open the table of interest.
2. Use Table - Add - Rank Column to add a Rank Column to the table.
3. In the Add Rank Column dialog, specify the name of the column.
4. Press New to add a new criterion to the Criteria pane.
5. In the Add Criterion dialog, choose the name for the criterion, the field (column) to be used and the type of criterion. Types such as High and Low provide presets that are automatically computed based on the data in the table. Press Apply to see the effect of the Type and press OK to create the criterion.
6. Continue adding criteria using steps 4 and 5 above for all the fields you wish to use. Criteria appear organized in a hierarchical diagram under the names of the fields they use.
7. Create a query by dragging and dropping criteria from the upper pane into the lower pane. Change the Junction from Or to And as desired by double clicking onto the Or. Place a Not in front of a criterion if desired by double clicking into the Not column and choosing Not.
8. Press OK and a Rank Column giving DSS values for all the records will appear in the table. Sort the column by clicking on the column head to see the records displayed in rank order. Records with a rank value of 100% most closely match the rank query.

Another way to make a selection using DSS is to use a ViewBot in the ViewBots pane. For example, suppose we have created a Rank Column named Ranking. We could add a ViewBot that reported for the Ranking field the records Greater or Equal To .90. This would report all records where the total Ranking was greater than 90%. We could then click Replace Selection in the ViewBots pane to select those records. Note that we use a value of .90 in the ViewBot since rankings are percentages.

Decision Support System Topics

Introduction to Decision Support - A quick and easy introduction to Decision Support.
Add Rank Column Dialog - Overview of all controls and panels in the main dialog used to create rank columns and to build criteria and queries reported in rank columns.

Take a moment to read the above topics in order to get the most out of Decision Support System.
Introduction to Decision Support

Much has been written about "fuzzy logic" in recent years. The basic idea behind fuzzy logic is to replace inflexible search criteria with criteria that have some give and take. Searches in real life often incorporate gray areas or subtle trade-offs that are not well represented by all-or-nothing selection parameters.

For example, suppose we are interested in finding automobile drivers who are "mature" in age. A traditional approach using SQL might be to select all records with an \texttt{Age} field value over 35. The problem with the traditional approach is that a driver of age 34 would never be selected even though such a driver when all other criteria are reckoned might well be considered as mature as a driver of age 35 or 36. Traditional systems are not well suited to making selections when one seeks flexible criteria such as "mature", since there is no magic age number at which (suddenly) 100% of the population becomes mature, with 100% of the population having been "immature" before that age.

In contrast, a fuzzy query might select records over 35, but would also allow some blurring of the criteria so that some records that are almost over 35 have a chance of being selected. At times (depending on other selection criteria) some records that are slightly over 35 will not be selected. A fuzzy selection criterion could define "mature" so that from age 20 on people are more likely to be considered "mature" with almost everyone by age 50 considered to be "mature."

Curves Show the Desirability of Different Values

How do fuzzy logic systems know when it is acceptable to use values that are close to 35 and when it is not acceptable? This turns out to be surprisingly easy to accomplish. We specify how likely values on either side of 35 are to be selected by specifying a weight or preference factor for their desirability. In Manifold's Decision Support System, we use curves to specify a criterion that shows the desirability (from 0 to 100 percent) of a particular value.

Since many people don't always think in curves or like to draw curves, Decision Support has several methods that make it easy to specify a criterion without having to draw a curve. For example, Decision Support provides "presets" that make it easy to pick common desirability criteria (such as \texttt{High}, \texttt{Low}, or \texttt{Average}) by clicking on a menu choice. Another method provided is the use of simple confidence intervals in the \texttt{Auto} method that Decision Support automatically translates into appropriate curves.

Let's take a look at how simple curves can show the desirability of different values. The following illustrations show grids and numeric values to help teach the concepts. The \textit{Add Criterion} dialog in Manifold used to add desirability curves is simpler and does not show grids labeled with numeric values.

![Desirability Curve](image)

The curve above shows an "all or nothing" choice of 35. Anything below 35 has zero interest, and anything above 35 has 100 percent desirability. Curves like this are called \textit{step functions}, for obvious reasons. Traditional SQL and other query systems use such all-or-nothing step functions.
The curve above shows a classic flexible approach to picking values at 35 and above. It’s been drawn so that desirability rapidly increases from 0% to 100% in the range from 32 to 37. Instead of an all or nothing step function that changes at 35, the numbers just above 35 are more desirable, but not absolutely so, than the numbers that are slightly lower than 35. Numbers that are well below 35 are not at all desirable while numbers far above 35 are 100% desirable.

The third curve shows a situation where there is a very gradual increase in desirability. It would be used in a case where one is very flexible about using values on either side of 35. In fact, depending on what one is searching for it might be a good criterion to use for age when seeking “mature” age groups. This might be a good criterion for “mature” age selection for marketing certain travel packages or upscale goods such as luxury full-sized automobiles.

Manifold’s Decision Support System combines criteria into queries where the desirability of various field values implied by the criterion are mathematically combined in a composite ranking of records. For example, suppose the values in the illustrations above represent the age of automobile drivers. Suppose for marketing purposes we wish to find all customers in our table who are mature drivers that live in an affluent area. We could begin by using the third criterion illustrated above for the Age field of our table under the name “mature”.

We then could create another criterion such as the one shown above using a Household Income field. In this case, we’ve drawn a criterion curve that increases rapidly for incomes around 40000, a level of household income well above average. We might give this criterion the name “affluent”.

To find regions with people who are both mature and affluent, we would use the above two criteria in a query that searched for mature AND affluent people. Decision Support System would spring into action on our behalf to sift through the entire table comparing the age and household income values of each record both to the mature
criterion as well as to the affluent criterion and ranking each record based on the composite desirability of the values.

For example, a person aged 54 with an income of 49000 would have 100% desirability in both criteria and thus would be ranked high. A person who is aged 54 but has an income of 40000 would have 100% desirability in the mature criterion but only about 70% desirability in the affluent criterion and so would receive a lower ranking. By mathematically combining the results of comparing individual records to the various criteria used in the query, Manifold Decision Support can create a composite ranking even within very complex queries. The result is a selection that incorporates our preferences in "gray areas" where inflexible selection rules cannot.

Using Decision Support System

The actual mechanism for using Decision Support System within Manifold is very simple: we add a rank column to the table that reports the relative ranking of records using the desired criteria in the desired way. We add a rank column with the Add Rank Column dialog, which also lets us specify criteria and their use within a DSS query.

See the Add Rank Column Dialog for details on adding rank columns to tables.
Add Rank Column Dialog

The Table - Add - Rank Column menu choice launches the Add Rank Column dialog. This dialog is used to create and manage criteria and Decision Support System (DSS) queries to be used with a table. The Add Rank Column dialog also appears when a rank column head is right clicked and Edit is selected from the context menu. It contains a criteria pane and a rank query pane. To add a rank column to a table we specify criteria and then use those criteria to create a ranking query. When we press OK the column will appear in the table with values computed by DSS.

Name
The name of the rank column as it will appear in the table.

Criteria
A hierarchical diagram of each field used in a criterion and the names of criteria created using that field. The illustration shows we have two criteria created: one using the Quantity field and one using the Unit Price field. The Criteria pane will show all of the criteria that have been created in this project for use in any rank column.

New - Add a new criterion.
Delete - Delete the highlighted criterion.
Properties - Edit the highlighted criterion.

Query
The lower pane shows queries created by dragging and dropping criteria from the upper pane to the lower pane. The query in the illustration finds all records that are Rare and very Expensive.

Not
Double click to prefix criterion with Not, for example, to create "Not Rare and …"

Hedge
Adjust the criterion by emphasizing or de-emphasizing its action. Double click into the cell to change. The illustration above shows the use of the hedge very to modify Expensive.

Criteria
Criterion dragged and dropped from the upper pane into
the query.

**Junction** Boolean **Or** or **And**. By default, criteria dropped into the query use **Or**. Double-click to change to **And** if desired.

### The Criteria Pane

The **Criteria** pane in the **Add Rank Column** shows all criteria that have been created in the project for use with any rank column. Criteria are shown organized under the field they use. Criteria can be used in queries as set forth below. A criterion may be used in a query in more than one rank column.

### Add Criterion Dialog

Clicking on **New** in the **Add Rank Column** pane launches the **Add Criterion** dialog. The dialog shows a curve in red with a vertical gray line at the **Center** value position and labeled with that value. The line along the bottom is labeled with the lowest and highest values found in the **Column** being used.

<table>
<thead>
<tr>
<th>Name</th>
<th>Name to use for this criterion.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Column</td>
<td>Field to use for this criterion. Criteria can only be created using numeric fields that are not Active Columns or other rank columns. The graphical display is labeled with the lowest and highest values found for the <strong>Column</strong> being used.</td>
</tr>
<tr>
<td>Preset</td>
<td>The type of criterion curve to create. Choose from <strong>Interval</strong>, <strong>Average</strong>, <strong>High</strong> or <strong>Low</strong> presets.</td>
</tr>
<tr>
<td>Center</td>
<td>Typically used with <strong>Average</strong> to specify the center of the bell curve. Also used to shift the center of the transition in <strong>High</strong> or <strong>Low</strong> presets. Check <strong>Auto</strong> to have Manifold reckon the center automatically. A gray line shows the value for <strong>Center</strong> with the value labeled.</td>
</tr>
<tr>
<td>Within</td>
<td>Typically used with <strong>Average</strong> to specify the width of the bell curve. Also used to widen or narrow the transition zone from high to low in <strong>High</strong> and <strong>Low</strong> presets. Check <strong>Auto</strong> to have Manifold reckon the width automatically.</td>
</tr>
<tr>
<td>(Interval Boxes)</td>
<td>Appear with <strong>Interval</strong> preset. Choose those values that bracket the given percentage above or below the region of transition. See discussion below.</td>
</tr>
</tbody>
</table>

The first step in running Decision Support System is to add one or more **criteria** to the Criteria list. Each criterion specifies the desirability (from 0 to 100 percent) of various possible values in one field. For example, we might create a criterion called "Mature" that specifies the desirability of various ages taken from a [Median Age] field in our table. We might create another criterion called "Affluent" that showed the desirability of various values taken from the [Household Median Income] field in our table. Each criterion describes the values we seek within a single field. We create criteria with the intention of using them in queries.
More than one criterion can be created for each field. For example, suppose we wish to characterize different patterns of median age in several different ways. We could create three different criteria, called "Mature", "Young" and "Old" that are all based on the [Median Age] field. We could then use whichever criterion was desired to rapidly customize a query. For example, we could rapidly switch from seeking areas that are "Mature" and "Affluent" to finding areas that are "Young" and "Affluent".

All criteria that appear in any rank column dialog in a table are available to all other rank column dialogs in the table. We might therefore create several different criteria using the same field and use them in several different rank columns in that table.

To Add a Criterion:

1. Press New to add a new criterion to the Criteria pane.
2. Enter a name for this criterion in the Name box.
3. Choose the field (column) from the table that will be used in this criterion.
4. Choose a preset type of criterion.
5. Make any manual changes desired using Center, Within or interval boxes. If any manual changes to Center or Within or interval boxes have been made, press Apply to apply these changes to the criterion curve.
6. Press OK.

Methods used to specify Criteria

Every criterion will be shown as a red curve in the criterion diagram. There are several methods that may be used to specify a criterion curve:

- **Use a preset** - Choosing an Average, High or Low method is the easiest approach because the system does all the work.
- **Customize a preset** - Each of the presets allows alterations, if desired, in the defaults picked by the system by un-checking the Auto boxes and then manually changing the values in the Center or Within boxes. For example, we might start with the Average preset but choose a wider bell curve by specifying a larger value in the Within box so that a wider range of values are more desirable. This is almost as easy as using a preset.
- **Upper and Lower confidence interval ranges** - Using the Interval preset, we can pick upper and lower confidence ranges and have the system figure out an appropriate criterion curve. This is good for situations where we can pick an approximate upper and lower bound for what we are seeking.

Standard deviation is used create some of the presets based on the actual distribution of values within the table. "Standard deviation" is a statistics measure that measures how much numbers are scattered about their average. If the numbers follow a perfect Gaussian ("bell shaped") distribution, than 68% of the numbers will be within one standard deviation +/- from the average and 95% of the numbers will be within two standard deviations of the average.

**Average**

The Average preset creates a bell curve that is Centered on the average value in the data field and which extends one standard deviation to either side of the average. We can customize the default preset by changing the Center to change the center line of the bell curve or by changing the width of the bell curve. We may change the width of the bell curve by changing the Within number. Press Apply after changing the values.

Why would we change the Center? Perhaps we want to create a criterion that we will name "Better than Average." To create this criterion we would like to have a bell-shaped curve but centered about a higher point than the average.

**High and Low**

We often wish to search using the "high" and "low" values of a data field. For example, seeking "Affluent" regions usually means find those areas with "high" household median income. Manifold Decision Support System provides High and Low presets that make it easy to create a criterion that finds above average or below average values for a data field.
• The **High** preset assigns zero desirability to all numbers below the average and then increases desirability in a smooth ramp to 100 percent for numbers that are greater than one standard deviation above the average.

• The **Low** preset assigns 100 percent desirability for numbers up to one standard deviation below the average, and then decreases desirability in a smooth ramp to zero for numbers above the standard deviation.

Both **High** and **Low** presets may be customized by changing **Center** or **Within** values.

**Interval**

The **Interval** method of specifying a criterion uses two desirability intervals (confidence values) to pin down a curve from zero desirability to 100 percent.

The default **Interval** curve uses a number that is 10% desired and a number that is 90% desired and draws a curve between them. The numbers in the boxes to the right (the 10% and the 90%) are desirability as a percent. The numbers in the left-hand boxes are data values for the data field being profiled. To use **Interval**, change the numbers given for what is 10% desired and what is 90% desired and then press **Apply**.

For example, if we were searching for values and knew that a number of about 15 was 10% desired and a number of 45 was 90% desired, we would choose **Interval** as the type of criterion and then use 15 = 10% and 45 = 90%.

Suppose we weren’t sure what was 10% desired, but we knew very well that 25 was 80% desired and 45 was 90% desired: we would enter 25 = 80% and 45 = 90%.

**Names**

When creating a criterion it helps to provide a descriptive, memorable name for the criterion. For example, perhaps a certain pattern of income characterizes people our marketing department calls “Boomers,” in reference to a particular demographic cohort arising from the post-World War II “baby boom”. If we add a criterion based on [Household Median Income] that matches this income pattern we might refer to that criterion as a “Boomer” criterion.

**Creating Queries for Ranking**

![Add Rank Column](Add%20Rank%20Column.png)
The lower pane in the Add Rank Column dialog hosts queries. The query in the illustration finds all records that are Rare and very Expensive. Queries are created by dragging and dropping criteria from the criteria pane into the query pane. As each criterion is dropped into the query it is added to previous criteria using Or by default.

- **Not**: Double click into the Not column to prefix criterion with Not, if desired.
- **Hedge**: Adjust the criterion by emphasizing or de-emphasizing its action. Double click into the Hedge column to specify, of desired.
- **Criteria**: Criterion dragged and dropped from the upper pane into the query.
- **Junction**: Boolean Or or And. By default, criteria dropped into the query use Or. Double-click to change.

**Boolean Combinations of Criteria in Queries**

"Boolean" refers to logical operators such as AND, OR and so forth. Suppose we have a query similar to the one in the illustration above. It includes two lines using criteria: Rare and Expensive with a junction of And. In addition, we could double click into the Not column to create constructions such as "Not Rare and Not very Expensive." Various combinations of the Junction and Not columns result in Boolean combinations such as And, Or, And Not ("NAND" in Boolean terminology) and Or Not ("NOR").

There can be as many query lines as we wish with each line after the first ending with a Boolean operator that shows the role it is to play in the query and the next line optionally preceded with a Not. The order of precedence is simply from first line to last. Decision Support System uses simple queries that do not use nested sub-expressions within parentheses. It is possible that complex queries will result in zero values for all records, meaning that no record comes close to the query criteria.

For a historical note on George Boole, the inventor of Boolean logic, see the Expressions topic.

**Hedges**

Suppose after creating a criterion such as Expensive we would like to use this criterion in a query searching for records where products are extremely expensive? One approach might be to create another criterion using the High preset and then use the Center box to shift the criterion curve towards higher values of unit price. Another method is to Double-click into the Hedge column in the query pane to choose extremely.

This will change how the criterion is used in the query without any need to go back and change the criterion. When we press OK the Expensive criterion will automatically be shifted so the rank column will be recomputed using extremely expensive.

**Hedge** choices provide standard modifications to the use of criteria as follows:

- **(blank)** Applies criterion "as is".
- **above**: Favors values above the last maximum of the criterion. Applying this hedge to an Average criterion yields a High
criterion with the same settings.

**below**  Favors values below the first minimum of the criterion. Applying this hedge to an Average criterion yields a Low criterion with the same settings.

**extremely**  Greatly strengthens the criteria defined by the criterion. If the original criterion rates a value of 250 dollars with a 50 % desirability level, applying extremely will rate the same 250 dollars a 79.4 % desirability level (79.4 % = 50 % ^ 1/3).

**slightly**  Greatly weakens the criteria defined by the criterion (weaker criteria than somewhat). In the example above, applying slightly will rate 250 dollars with a 12.5 % desirability level (12.5 % = 50 % ^ 3).

**somewhat**  Weakens the criteria defined by the criterion, but not as weak as slightly. In the example above applying somewhat will rate 250 dollars with a 25 % desirability level (25 % = 50 % ^ 2).

**very**  Strengthens the criteria defined by the criterion, but not as strong as Is Extremely. In the example above applying Is Very will rate 250 dollars with a 70 % desirability level (70 % = 50 % ^ 1/2).

---

**Deleting Criteria**

When deleting a criterion, keep in mind that it may be used in other rank columns than the one being edited. Deleting a criterion will remove it from all queries in which it participated. This can change the meaning of a DSS query used to generate a rank column.

For example, suppose we have a criterion called Populated that finds all records where a population field is High. Suppose we also have a criterion called Small that finds all records where area is Low. Suppose we have created a rank column called Crowded that uses a query with both of these criteria to find records that are Populated and Small.

If we open some other rank column for editing and then delete the Small criterion without realizing that it is used in the Crowded rank column, we will change the meaning of that rank column. When the Small criterion is deleted, what is left of the query for the Crowded column will simply find records that are Populated.

If a rank column uses only one criterion and that criterion is deleted, the rank column will be deleted as well.

Charts

Charts
Manifold provides two pathways to charting data:

- **Charts** are project components created from database tables. Manifold's Chart system provides a simple bar chart style that shows data from tables in 2D charts.
- **Minicharts** are small, simple charts that hover above objects in a drawing. They are kept deliberately small and simple since there are often many of them in view in a drawing or map.

To Create a Chart from a Table

1. Choose **File - Create - Chart**.
2. In the **Table** box choose the table that will be used to create the chart.
3. In the **Labels** box choose the field that will be used for the X-axis in the chart. To group records and present them on the X-axis choose the grouping field in the **Group by** box. This will override the **Labels** box.
4. In the **Display** pane choose the fields that will be plotted on the Y-axis in the chart.
5. Press **OK**. The chart will appear in the project pane under the table from which it is created.

Create Chart Dialog Controls

- **Name**: Specify a name for the chart component in the project.
- **Table**: The table to be used to create the chart.
- **Group by**: Field to use to group displayed values. If a **Group by** field is specified it will be used to order the results on the X axis and will override any **Labels** setting.
- **Labels**: Field to use to arrange results on the X axis.
- **Display**: Choose one or more fields to display on the Y axis.
- **Select All**: Check all columns. All data fields will be charted.
- **Select None**: Uncheck all fields. No data will be charted.
- **Select Inverse**: Use this to uncheck all fields before checking those desired.
- **Move to Top**: Move the highlighted field to the top of the field stack. If several fields are displayed in the chart, this displays it as the leftmost bar within a group of bars.
- **Move Up**: Move the highlighted field up one position in the field stack. This displays it one position to
the left within a group of bars.

- **Move Down** Move the highlighted field down one position in the field stack. This displays it one column position to the right within a group of bars.

- **Move to Bottom** Move the highlighted field to the bottom of the field stack. This displays it as the rightmost column within a group of bars.

- **View Types** Show a column displaying database types for each field.

**Numeric and Non-Numeric Fields**

Numeric fields chosen for display will be shown using their numeric value in the Y axis. Non-numeric fields chosen for display will be counted and the total count in each grouping will be shown in the Y axis. For example, suppose we have a table that shows customer address records. The table includes a **City** field and a **State** field, both of which are text fields. If we selected **State** as the **Group by** field and in the display pane checked **City**, the chart would show how many cities are in each state.

**Changing Colors**

Colors in charts will be assigned using a default palette. Choose **View - Format** to change colors. Colors may be changed for each individual field displayed by double clicking into the color well shown for that field. Colors may also be changed for all fields at once by loading a different palette. Colors will be the same in all windows showing that chart.

- **Load Palette** Load a new palette from the collection of palettes available within Manifold.

- **Interpolate** Adjust colors in a smooth gradation from the upper color to the lower color.

- **Reverse** Reverse the order of colors used.

The **Load Palette**, **Interpolate** and **Reverse** commands are normally used only when several fields are charted since it is faster to change colors with only one field by double-clicking into the color well.

**Labels**

Choose **View - Labels** to place labels on the X axis or on the Y axis. Reasonably round numbers will be chosen for the Y axis labels based on the values of the data displayed. X axis labels will be drawn from the **Labels** field or from the **Group by** field, if one is specified.

X axis labels may be rotated vertically to allow more labels to fit on the X axis. Labels will be clipped to avoid overlaps. Therefore, every cluster of bars might not be labeled.

Charts will automatically expand as the chart window is resized. To see more labels, make the chart wider. On low resolution monitors, undock or close the project pane and other panes if need be to allow the full width of the screen to be used.

**Logarithmic Scaling**
Charts

Click **View - Logarithmic Scale** to use logarithmic values on the Y axis. This will re-scale the Y axis using values such as \(10, 100, 1000, 10000\) and is a good way to show two different series of values where one series has relatively small values and the other has relatively large values.

**Changing Fields Displayed**

Once a chart is created we can choose **Chart - Data** to change the fields displayed or the **Group by** or **Labels** fields used.

**Example**

Import `mexico_eg.mif`, the sample drawing of Mexican provinces. Use **File - Create - Chart** to launch the **Create Chart** dialog. Choose `Mexico_eg Table` as the table to use. Group by **Place_name**. In the **Display** pane check the boxes for **BUSES_1991** and **TOTVEH_199**. Press **OK**.

A new chart component appears in the project pane under `Mexico_eg Table`. We can double click on the chart to open it. Note that labels are arranged on the X axis to avoid overlaps, so that not all bars are labeled.

We can choose **View - Labels** and check the box to rotate the X labels vertically. This allows more labels to be visible on the X axis.
If we want more labels to appear, we can widen the chart window to allow room for more labels. Some of the bars are very short because there are relatively few buses in comparison to total vehicles.

We can remedy this by choosing View - Logarithmic Scale so that the bars representing buses become more visible.

**Non-Numeric Example**

Import the Customers table from the Nwind.mdb sample database (the same as the Northwind.mdb sample database shipped with Microsoft Access).

<table>
<thead>
<tr>
<th>Customers</th>
</tr>
</thead>
<tbody>
<tr>
<td>Custo...</td>
</tr>
<tr>
<td>AUPK1</td>
</tr>
<tr>
<td>ANATH</td>
</tr>
<tr>
<td>ANTON</td>
</tr>
<tr>
<td>ARORH</td>
</tr>
<tr>
<td>BERGS</td>
</tr>
<tr>
<td>BLAUS</td>
</tr>
<tr>
<td>BROWD</td>
</tr>
</tbody>
</table>

We would like to see what is the most frequently occurring customer title in our database. To find out, we create a chart from this table using **Contact Title** as the Group by field and use **Contact Name** as the Display field.
The chart shows a bar for each **Contact Title** that exists. The height of the bar is set by how many different records exist with a value in **Contact Name** that also have that particular **Contact Title**. We can see the "Owner" and "Sales Representative" are the most frequently occurring titles.

The **Contact Name** field is used as a counting field. We could have used any field where we know there is a value in the field whenever there is a value in the **Contact Title** field. Looking at the table it seems reasonable that every record that has a value in the **Contact Title** field will also have a value in the **Contact Name** field so we used that field as a counting field.

**Saving Charts as Images**

The Tools - Make Image command captures the current scene displayed in a chart window as an image. Images made of chart windows are captured at screen resolution.
Minicharts
Minicharts are small charts that hover above objects in a drawing. They are frequently used with drawings showing areas, but they may also be used within drawings that show points.

They display the relative values for each object of specified numeric data fields from tables associated with the drawing.

To Create Minicharts in a Drawing

1. Click open a drawing.
2. Choose Drawing - Minichart
3. In the Minicharts dialog, check the field boxes for numeric fields that are to participate in the minichart.
4. Double click into color wells to change colors from defaults, if desired.
5. Choose the display Style, Size and Frame color and other parameters. Press OK.

To Remove Minicharts from a Drawing

1. Open the drawing.
2. Choose Drawing - Minichart
3. In the Minicharts dialog click the Select None button to uncheck all fields. Press OK.

The minichart dialog appears with a range of colors for each numeric field that may be used to create a minichart. Double click into any well to change the color.

Minichart Dialog Controls

- **Select All** - Check all fields in the Chart pane.
- **Select None** - Uncheck all fields in the Chart pane.
- **Select Inverse** - Uncheck all checked fields and check all unchecked fields. A fast way to show all but one field: click Select None, check the one column not desired and then click Select Inverse.
- **Move to Top** - Move highlighted field to the top of the list.
- **Move Up** - Move highlighted field up one position in the list.
- **Move Down** - Move highlighted field down one position in the list.
**Move to Bottom** - Move highlighted field to the bottom of the list.

**Style**
Choose from common types of simple charts.

**Frame color**
Color to use for frame border or other outlining element in the minichart.

**Offset point charts by**
When a minichart is created based on data from point objects, specifies the number of printer's points in the X and Y directions to offset it from the point. By default, the offset is 6 points in both X and Y. Increase these values to position the minichart farther away from the point. Offsets must be in the range from -100 to 100 points.

**Size**
Size of the minichart in points.

**Resolve overlaps**
Checked by default. Do not show minicharts that overlap each other. Uncheck to show all minicharts.

**Spacing**
Minimum spacing between minicharts in points before minicharts will be hidden to resolve overlaps.

**Use with Restraint**

Minicharts are visually pretty and fun to use but they should be used with restraint. When used with too many fields they may cause confusion instead of enlightenment. When used tastefully with a few fields they can convey information that is otherwise difficult to show.

Readers interested in creating clear and effective maps and charts will probably enjoy the spectacular series of books on this theme by Edward Tufte, beginning with "The Visual Display of Quantitative Information", ISBN 0-9613921-0-X. This is a fabulous book that is light on text, easy to read and full of wonderful illustrations.
Surfaces and Terrains

Surfaces are components similar to images in that they contain data organized as pixels. Surfaces are made up of numbers arranged in a regular array. Surfaces are imported from formats in which the data are organized in regular form, usually in a raster format similar to images. Surfaces differ from images in that whereas images save color or grayscale in the regularly organized data, the numbers in a surface normally will store elevations, temperatures or other abstract data.

Surfaces may also have Terrains created for them. A terrain is a 3D view of a surface. When a surface is imported a default terrain is created for that surface. Additional terrains may be created for a surface and each such terrain can have its own coloring and other characteristics. Creating an additional terrain for a surface does not require any more storage space since terrains are just different views into the one data set contained in the surface. An unlimited number of terrains can be created for each surface. If desired, the default terrain created for a surface may be removed so that the surface has no terrains.

Because surfaces are structurally similar to images they are imported into Manifold as components that have many characteristics that are similar to images. Surfaces will have commands available that are very similar to images. In particular, one can:

- Make selections in surfaces as in images using the pixels in surfaces.
- Modify selections using Edit - Modify Selections.
- Save and Load masks as with images.
- Use many transform operators similar to those used with images.
- Add a surface to a map as a layer.
- Georegister a surface.
- Print a surface.
- Analyze a surface using Surface Tools or the Volume function in SQL.

By default, when a surface is opened it appears in a 2D window like an image.
The default settings used with surfaces provide a 2D visual image of the data set contained in the surface. By default, images are shown shaded with autocontrast. By changing Display Options they can change their appearance, for example to show simple grayscale or to be colored with a palette like the first illustration in this topic.

The illustration above shows part of a DTED Level 2 terrain elevation surface from NIMA that is overlaid in a map with hydrology layers from the analogous VMAP Level 2 vector data set. The surface Surfaces may be used within maps as layers by dragging and dropping the surface into the map. Surfaces may also be copied and pasted as images, and those images can then be used as layers in a map as well.

When a surface is imported into Manifold, a Terrain for that surface is automatically created and placed in the project pane hierarchy under the parent surface. Terrains are components that provide a 3D view of a surface.
Data sets imported as surfaces usually are elevation data showing the height above sea level for various regions. Typical formats used for such data are NIMA's DTED or various DEM formats. However, we may use any regularly organized X,Y data set containing a third numeric value to be used as an "elevation." In general, any raster data set can be used as a surface.

Surfaces can be used for displaying terrain surfaces as well as for showing abstract data in gradient maps. See the Displaying Data in a Gradient Map topic for an example that shows demographic data displayed in a continuously varying gradient throughout the United States using a surface.

Some formats can be imported into Manifold either as an image (with File - Import - Image) or as a surface (with File - Import - Surface). When a surface data set is imported, a 2D image component will be created as well as a 3D terrain component.

We import a surface using File - Import - Surface. Manifold's importers can handle a wide array of formats with some overlap between the surface format importers and the image format importers. A few formats, such as USGS Digital Elevation Modules (DEM) can make sense either as surfaces, drawings (a field of points arranged in a regular grid), or images (with a palette applied to show a 2D image of elevations). Which component type is used for such data depends on its intended usage within the project. See the Import and Export topic for more information on specific import dialogs used to import surfaces.

**Surface Windows**

When a surface is opened in a surface window or appears as a layer in a map, the appearance of the surface is controlled by options in the View - Display Options dialog. By default, the surface appears as a grayscale image with shading and autocontrast. These options are suitable for images that represent terrain elevations. They may be modified to better show surfaces that represent abstract data, such as land use codes.

Note that although surfaces appear in windows like images and share many commands that may also be applied to images, they are not images. The appearance of the data within the surface window is controlled by the display options, some of which (such as slope or aspect) may involve computation. In contrast, the appearance of images within an image window is "hard wired" by the color values of the pixels.

If desired, a surface may be converted into an image by copying the surface and pasting it as an image. In that case, the colors in the image pixels will be taken from the display options currently set for the surface.
The image above shows the bathymetry of the Northern half of Lake Tahoe on the Nevada-California border in the United States. It was imported from an .e00 grid file as a surface and then copied and pasted as a detailed, 1995 x 3416 pixel image. The Invert command was then used to invert the grayscale in the image to give it a greater sense of depth.

Creating Surfaces

Surfaces are used for two main purposes:

- To show terrain elevations or bathymetry.
- To show abstract data such as population or temperatures as a continuously varying surface.

Surfaces showing terrain elevations or bathymetry are usually imported from pre-existing DEM or other surface formats since data sets for terrain elevations are usually so extensive that few users can create such data sets.

Surfaces showing abstract data are often created from drawings or tables. In this case, the drawing or table is copied and then pasted as a surface. The surface can then be colored with display options or seen in 3D as a "terrain." See the Creating Surfaces from Drawings and Tables topic for details.

Touch Selection in Surfaces

Touch selection in drawings will select the objects touched. In images, touch selection will select pixels within the tolerance setting in the Tool Properties pane. With surfaces the tolerance setting for touch selection is automatically set to be five percent of the overall height range. Clicking on a surface with height values that range from 1000 to 2000 at a point with a height of 1820 will select heights between 1770 and 1870.

Converting Data Types in Surfaces

Surfaces internally consist of a regular array of numbers. The numbers within surfaces can be any one of a variety of numeric types, either integers of various types (signed, unsigned, 8-bit, 16-bit, 32-bit or 64-bit) or single or double precision floating-point numbers.

The Surface - Convert To command allows conversion between different types of numbers within the surface.

Masks and Surfaces

Masks can be used with surfaces as they are with images. Saving a mask from a surface results in an image that is georegistered to the surface and that retains any selection that was made in the surface. This is a handy way of saving complex selections made in a surface as an alternative to using the Selections pane.

Using the Layers Pane with Surfaces
The Layers pane helps control the appearance of surfaces within surface windows. The layers pane includes checkboxes for two system "layers" - a background color layer and a border layer that shows an enclosing box about the height and width of the surface.

By default, surfaces are shown using the checkerboard background Manifold uses to provide a backdrop for any transparent regions. Checking the Border box in the layers pane will draw a one-pixel border around the height and width of the surface. This is a good way to see the actual extent of a surface that contains regions of invisible pixels.

Checking the Background box in the layers pane will replace the checkerboard background with whatever is the default background color. This is a good way to see the actual extent of a surface that contains regions of pixels that are the same color as the background (usually white).

Note that only maps can have true "layers" in Manifold in the sense that they can layer more than one component within the same map window. The border and background "layers" in the Layers pane for surfaces are not true layers even though they appear in the Layers pane in the same manner as do layers in maps. These are simply system controls that take advantage of the Layers pane as a conceptually convenient user interface.

**Layouts and the Layers Pane**

If a surface has any Layouts created they will appear as "layers" in the layers pane for that surface. Checking the box for one of these print layout layers will cause a layout rectangle to appear in the surface that shows the region covered by the layout.

Right clicking onto the hatched border of one of the layout rectangles in the surface will cause a context menu to appear with controls based on that layout rectangle. For example, we can **Zoom** to a given layout rectangle, **Print** it or change its **Properties**. If a layout is empty (for example, if the layout scope is set to **selection** and no pixels are selected in the parent surface) zooming to the layout will do nothing.

Use **Tools - Options - Colors - Layout Rectangle** to change the color in which layout rectangles are shown. The default color is black.

**Tech Tip**

The status bar will report the height of a surface at the cursor position when a surface window is open. When one or more surfaces appear in a map window, the status bar will report the height of the uppermost visible surface at the cursor's position.

**Notes**

See the Import a Raw Binary File - NLCD to see an example of a surface that shows data other than terrain elevation. The example shows a surface that represents data from the National Land Classification Data system.
Surface Window Menus and Controls

This topic lists default menus and controls that appear when a surface window is active. These will also appear when a surface tab is active in a map. Surface commands are all listed under the Surface menu. Some commands are organized under submenus called Adjust and Effects. These somewhat arbitrary categories like those used for images so Manifold users who are familiar with Adobe PhotoShop will find the menu structure more familiar when seeking analogous commands.

Edit Menu

**Undo**
- Undo last command.

**Cut**
- Windows clipboard cut operation. Copy pixels to the windows clipboard and delete them from the surface.

**Copy**
- Windows clipboard copy operation. Use this to copy pixels from the surface onto the clipboard for pasting elsewhere.

**Paste**
- Paste the contents of the Windows clipboard into the surface and deletes any selected pixels. Creates new pixels in the surface.

**Paste Append**
- Paste the contents of the Windows clipboard into the surface without deleting any selected pixels. Creates new pixels in the surface.

**Delete**
- Permanently delete selected pixels from the surface.

**Delete All**
- Permanently delete all pixels from the surface.

**Assign Projection**
- Used with drawing, image, labels and surface windows to change the interpretation of the data. This is a specialized function that is applied only when manually specifying the projection of a component imported from a format that does not correctly store projection information. To change the native projection of any component other than a map, use the Edit - Change Projection command.

**Change Projection**
- Used with components like drawings and images to re-project the component and thus permanently change the data.

**Select All**
- Select all pixels in the surface.

**Select None**
- Deselect all pixels in the surface.

**Select Inverse**
- Invert selection: those pixels that were selected will be deselected while those pixels that were not selected will be selected.

**Select Mode**
- Choose the selection mode to be used for mouse selection:
  - **Replace** - Any selection made with the mouse will replace the previous selection.
  - **Add** - Any selection made with the mouse will be added to the previous selection.
  - **Subtract** - Any selection made with the mouse will be subtracted from the previous selection.
  - **Invert** - Any selection made with the mouse will be inverted with the previous selection.
  - **Intersect** - Any selection made with the mouse will be intersected with the previous selection.

**Modify Selection**
- Changes the shape of regions of selected pixels.
  - **Border** - Select those pixels on the border of the selected region(s).
**Contracts and Terrains**

**Contract** - Uniformly contract selected region(s) by given number of pixels.

**Expand** - Uniformly expand selected region(s) by given number of pixels.

**Smooth** - Provide a smoother edge to the region(s) of selected pixels.

**Snap To**

**Snap To** Enable/Disable snap modes:

**Graticule** - Snap to graticule intersections if a graticule is displayed.

**Grid** - Snap to grid intersections if a grid is displayed.

**Save Mask/Channel**

Create masks from the current surface or save channels of the current appearance of the image as grayscale images.

**Load Mask/Channel**

Load a mask or a channel from a grayscale image.

**Open Data Source**

Opens in Database Console the data source of a surface linked from a table in an external data source.

**Go To**

Go to the entire surface or to a selection.

**View Menu**

**Back**

Go back one view.

**Forward**

Go forward one view.

**Zoom In/Out**

Zoom in brings us closer to the surface while zoom out moves us farther away.

**Zoom To Fit**

Zoom so that the surface fits the existing window size.

**Zoom To**

Zoom to a specified zoom level.

**Graticule**

Show a graticule (latitude/longitude lines).

**Grid**

Show a grid that may be used to measure or to align editing and snap commands.

**Legend**

Display a legend showing formats.

**North Arrow**

Display a North arrow.

**Scale Bar**

Display a scale bar.

**Display Options**

View and modify surface display options.

**Panes**

Call a dialog that allows displaying or hiding all panes.

**Full Screen**

Show the surface over the entire monitor area.

**Refresh Data**

Update a linked surface with the latest data from the controlling geocoded table.

**Refresh View**

Update the visual appearance of the surface with any changes made since the last refresh. Enabled only if Autorefresh View is off and some change (such as a selection) has been made that might affect the visual appearance of the surface.

**Autorefresh View**

Automatically update the surface whenever any changes are made that might affect the visual appearance of the surface. Turn this option off when working with very large surfaces where there is no desire to take the time to show, say, a selection when it is made (repainting a very large surface on every selection step might take longer than desired). When Autorefresh View is off, we
can always cause a refresh on demand using the Refresh View command.

Properties View the properties dialog for this surface.

View - Panes Menu Panes of special interest when working with surfaces include:

Selection Save and recall regions of selected pixels.

Surface Menu

Open Data Source Open Database Console focused on the data source of a linked surface.

Transform Transform surfaces using formulas. Available only when the Surface Tools extension has been installed.

Quantize Convert surface to the specified number of height values using the most frequently occurring heights.

Resize Change the number of pixels in the surface using desired interpolation method.

Convert To Convert the numeric types used for height information in the surface.

Contours Create contours using this surface.

Watersheds Compute streams, watersheds and upstream areas. Available only when the Surface Tools extension has been installed.

Relink Enabled for a linked surface only. Relinks (reconnects) the linked surface to another data source.

Unlink Enabled for a linked surface only. Converts the linked surface to a local surface with no connection to the originating data source. Linking and then unlinking a surface is equivalent to importing it.

Surface - Adjust Menu

Invert Invert pixel height value. Creates a topographic negative so that heights become low regions and vice versa.

Threshold Forces height pixels to maximum, minimum or unchanged based on a histogram.

Posterize Convert surface to a limited number of height values. Height values are chosen to be evenly spread throughout the total range of heights for the number of levels specified.

Surface - Effects Menu

Filter Applies convolution filters, either custom filters or a choice from numerous presets.

Noise Add random height values.

Tile Convert surface into rectangular tiled regions of appropriate height.

Tech Tip
The status bar will report the height of a surface at the cursor position when a surface window is open. When one or more surfaces appear in a map window, the status bar will report the height of the uppermost visible surface at the cursor's position.
Surface Display Options

Surfaces appear in a surface window as grayscale images where lighter colors indicate greater heights. The word "Height" is used even though the data values of a surface may convey some other meaning, such as temperature.

To change the appearance of a surface window, use View - Display Options to change the settings.

**Display Options**

By default, surfaces will appear as shaded surface renderings with the color of each pixel corresponding to the data value at that spot as adjusted for highlights and shadows from a Sun in the East. Other options include display of aspect or slope, or use of shading. Palette controls are similar to those used in Thematic Formatting of drawings.

**Display**
Choose the computation used to display the surface in 2D.

- **Height**: Color each surface pixel by its height.
- **Aspect**: Color each surface by its aspect, that is, the azimutal direction in which a tangent plane faces at that spot, for example, a north-facing section of hillside. Aspects vary from -180 to 180 degrees.
- **Slope**: Color each pixel by the inclination of the surface at that point. Slopes are given in degrees.

**Palette**

Preset color combinations that may be applied to surfaces. Press **Apply** to apply the palette to the surface. Palettes use a fixed number of intervals and corresponding colors.

**Apply**
Apply the chosen palette to the Colors pane. This allows scrolling through the palettes without changing colors until we press **Apply**. Pressing **Apply** only changes the color...
scheme in use for values. It does not change the formatting of the surface until the OK button is pressed. To see a preview of how the applied colors will look, use the Preview check box.

Reverse  Reverse the formats used in the colors box from high to low.

Interpolate  Change the colors or sizes used in the colors boxes by interpolating between the top and the bottom boxes. A quick way of creating smooth gradients of colors or sizes.

Lighten  Lighten all colors. Each click of the Lighten button lightens the colors a bit more.

Darken  Darken all colors. Each click of the Darken button darkens the colors a bit more.

Grayscale  Convert all colors to grayscale.

Load  Load a previously saved theme from an XML file. The loading rules allow omitting color specifications in the XML file to load values using whatever is the default color. Loading rules also allow omitting any of the colorDef, colorMax, colorMin, interval and type tags.

Save  Save this theme to an XML file.

Shading  Shade the surface with highlights and shadows as if illuminated by the Sun from a given azimuth and elevation.

Autocontrast  Automatically adjust contrast for even dispersion of light and dark tones.

Azimuth  The angle to the Sun’s position in degrees from North: North = 0, East = 90, South = 180 and West = 270 degrees. Keep in mind that in most latitudes in the Northern Hemisphere the Sun traverses azimuthal angles from East to South to West. Used to compute shading.

Altitude  The Sun’s altitude above the horizon in degrees. 0 is at sunrise or sunset and 90 is directly overhead. Used to compute shading.

Slopes are measured in degrees such that 0 degrees is a horizontal slope (an absolutely flat surface). 45 degrees is equivalent to a slope where for each meter in a horizontal direction the surface moves one meter vertically up. 90 degrees is an impossible example of a vertical slope. There are no slopes higher than 90 degrees. There are no negative slopes since every tilt of a surface can be viewed as either negative or positive and Manifold always regards it as positive.

Shading is computed based on a given position of the Sun as set by Azimuth and Altitude values. In the Northern Hemisphere in the course of a day the Sun moves in azimuth approximately from 90 degrees (East) to 180 degrees (South) to 270 degrees (West). Depending on the time of year and the latitude the Sun’s altitude will range from 0 degrees (on the horizon, at sunrise and sunset) to 90 degrees (directly overhead, in the tropics). To allow artistic effects and for usage in unusual latitudes (such as above the Arctic Circle), Manifold allows Sun azimuth and altitude values beyond these ranges.

Save Mask/Channel

The Edit - Save Mask/Channel dialog for surfaces includes choices to save aspect or slope data in single-precision floating-point format into new surfaces. Aspects vary from -180 to 180 degrees. Slopes vary from 0 to 100 percent. Surfaces created using this dialog will retain the coordinate system (projection) and saved selections of the original surface.

Example
We will use **File - Import - Surface** to import the *montara_mountain* DEM files from SDTS format.

This file came from the USGS free Internet servers. It shows a portion of the San Francisco peninsula approximately centered on the region where Highway 92 cuts across the San Andreas fault and the coast range on its way from the Bay to the ocean.

DEM's are "Digital Elevation Modules" and give the height of the Earth's surface. High resolution DEMs (1:24,000-scale) are provided by USGS in SDTS format. They may be imported from the **File - Import - Drawing** dialog or form the **File - Import - Surface** dialog. When an SDTS file containing a raster elevation data set is imported via the "drawing" dialogs, Manifold knows to create a surface.

DEM's are "Digital Elevation Modules" and give the height of the Earth's surface. High resolution DEMs (1:24,000-scale) are provided by USGS in SDTS format. They may be imported from the **File - Import - Drawing** dialog or form the **File - Import - Surface** dialog. When an SDTS file containing a raster elevation data set is imported via the "drawing" dialogs, Manifold knows to create a surface.

The result is several new components in the project: the surface, the surface's terrain and comments taken from the DEM file. Manifold takes the name for the component from the name embedded in the SDTS file. If we double-click open the surface component, what we see in the surface window is determined by the settings in the **View - Display Options** dialog.

The illustration above shows the default **Height** display with **Shading** and **Autocontrast** boxes checked. By default, Manifold will show the surface as a shaded surface as if it were illuminated from the specified direction (an **Azimuth** of 90, East, sunrise, by default). Very cool! This is probably the most frequently used display option for surfaces. In the Northeast quadrant we can see a linear valley cutting across from the northern edge of the surface to just below the middle of the Eastern edge of the surface. That valley marks the path of the San Andreas fault, locus of the famous 1904 earthquake that destroyed San Francisco.
If we choose the **Height** display and uncheck the **Shading** and **Autocontrast** boxes we get a simple grayscale display that shows lower elevations as darker tones and higher elevations as lighter tones.

Choosing **Aspect** for display option we see the surface color-coded to show the aspect of each pixel. **Aspect** is the direction in which terrain faces. Aspect is the direction in which the surface at that point faces. We would use an aspect display to find, for example, all of the southern-facing regions that would provide a sunnier place to locate a house.
Because aspect displays are difficult to interpret if too many aspects are shown at once, they are usually formatted with a simplifying palette. The display above uses the Black to White palette to reduce the number of aspects that are displayed into four major ranges.

Choosing **Slope** shows the inclination at each location, with lighter pixels indicating greater slopes. **Slope** is the angle that the perpendicular to the face makes with the vertical. Black pixels show flat regions. Note the black color of the regions covered by the lakes in the valley of the San Andreas fault. Since lakes are flat, the slope in these regions is flat. **Slope** is a good way of finding reasonably level regions to use for building sites, helicopter pads, weapons emplacement and so forth. It may also be used to find paths through terrain that do not traverse steep ground.
Palettes

Surfaces may be automatically colored by palettes other than the default black and white palette.

Applying the Altitude palette will color the display by elevation to produce the effect seen above. The Shading and Autocontrast options have been checked.

Fixed Interval Palettes

Palettes in Manifold occur in two forms:

- Relative palettes, where colors from the palette will be "stretched" and interpolated as necessary for use in the number of breaks specified in the Colors pane. The example above uses relative palettes.
- Fixed palettes, where colors are associated with specified intervals. When a fixed palette is used in thematic formatting, applying the palette will automatically create as many intervals as are required by the numbers specified for the palette.

Fixed palettes are most frequently used to color surfaces that show terrain elevations. They allow a standard color scheme to be applied for specific elevations that is the same from surface to surface. Manifold includes a few fixed palettes for use with surfaces. Altitudes are predictable since the general elevation of the Earth is known and covers a fairly narrow range. Standardized palettes may therefore be created for altitudes and incorporated into Manifold.

The fixed interval palettes provided in Manifold are named Altitude... and are provided in three variations: a palette where color intervals have round numbers intended to indicate meters, where round numbers are intended to indicate feet and a relative version of the same palette.

Surfaces usually originate in either meter-based data sets, where the elevation values are given in meters, or in foot-based elevation values such as US SDTS DEMs where the elevations are in feet. It is convenient to have the same fixed palette available with both meter-based as well as foot-based palettes so that the color scheme can be used for the same elevation above or below sea level regardless of whether the numbers in the surface represent meters or feet.

It is also convenient to have a version of a fixed palette available as a relative palette. This is allows a quick look at how the full range of palette colors appears in use. We can use whatever data set we want and even if it only ranges between -100 and 1000 we will still see the full set of colors.
The Altitude and Altitude and Bathymetry palettes are typical of those used in large printed atlases. The colors are organized to provide good displays throughout most of the world. Since most world atlases are in meters, the elevations chosen for the color intervals will be round numbers in meters.

The Altitude, Aeronautical palette provides a simple color scheme similar to that used in NOAA sectional aeronautical charts in the United States. This palette has elevations chosen for color intervals that are round numbers in feet.

**Customization**

Palettes used in thematic formats may be customized, and new palettes may be added to Manifold. See the Customization topic.

**Tech Tip**

Change the appearance of surfaces by selecting parts of the surface and then deleting them and letting the background show through. For example, one way to show lakes or other water bodies in surfaces (which are at the same elevation) is to select their pixels and then delete them. Make the background of the surface blue so that the water regions are all colored blue no matter what their elevation.

For example, suppose we start with a surface that's been colored with a palette using View - Display Options. The background for this surface is turned on in the Layers pane. The background has been set to blue color in the View - Properties dialog for this surface.

We click on regions using SHIFT - touch select to select all portions of the surface at a given elevation. Using Add to Selection mode, click on the desired elevation and on regions below the desired elevation.
Press **Delete** and the selected pixels disappear, allowing the blue background to show through. Note how this method provides a "waterline" effect to instantly show which regions are above a given elevation.

This method can also be used to remove flatter parts of a surface, leaving only very mountainous areas. The surface can then be used in a map overlaid upon drawings to provide visual cues of mountainous terrain.

### A Note on Computation of Slopes

There are many ways to compute the "slope" of a surface. If a surface consists of an even, flat plane tilted in only one direction that extends over a great distance then most people and algorithms would agree what the "slope" is. However, in reality surfaces often consist of numerous undulations in small scale and large and the "slope" computed depends upon how the computation is made. "Slope" is an artificial approximation based upon a subjective judgement or other heuristic as to what plane should be taken as an approximation for a particular surface or a portion thereof.

At the lowest level, surfaces are ordered sets of pixels arranged in a regular array with a height for each pixel. To compute the slope of a surface one must consider some window, that is, some subset matrix of pixel values, and then perform a computation on it. Let's consider three possible ways to compute the slope of a surface given a $3 \times 3$ pixel window.

Consider the following window:

\[
\begin{array}{ccc}
  z_1 & z_2 & z_3 \\
  z_4 & z_5 & z_6 \\
  z_7 & z_8 & z_9 \\
\end{array}
\]

To compute the slope we have to approximate this window with a plane that will give us $dx$ and $dy$ factors. We can then use the $dx$ and $dy$ factors to compute the slope (a simple matter of $\tan(\text{hypot}(dx, dy) / 2)$ with some scale correction).

Here is one way to do this:

\[
\begin{align*}
  dx &= z_6 - z_4 \\
  dy &= z_2 - z_8
\end{align*}
\]

Here is another way to do this:

\[
\begin{align*}
  dx &= ((z_3 - z_1) + (z_6 - z_4) + (z_9 - z_7)) / 3 \\
  dy &= ((z_1 - z_7) + (z_2 - z_8) + (z_3 - z_9)) / 3
\end{align*}
\]

Here is yet another way to do this ($k > 1$):

\[
\begin{align*}
  dx &= ((z_3 - z_1) + k*(z_6 - z_4) + (z_9 - z_7)) / (2 + k) \\
  dy &= ((z_1 - z_7) + k*(z_2 - z_8) + (z_3 - z_9)) / (2 + k)
\end{align*}
\]

For example, in the above case one might use $k = 2$ to weight the central comparison more. There are numerous other ways as well, but the above three show in simple fashion three possible approaches.

If different software uses different methods, it will provide different values for "slope" at any given location. In general, Manifold uses the second method but there are software packages that use the first method, the third method and many other methods.

### Example: Transferring Aspect to Points

Manifold's raster extensions to SQL allow us to exploit computations on surfaces from within SQL. For example, suppose we have a drawing of points that are located in the same region of interest as a surface and we would like to compute the aspect of the surface at each point and to save that value as a data attribute for each point. This is easy to do using SQL as follows:
1. Open the drawing's table and add a new floating-point column named Aspect.
2. Create a new query.
3. Open the query and enter the following text for the query (substitute the name of the drawing for "Drawing" and the name of the surface for "Surface"):  
   \[ \text{UPDATE } [\text{Drawing}] \text{ SET } [\text{Aspect}] = \text{AspectHeight}([\text{Surface}], \text{Centroid}([\text{Geom (I)}])); \]
4. Run the query. This will set the values in the Aspect column for each point to the aspect of the surface at that point's location.

**See Also**

Using Surfaces as Images - Surfaces are virtual views either in 2D or 3D. They can be dragged and dropped into maps as is. They can also be copied and pasted as images to allow subsequent effects using image manipulation tools.

Stylistically, the Display Options dialog has much in common with the thematic formatting dialog. See Thematic Formatting for examples.

See the Displaying Data in a Gradient Map topic for an example that shows demographic data displayed in a continuously varying gradient throughout the United States using a surface.
Using Surfaces as Images

When a surface is opened in a surface window, Manifold computes the view to present based on the settings in View - Display Options for that surface. The views presented in the surface window are the results of computations and usually represent greater information than simply color coding the values in the Surface. To capture the view presented, we can Copy the surface and Paste As an image. We can then use the resulting image as desired.

To Capture a Surface as an Image

1. Open the surface in a surface window by double-clicking on the surface in the project pane.
2. Use View - Display Options to specify the appearance of the surface.
3. At any time thereafter, Copy the surface component in the project pane and Paste As an image. The resulting image will capture the appearance of the surface component using the current display options.

Example

See the Surface Display Options topic for an example of importing the Montara Mountain USGS high resolution SDTS - DEM as a surface.

Importing the file creates a surface component and a terrain, as well as some comments components.

We can double-click open the surface and set the View - Display Options to show Height with Shading and Autocontrast as shown in the Surface Display Options topic.

In the project pane we can right click on the surface and choose Copy. We can then right click into the project pane and choose Paste As - Image.

A new image appears in the projection pane. It is a grayscale image capturing the view of the surface seen in the surface window.
If we open the resulting image we can see it is the same as the surface window view. However, we now have a real image. We can paint into it, we can covert it into an RGB or RGBA image and we can use it as a layer within a map. We could use the original surface as a layer in a map too, but converting it into an image allows us a wider range of editing effects such as partial transparency applied to individual pixels as can be done with RGBA images.

For example, we could create an image from a surface and then use it within a map as seen below. The map was created using DTED Level 2 and VMAP Level 2 sample data downloaded from the NIMA web site.

Create the image above using the following steps:

1. Import a surface from DTED Level 2 sample file for Kileen, Texas.
2. Import the VMAP Level 2 file for the same area, checking hydrography and roads layers.
3. Open the surface and set display options to use Height, Shading and Autocontrast.
4. Copy the surface and paste as an image.
5. The VMAP Level 2 importer creates hydro and roads maps. Open the hydro map.
6. Drag and drop the image into the hydro map. Place it at the bottom of the map layer stack.
7. Drag and drop the roads layer into the hydro map.
8. Format the water areas in the hydro map in blue colors. Set their opacity to 50%.
9. Format labels and hydro lines to taste.

Note that importing a surface usually results in a georeferenced surface, since almost all formats used for surfaces are geographically aware formats. When a georeferenced surface is copied and pasted as an image, the resulting image is also georeferenced. It may be immediately combined with drawing layers in maps without further georeferencing.
Linked Surfaces

Linked surfaces are surfaces that are dynamically created from tables or queries. The tables and queries used to create linked surfaces may be inside the Manifold project or they may be in external databases. Linked surfaces are shown in the project pane using an icon that includes a yellow "database" cylinder to show they are created from a database table or query. Linked images are normally read-only.

Linked surfaces may also be created in a two step process, where the virtual table for an existing surface is used in a query to manipulate that surface or to fetch part of the surface based upon desired criteria. A linked surface can then be created from that query. This technique is often used within Manifold projects that will be used in an IMS website.

Linked surfaces may also be created from tables or queries stored in external databases. For example, we could use a query to select all columns for all pixels in an surface's virtual table and then export that query as a table into an .mdb file or to some other database storage.

When a surface is linked from a table or query, each record in the table or query produces a pixel. The coordinates of the pixel are taken from the X and Y columns (cast to integer) specified in the Link dialog. The height of the pixel is taken from the Height column.

Editing Linked Surfaces

Although a linked surface that appears in the project pane is normally read-only, it is usually possible to edit that linked surface by editing the data source from which it is created. For example, suppose we have a linked surface created from a query that uses the virtual table of another surface. We could change that linked surface by editing either the original surface or by editing the query.

Relink and Unlink

If a connection is lost between a linked surface and its originating data, the Surface - Relink command allows us to restore the connection. If we would like to convert a linked surface into a regular surface, the Surface - Unlink command will sever all connections to the originating table or query and will convert it into a regular surface.

Virtual Tables for Images and Surfaces
Queries and Images or Surfaces
Raster Extensions
Linking Surfaces
Terrains

Terrains are 3D views of Surfaces. Surfaces are raster data sets that may be seen either in 2D or in 3D. The default view for a surface is as a 2D image. Clicking open the surface will show the surface in a 2D view like an image.

When a surface is imported, a terrain component for that surface is automatically created.

Terrains are shown under their parent surface in the project pane hierarchy. Creating another terrain for the same surface will also show it under the parent surface.

Create a terrain for a surface by right clicking the surface and choosing Create - Terrain.

Additional terrains may be created for a surface and each such terrain can have its own coloring and other characteristics. Creating an additional terrain for a surface does not require any more storage space since terrains are just different views into the one data set contained in the surface. An unlimited number of terrains can be created for each surface. If desired, the default terrain created for a surface may be removed so that the surface has no terrains.

Clicking open a terrain will present a 3D view of the data in the surface.

Once a surface is imported into Manifold, we can see it as an image by opening the surface, or we can see it in a 3D terrain window by clicking open the surface's terrain in a terrain window.

When open, the terrain window shows a view of the terrain from a particular viewpoint, as if seen from a camera at that position. The initial view is seen from a camera position at the center of the data set. What is seen in the window may be adjusted using keyboard navigation commands to alter the position of the camera, the direction it is pointed, and the field of view. In addition, we can use Linked Views to navigate to different locations in the terrain.
Controlling the Appearance of the Terrain

The contents of the terrain window are controlled by menu options that appear under the Terrain menu. These options also appear in the context menu when right clicking into a terrain window.

- **Open Surface**
  - Open the parent surface for this terrain.

- **Surface**
  - Specifies how the data surface that defines the terrain should be visualized. Includes options such as the texture used for the surface, the color determined by the elevation, the level of details computed, the size of the data set in view and whether the surface is shown with walls and in wireframe style or not.

- **Overlay**
  - Overlay the terrain surface with images or with drawings. Specifies options to be used to display objects from drawings.

- **Clouds**
  - Display synthetic "clouds" in the sky in accordance with given options.

- **Fog**
  - Apply a haze effect that can appear as fog or as a subtle haze in the distance. Provides a greater sense of reality and depth.

- **Lighting**
  - Choose options for creating highlights and lowlights in the surface to represent the angle of lighting.

- **Water**
  - Create an opaque or semi-transparent "waterline" plane of given color. Used to simulate waterline effects.

- **Snap to Surface**
  - Forces the "camera" from which the terrain window is seen to hover just above the surface by applying slight gravitation to camera movement.

**Note:** The Snap to Surface function assumes the camera begins above the surface so that gravity pulls it down to the surface. If the initial camera position is below the surface the camera must first be moved above the surface using a keyboard Q command.

**North Arrow**

In addition to the above controls, use View - North Arrow to show or hide the "compass" North arrow in the terrain window. We can also right click on the North arrow in the terrain window to hide it or to change alignment or properties.

**Saving Terrain Views as Images**

The Tools - Make Image command captures the current scene displayed in the terrain window as an image. This command allows us to specify the pixel dimensions, and thus the detail seen, of the image.
For example, suppose we open a terrain window like the one above. This shows a view into a terrain created from the Montara Mountain sample surface. We can use Make Image to create an image of this view, for example, if we wanted an image to use in a brochure or to include in some other document.

Suppose, however, we would like to capture this view at higher resolution that seen at screen resolution on our computer monitor. If we save the image at screen resolution and then we print an enlarged version of the image within a document such as a poster, the image would appear overly pixilated. To see this effect, consider the region of the view marked by the red box.

When enlarged (as might occur when printing the image in a large size in a poster) we can see the detail in the terrain is limited by the screen resolution of the view. We can create the image with resolution higher than screen resolution by simply specifying a larger number of pixels to use for the image in the Make Image dialog.
For example, we might specify that the image be created in a pixel size of 2325 by 1450 pixels, about five times the resolution of the original terrain view at screen resolution.

In that case, when Manifold creates the image from the terrain view it internally will re-compute and re-render the terrain view at higher resolution so that the view will be seen in the image at the desired number of pixels horizontally and vertically. This shows the same view with greater detail.

The view above shows a small portion of the resultant image (which is too large to appear in Help), zoomed so that it shows approximately the region marked by the red box in the original terrain view. We can see that the distant mountain peaks that were rendered in an overly pixilated manner at screen resolution are now rendered in much higher detail.

**Saving Terrain Views in the Views Pane**

Terrain views may be saved in the Views pane to go back to the same view at a future time.

**Keyboard Navigation**

In addition to the keyboard arrows, Manifold uses keyboard navigation shortcuts to control the view seen in the Terrain window.
Surfaces and Terrains

W  Move forward.
S  Move backward.
Q  Strafe Up. (Move vertically up)
E  Strafe Down. (Move vertically down)
A  Strafe Left. (Move horizontally left)
D  Strafe Right. (Move horizontally right)

SHIFT  Pressing the SHIFT key with any of the above key commands will increase the effect of that command.

Up / Down Arrow  Tilt view up / down to +60 or -60 degrees from horizontal.
Left / Right Arrow  Rotate view left / right.
+  Increase field of view (up to 130 degrees).
-  Decrease field of view (down to 30 degrees).
*  Reset field of view to 90 degrees
/  Move camera position to center of terrain.

The keyboard shortcuts are designed to allow "two handed" fast keyboard navigation as favored by experts in various computer tactical games. Strafe is gamer-speak for moving sideways or up/down without rotation. A Q move is thus the same as moving straight up, as in a helicopter.

To fly upward from the terrain surface, make sure that Terrain - Snap to Surface is unchecked. Next, either use Q to fly directly upwards or use the keyboard up arrow to rotate the view upwards and then use W to move forward. The Q move lifts us up as if in an elevator or helicopter moving straight up. The up arrow followed by a W is like angling an airplane upwards and then flying forward and up the angle.

Keyboard Shortcuts for Z Scale in Terrain Windows

With the focus on the terrain window we can use the following keyboard shortcuts to modify Z scale.

Page Up  Increase Z scale by .01
SHIFT-Page Up  Increase Z scale by .10
Home  Set Z scale to 1.0
Page Down  Decrease Z scale by .01
SHIFT-Page Down  Decrease Z scale by .10

Performance Notes

Manifold's terrain view window uses the OpenGL subsystem in Windows for 3D visualization. Manifold requires a functioning OpenGL subsystem to display terrains. If there are no OpenGL capabilities in the system terrain windows will be blank when opened.

The visible performance of a terrain window is determined by two factors. The first factor is the time required for Manifold to access data and to generate parameters for rendering (heights, colors and textures). The second factor is the time required by the OpenGL system to process the generated data. Because Manifold is so fast at computing terrains, quite frequently the limiting factor in processing speed is the speed of the OpenGL system, not the time it takes Manifold to fetch data and set up the view.

It is therefore critically important that your OpenGL system is as fast as possible. The speed of the OpenGL system will depend upon the ability of the video graphics card to support OpenGL in hardware as well as upon the
quality of the OpenGL drivers in use, which are normally provided by the graphics card vendor. For terrains, charts and other 3D work, get a fast graphics card with OpenGL support in hardware and lots of local graphics memory. The manifold.net team recommends cards based on NVIDIA chips. It is critically important to use good drivers. Efficient, well-written drivers are more important than raw hardware capability.

Check your graphics card vendor's web site for their latest drivers for your version of Windows. Check also the web site for the chip vendor who makes the graphics chip used by your graphics card. The chip vendor will often provide faster drivers than those available from the card vendor. Using good drivers can make the difference between smooth "fly through" motion and very slow, jerky motion in terrain views.

For example, during the development of Manifold System a number of low-cost (under $100) AGP graphics cards using NVIDIA chips were installed to test terrain window performance. When using the drivers packaged with the cards the terrain window moved painfully slowly. Several seconds were required for each slight scene change when a key was pressed to move forward, backward or to rotate left or right. After downloading and installing the latest graphics driver from the NVIDIA web site the terrain window provided smooth motion, "fly-through" quality graphics. The graphics motion seemed literally hundreds of times faster with the latest driver.

Because the quality of the graphics driver has such a great effect on the performance of the card it can be difficult to purchase a graphics card on the basis of hardware specifications only. Some of the best-known brands in graphics cards have surprisingly poor graphics drivers for OpenGL and DirectX, and some of these best known brands are also very poor at providing timely support for new versions of Windows such as Windows XP x64.

An especially frustrating situation can arise when a chip vendor sells a special version of a common graphics chip to a laptop vendor for use in a built-in graphics capability. In such cases it is frequently the case that the drivers initially shipped with the laptop are not as fast as those developed later on for the graphics chip. It is possible that users will have to wait for the chip vendor to release a special version of updated drivers to the laptop maker and then wait for the laptop maker to release the updated drivers to the user. In some cases, even famous name laptop makers have "orphaned" some products by failing to provide improved drivers for their graphics systems or even by failing to support more recent versions of Windows, such as XP.

One strategy for avoiding such problems is to buy laptops that use NVIDIA chips, because NVIDIA has in the past taken responsibility for the good performance of its products no matter how a subsequent manufacturer has used them, and has posted updated drivers on the NVIDIA website that can be used for all of its chips, even in laptops. In particular, NVIDIA has made it very easy to get 64 bit drivers, including 64 bit drivers that work correctly with AMD dual core 64 bit processors.

If you are assembling a new system, as graphics cards have increased in speed it has become difficult to buy a new graphics card that does not display Manifold terrains with great speed. If you use a reasonably recent (no need to buy the latest, hottest version) NVIDIA based card from a vendor who advertises support for new versions of Windows and OpenGL and if you also utilize the latest NVIDIA drivers, the rendering speed of terrains will be very good.

For maximum terrain viewing performance, use SLI-capable NVIDIA PCI Express graphics cards in an SLI-capable motherboard to team up two graphics processors for rendering. Prices on graphics cards are dropping rapidly: as of this writing, installing two high-end, SLI-capable NVIDIA graphics cards with 256 MB of RAM each costs a total of $250, an amazing deal for the resultant throughput. It is often faster to use two cards via SLI than it is to spend disproportionately more money for a single card that uses the very latest, super-hot graphics chip. For example, two SLI cards using slightly downrev, but still awesome chips might be had for $150 each and the combination could end up being as fast as or faster than the latest superchip board at $750 each. Of course, if money is no object, get two of the latest boards!

A typical machine at manifold.net used to explore large terrains is an AMD Athlon 64 x2 with four gigabytes of RAM running Windows XP x64 or Windows Server 2003 x64. It will have a motherboard that can host two SLI cards with 16x PCI Express slots and run two graphics boards using whatever is a notch or two down from NVIDIA’s latest chipset. Such machines can twirl full-sized terrains around effortlessly with perfectly smooth motion and no delays.

See the discussion in Performance Tips and in Using RAM and other Machine Resources for more on optimizing performance.

**Tech Note**

The speed with which Manifold sets up the terrain rendering job depends on the dimensions of the underlying surface, so larger surfaces will generally be slower than smaller surfaces. However, the speed penalty is semi-logarithmic: the time to generate the rendering data for a surface P that is two times as large as a surface Q is much smaller than two times the time required for surface Q. Therefore, although the speed of terrains does
depend somewhat upon the size of the underlying surface the dependency is non-linear so that greatly scaling up
the size of a terrain does not have that great an impact on rendering speed. The greatest impact will be the
speed of the graphics system.

Linked Views - Most navigation in terrains will be accomplished using the surface window as a "mini-map" via the
linked views capability of Manifold. Please take a moment to read the Linked Views topic. No matter how expert
one becomes in using keyboard shortcuts, usually using linked views is by far the fastest and easiest way to
navigate the view in a terrain window.

Overlays

Terrains may be overlaid with images, drawings, labels or even other surfaces using the Terrain - Overlay command. See the Terrain - Overlay topic for details on controls in this dialog.

To overlay a component onto a terrain:

1. Georegister any components to be used so they are in the same geographic location as the surface and terrain being used.
2. Open the terrain in a terrain window.
3. Choose Terrains - Overlay from the main menu.
4. The upper pane shows components available in the project for overlay. Check those components to be overlaid.
5. Choose display options for showing points, lines and areas.
6. Press OK.

Overlaying several components or complex components can require much computing time and will result in a long delay (potentially many minutes on a slow machine) while the overlays are rendered in the terrain window.

Example: Overlay a drawing

Using File - Import - Drawing with SDTS Files type we've imported the 1:24K scale SDTS DEM for the Montara Mountain, California, USGS quad. We've also imported the roads lines from the equivalent 1:24K scale SDTS DLG for this same quad. See the Combine a Surface and a Drawing in a Map example topic for details of import.

The drawing is a typical vector drawing. We've imported only the lines from the SDTS file.
We can open the surface and use View - Display Options to color it with a palette. The illustration shows a view zoomed into the upper right corner of the surface onto San Andreas lake in the valley of the San Andreas Fault.

We can double click open the terrain, color it using Terrain - Surface and then navigate to a position showing a view to the northwest down the axis of the San Andreas Fault.
To overlay the terrain with objects from the drawing we choose Terrain - Overlay. In the Overlay dialog we check the box for the roads drawing and check the Paint over terrain box as well as the Smooth line body box (for pretty, anti-aliased lines). We uncheck the Points boxes since there are no points in the drawing we will overlay. Press OK.

The result shows lines from the drawing overlaid on top of the terrain. If the drawing had any points we could have checked the Paint over terrain option for points and those too would have appeared.

**Example: Overlay a surface**

At first glance it may seem strange to overlay a terrain with a surface. After all, aren't terrains a 3D view of a surface? It makes sense to overlay a terrain with a surface because this allows creating a terrain with one surface while coloring it with data from a different surface.

Suppose for example we have a DEM that we use to create a surface and thus a terrain that shows elevation. Suppose we also have another surface that shows abstract data, such as infrared reflectivity, temperature, samples of pollutants, or some other data that we have colored as an abstract data surface. We can open the terrain to see the 3D lay of the land and we can also color the surface by overlaying a surface onto that terrain.
Using the Montara Mountain DEM again we've imported a surface and have opened the terrain in a window. The illustration above shows the terrain with no palette or texture applied in a view looking down the San Andreas Fault.

Suppose we also have another surface in our project that gives temperatures as measured by airborne sensors during an overflight. We see that surface opened above colored with a palette and using shading and autocontrast to give it apparent depth, as if it showed terrain elevation.
To color the terrain using the temperature scan surface, we open the **Terrain - Overlays** dialog and check that surface. The **Areas**, **Lines** and **Points** options are irrelevant when only images or surfaces are overlaid upon the terrain, so it doesn't matter what we use for them.

The result is that the terrain is colored by the surface overlaid upon it. We now see not only the terrain elevations but also their temperatures.

**Example: Displaying Contour Lines on a Terrain**

Importing the **hypsoigraphy** modules from SDTS files will result in drawings showing detailed contour lines. These may be overlaid onto terrains as well.
The illustration above shows a terrain with no overlays and no palette or texture. The illustration below shows the same terrain with contour lines from a 1:24K-scale SDTS DLG hypsography module. High resolution detailed drawings such as 1:24K-scale SDTS DLG hypsography files can take a long time to render. This example uses the Montara Mountain SDTS files and took 10 minutes on a 600Mhz PIII machine to overlay onto a terrain.

Manifold, of course, can also produce Contour areas that can be overlaid onto terrains.

**Notes**

Manifold uses OpenGL to render 3D views within terrain windows. A fast graphics card with well-implemented OpenGL drivers using hardware acceleration is a must.
On occasion one encounters graphics cards with bugs in their OpenGL drivers. The appearance of fine grid lines like those above when a terrain is overlaid with an image or a surface is a typical bug. The previous images were rendered on an NVIDIA card while the screenshot above was rendered using an ATI card. To remedy such problems, try downloading the latest drivers for your graphics card from either the card manufacturer or the manufacturer of the graphics chip used on the card.

If new drivers don't solve the problem consider switching to a different graphics card. The manifold.net team recommends cards with NVIDIA graphics chips since NVIDIA at the present writing has consistently turned out the best drivers for OpenGL and other graphics standards.

The "temperature scan" surface is fake data contrived for the purpose of this example. If it were real, the body of the lake would be cooler than the land.

**Tech Tip**

In drawings and labels, setting the foreground color to be transparent color will hide the entire object or label. Terrains respect this convention: if a drawing object or label has foreground color set to transparent color it will not appear in a terrain overlay. Likewise, if an area border foreground color is set to transparent color the area walls will also be hidden.

**See Also**

Area Overlays - Areas overlaid on terrains with 3D walls.
Terrain - Overlay - For examples of overlays of labels and surfaces and other detailed examples.
Area Overlays

When drawings that contain areas are overlaid upon terrains, Manifold will "float" the areas above the terrain and, if desired, render walls for the areas to give the appearance of extruded shapes. Areas take their color from the area background color and walls take their color from the border foreground color specified for the overlaying drawing. When representing areas as overlays, area style and foreground color are not used.

Such overlays are particularly handy for the schematic representation of buildings and other structures in 3D views of terrains.

Area overlays are turned on using the controls in the Terrains - Overlays dialog when a terrain is open.

Example

Consider a map with a drawings layer that appears above a surface. The surface is the Montara Mountain sample surface that has been colored using the View - Display Options dialog using the Altitude and Bathymetry palette.

<table>
<thead>
<tr>

<tr>
<td>10</td>
<td>40</td>
</tr>
</tbody>
</table>
The drawing consists of areas only, and has only one column in the drawing's table, a **Height** column that gives the height of each area above the local ground level. Note that this value is not an absolute height above sea level, but rather is intended to represent a height above ground.

![Format](image)

The drawing layer has been thematically formatted for area background color using the **Height** value so that each area is colored according to the height. The area border has also been colored by the same thematic format.

![Overlay](image)

If we open up the terrain for the surface and choose **Terrain - Overlay** we can set up the **Overlay** dialog to show area overlays. We click on the **Paint over terrain** box and make sure the **Walls** and **Vary height by column** boxes are also checked. The latter box will vary the height at which areas are rendered over the terrain by the contents of a column named **Height**.
The result is the scene illustrated at the beginning of this topic. Areas have been rendered using the colors specified in the thematic format for area background color for each area. Walls have been rendered using the area border foreground color. Area walls and areas are rendered using the Terrain - Overlay dialog settings for Opacity for areas (100% in this case), as well as lighting specified for the terrain.

If we were to change the Opacity setting for areas in the Terrain - Overlay dialog to 50% we could see that the extruded 3D area shapes shown in the terrain become partially transparent.

Area overlays may be combined with other effects, such as overlay of images. The above scene was created by first overlaying a TerraServer image upon the terrain and then overlaying a drawing containing areas showing building outlines. The area objects have a Height field giving the height of each building. (This image was created at Cornell University and is used by permission.)

**Tech Tip**

In drawings and labels, setting the foreground color to be transparent color will hide the entire object or label. Terrains respect this convention: if a drawing object or label has foreground color set to transparent color it will not appear in a terrain overlay. Likewise, if an area border foreground color is set to transparent color the area walls will also be hidden.

Terrain - Overlay
Contours

The Contours dialog works with surfaces to create a drawing that includes areas representing contours from the surface.

To create contours:

1. Open a surface in a surface window, or click on a surface layer in a map.
2. Choose Surface - Contours from the main menu.
3. Supply a Name for the drawing to be created and (optionally) a description.
4. Choose the type of contours to be created in the Create box.
5. Specify the contour values to be used in the Height pane.
6. Press OK.

The Add button is used to add one new contour interval.

To specify values to be used in the Height pane:

1. Click the Add button.
2. Double click into the resulting new row and change the Height value to the value desired.
3. Organize the heights by using the Move Up / Down / to Top / to Bottom buttons.

The Add Sequence button automatically creates a series of contour intervals.

To specify a series of contours automatically:

1. Click the Add Sequence button.
2. In the Add Sequence dialog, specify the Step between intervals and press OK.
3. A series of rows with heights from the lowest to the highest at the specified interval step will be created automatically.

Note that the Contour dialog refers to "heights" because most often in a GIS context it is used with surfaces that represent terrain elevation data. It can also be used to create contours with abstract data where the value in the surface represents some other value such as temperature or population.

<table>
<thead>
<tr>
<th>Name</th>
<th>Name for the drawing to be created that will contain the contours.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Description</td>
<td>Optional description for the drawing.</td>
</tr>
</tbody>
</table>
Surfaces and Terrains

Create
How contours will be created:

Areas above heights - Create contour areas that show all locations higher than a particular contour height. Contour areas for higher heights will overlap contour areas for lower heights. This is the “wedding cake” effect.

Areas below heights - Create contour areas that show all locations lower than a particular contour height. Contour areas for lower heights will overlap contour areas for higher heights. This is the “inverse wedding cake” effect.

Areas between heights - Create contour areas that show all locations with height between the height intervals given. No contour areas will overlap. The most frequently used option when creating contour areas.

Lines - Create lines at a given contour level. The classic contour line effect use within printed topographic maps.

Heights Pane
A list of heights to be used for contours. Can also be used to specify abstract values when a surface represents data other than terrain elevation.

Add - Add a new height range from the contours to be created.

Add Sequence - Automatically create a series of contour intervals.

Delete - Delete highlighted height range from the contours to be created.

Move to Top - Move the highlighted height range to the top of the heights pane.

Move Up - Move the highlighted height range up one position in the heights pane.

Move Down - Move the highlighted height range down one position in the heights pane.

Move to Bottom - Move the highlighted height range to the bottom of the heights pane.

(status info) The bottom of the dialog will report the minimum and maximum heights found in the surface.

Example

Visiting the USGS web site we’ve downloaded the Montara Mountain 1:24K-scale SDTS file that provides a DEM module for terrain elevation. We’ve imported it as a surface. Open the surface in a window.
Choose **Surface - Contours** to launch the **Contours** dialog.

In the **Contours** dialog click **Add** to add a new row in the **Heights** pane.

Double click into the new row that’s created and add a **Height** of 3.

Click **Add** again and add a **Height** of 100.

Click **Add** and add **Heights** at levels of 250 and 500 as well. Press **OK**.
The result is a new drawing in the project. If we open the drawing we see it consists of non-overlapping areas, where each area shows the contours between a given height range. The drawing's table has one field, the **Height** field, which gives the value of Height used to create each area.

We can thematically color the new drawing using thematic formatting controlled by the **Height** field, or simply by using the Color dialog to quickly color the areas with different colors.

For a nice effect, we can create a map using the original surface and then drag and drop the thematically colored contour drawing into the map in a layer above the surface. We then change the opacity of the drawing's layer to 50%. This creates a visual mixture of the thematically formatted contours and the surface shading.
Another classic map can be created by choosing the Lines option in the Create box in the Contours dialog and to then layer the resultant contour lines in a map above the surface, or to use contour lines drawing in a map above a different drawing.

Using the Add Sequence Command

The Add Sequence button allows us to add a series of contour heights.

Suppose we would like to add many contours at once for a surface that has a minimum height of 389 feet and a maximum height of 1708 feet. We launch the Contours dialog and press the Add Sequence button.
In this example we will start the series at 1000 feet by entering that value in the **Offset** box and we will enter **100** in the **Step** box to create a contour every 100 feet.

![Contours dialog box]

The result is a sequence of heights in the **Heights** pane that are 100 feet apart beginning at the 1000 foot level.

**Surfaces and Terrains**
Editing Surfaces

Surfaces may be edited using many of the same methods used to edit images. Methods include:

- Changing the surface "free hand" by making selections and the deleting pixels or otherwise modifying them.
- Using the Transform toolbar to change many pixels at once throughout the surface.
- Using effects or adjust commands from the Surface menu such as Quantize to edit the surface.
- Changing the surface by projecting or georeferencing it.
- Altering surfaces with scripts or other tools.
- Use View - Display Options to change the appearance of the surface, including computing slope and aspect.
- Creating new surfaces from drawings or other components via copy and paste as.
- Cutting, copying and pasting between surfaces.
- Copying a surface, pasting as a table, changing the table values and then creating a surface from the table.
- Edit the image using update queries that operate on the image's virtual table to directly change the colors of pixels or other characteristics. See the Virtual Tables for Images and Surfaces topic as well as the Queries and Images or Surfaces topic.
- Use the Surface - Transform command dialog packaged with the optional Surface Tools extension to perform arbitrary transformation of surfaces, including computations that involve multiple surfaces such as subtracting one surface from another.
- Use commands on the Surface Menu to change the surface.

Cropping a Surface

Cropping a surface to a given size by making a selection and then choosing [Selection] Crop in the transform toolbar and pressing Apply. The surface will be cropped down to the minimum enclosing rectangle of the selection.

Use Crop Margin to crop the surface by the given number of pixels at the border. Use Add Margin to expand the size of the surface by the given number of pixels at the border.

Eliminating "No Data" or spurious values

Some surfaces may contain pixels coded with a value of -9999 or some other distinctive value to indicate there is no reliable data for that pixel. To eliminate such pixels we have two options:

- Select pixels representing no data using Select Touch or other selection method and delete them.
- Use the Surface - Transform dialog provided in Surface Tools to cut out values lower or higher than the given threshold.

Copying a Surface and Pasting as a Table

Surfaces may be copied and pasted as tables. When pasting a surface as a table, the system will compute intrinsic fields for each pixel in the surface. The Paste As dialog offers the following choices:

- Select All - Paste all fields.
- Select None - Do not paste any fields.
- Select Inverse - Do not paste all current Paste As fields and paste all other fields. A fast way to use all but one field: click Select None, specify a Paste As choice for the one field not desired and then click Select Inverse.

Center Easting (I)  X coordinate of the center of this pixel in native coordinate system units adjusted with the values of the local scale and local offset parameters.
**Center Latitude (I)** Latitude of the center of this pixel in degrees latitude.

**Center Longitude (I)** Longitude of the center of this pixel in degrees longitude.

**Center Northing (I)** Y coordinate of the center of this pixel in native coordinate system units adjusted with the values of the local scale and local offset parameters.

**Center X (I)** X coordinate of the center of this pixel in native coordinate system units.

**Center Y (I)** Y coordinate of the center of this pixel in native coordinate system units.

**Height (I)** Height value.

**Invisible (I)** 0 or 1 to indicate invisible pixels, normally used for missing height values.

**Latitude (I)** Latitude of the lower left corner of this pixel in degrees latitude.

**Longitude (I)** Longitude of the lower left corner of this pixel in degrees longitude.

**Easting (I)** X coordinate of the lower left corner of this pixel in native coordinate system units adjusted with the values of the local scale and local offset parameters.

**Northing (I)** Y coordinate of the lower left corner of this pixel in native coordinate system units adjusted with the values of the local scale and local offset parameters.

**Selection (I)** Boolean: currently selected or not.

**Selection Mask (I)** A byte giving the saved selections mask.

**X (I)** X coordinate of the lower left corner of this pixel in native coordinate system units.

**X Offset (I)** X position in pixel coordinates from the lower left corner.

**Y (I)** Y coordinate of the lower left corner of this pixel in native coordinate system units.

**Y Offset (I)** Y position in pixel coordinates from the lower left corner.

Copying a surface and pasting as a table is a good way to make sophisticated edits or to perform analyses. For example, one can copy a surface and paste it as a table and then use the transform toolbar to change the values in the Height field. After making modifications, one can then copy the table and paste it back as a surface.

Suppose we would like to know the average height in a surface in regions that are within 100 meters of certain roads in a drawing. We create a buffer zone about the roads in the drawing, select the buffer zone and then transfer the selection to the surface. We can then copy the surface and paste as a table including the Height (I) and Selection (I) fields. We select all records in the table where Selection (I) is 1 and then use a ViewBot to report the average value of Height (I) for all records in the selection.

**Note:** When copying surfaces and pasting as tables, don't forget to paste the Longitude (I) and Latitude (I) fields or the X (I) or Y (I) fields to allow subsequent conversion back to a surface, if desired.

**Tech Tip**

Change the appearance of surfaces by selecting parts of the surface and then deleting them and letting the background show through. For example, one way to show lakes or other water bodies in surfaces (which are at the same elevation) is to select their pixels and then delete them. Make the background of the surface blue so that the water regions are all colored blue no matter what their elevation.
For example, suppose we start with a surface that's been colored with a palette using View - Display Options. The background for this surface is turned on in the Layers pane. The background has been set to blue color in the View - Properties dialog for this surface.

We click on regions using SHIFT - touch select to select all portions of the surface at a given elevation. Using Add to Selection mode, click on the desired elevation and on regions below the desired elevation.

Press Delete and the selected pixels disappear, allowing the blue background to show through. Note how this method provides a "waterline" effect to instantly show which regions are above a given elevation.

This method can also be used to remove flatter parts of a surface, leaving only very mountainous areas. The surface can then be used in a map overlaid upon drawings to provide visual cues of mountainous terrain.

Converting Data Types in Surfaces

Surfaces internally consist of a regular array of numbers. The numbers within surfaces can be any one of a variety of numeric types, either integers of various types (signed, unsigned, 8-bit, 16-bit, 32-bit or 64-bit) or single or double precision floating-point numbers.

The Surface - Convert To command allows conversion between different types of numbers within the surface.

Masks and Surfaces

Masks can be used with surfaces as they are with images. Saving a mask from a surface results in an image that is georegistered to the surface and that retains any selection that was made in the surface. This is a handy way of saving complex selections made in a surface as an alternative to using the Selections pane.

Editing a Surface for Visual Effect
Creating Surfaces from Drawings and Tables

Surfaces may be created from drawings or tables by copying the drawing or table and pasting it as a surface.

When imported from a surface, image or drawing (for those drawing formats like SDTS that can contain surfaces), surfaces are already created as raster, grid data. At times, however, we might want to create a surface using an irregular pattern of points or from a geocoded table that contains a spatially irregular set of records. To do so we simply copy the drawing or the geocoded table and then we paste it as a surface. We may even copy an image and paste it as a surface if it makes sense to do so. The Paste As Surface dialog will be raised to allow us to specify interpolation method and other parameters of interest in creating the surface.

Pasting Images as Surfaces

Height Specify the values to use for elevation values for the surface.

Type Choose the data type to use for elevation values.

Pasting Tables as Surfaces

X / long Choose which field in the table should be used for an X or longitude coordinate.

Y / lat Choose which field in the table should be used for a Y or latitude coordinate.

Latitude / longitude coordinates Check if the values in the X / long and Y / lat boxes are in degrees latitude and longitude. If this box is not checked the surface will be created in Orthographic projection treating the X and Y values as meter-based coordinates.

Height Choose the field to be used for elevation values for the surface.

Type The data type to use for elevation values in the surface. If the originating field is a different type, Manifold will convert to the given type when writing to the surface.

Margins Margins in the specified unit of measure (shared with the Pixel Size combos) in X and Y directions that the surface should be extended beyond the bounding box of the objects or records being pasted to create the surface. This allows extending the created surface by some margins beyond the data being pasted to create the surface, allowing some interpolation at the edges for smoother edge effects in some cases. 0 by default.

Pixel Size Size of pixels in the created surface, in the specified unit of measure.

Same size in X and Y direction If checked (default), any edits in the X pixel size will also update the Y pixel size, for "square" pixels.

Method Gravity, Kriging, Median-polish Kriging, No Interpolation, Triangulation (flat) or Triangulation adjusted for contours. The type of interpolation algorithm (model) used to create the surface. Options other than Kriging will appear only if the optional Surface Tools extension has been installed. The Triangulation adjusted for contours method uses triangulation adjusted using the DEST algorithm for increased accuracy.

Neighbors Appears when using the Gravity, Kriging or Median-
Surfaces and Terrains

**polish Kriging** method. The number of neighboring points to consider when making the interpolation. Manifold will automatically use all points as neighbors for interpolations up to 1000 points. Note that it is faster to use all points as neighbors up to 1000 points than it is to use some subset of points (such as, only 990 neighbors out of 1000 points).

**Model**
Appears when using the Kriging or Median-polish Kriging method.

- **Auto** (default), Exponential, Gaussian, Linear, Power, Rational or Spherical interpolation models. The Auto setting allows Manifold to choose which of the interpolation models it thinks will work best in this case.

- **Linear, Power, Rational or Auto** choices will appear only if the optional Surface Tools extension has been installed.

**Use only Voronoi neighbors**
Interpolate over each location using only those neighbors that would be adjacent in a Voronoi diagram. This helps achieve a balance between a too-smooth interpolation achieved with a high number of neighbors and a too-coarse interpolation achieved with a low number of neighbors. Using this option will increase processing time.

**Use radius**
Appears when using the Gravity, Kriging or Median-polish Kriging method. The distance in the given units from any data point over which an interpolation can extend. Not checked by default to allow Manifold to choose the radius.

**Save error surface as**
Appears when using the Kriging or Median-polish Kriging method.

Allows saving of an error surface using the given numeric type.

**Set corner values to**
Appears when using the Triangulation (flat) or Triangulation adjusted for contours methods.

Optionally set the values in the corners of the computed surface to the given values. If this option is used, the entire surface (to the full rectangular extents) will be interpolated using the corner values as anchors. If this option is not used, those regions outside the convex hull of the existing data points will remain invisible.

**Pasting Drawings as Surfaces**

Pasting a drawing as a surface is similar to pasting a table as a surface except that there is no need to specify the fields to be used as latitude and longitude, since the coordinates of objects in the drawing are built into the geometry of the drawing.

Likewise, there is no need to specify whether the coordinates are latitude and longitude coordinates, since the coordinate system used by the drawing is also known. When pasting a drawing as a surface, the surface will inherit all projection parameters from the drawing.

When pasting a drawing as a surface, Manifold can use point and line objects to create a surface. Point objects are taken as point data from which the surface is interpolated. Line objects will have point data created at each coordinate ("inflection point") that defines the line.

**Height**
Choose the field to be used for elevation values for the surface.
Type
The data type to use for elevation values in the surface. If the originating field is a different type, Manifold will convert to the given type when writing to the surface.

Margins
Margins in the specified unit of measure (shared with the Pixel Size combos) in X and Y directions that the surface should be extended beyond the bounding box of the objects or records being pasted to create the surface. This allows extending the created surface by some margins beyond the data being pasted to create the surface, allowing some interpolation at the edges for smoother edge effects in some cases. 0 by default.

Pixel Size
Size of pixels in the created surface, in the specified unit of measure.

Same size in X and Y direction
If checked (default), any edits in the X pixel size will also update the Y pixel size, for “square” pixels.

Method
Gravity, Kriging, Median-polish Kriging, No Interpolation or Triangulation (flat). The type of interpolation algorithm (model) used to create the surface. Options other than Kriging will appear only if the optional Surface Tools extension has been installed.

Neighbors
Appears when using the Gravity, Kriging or Median-polish Kriging method. The number of neighboring points to consider when making the interpolation. Manifold will automatically use all points as neighbors for interpolations up to 1000 points. Note that it is faster to use all points as neighbors up to 1000 points than it is to use some subset of points (such as, only 990 neighbors out of 1000 points).

Model
Appears when using the Kriging or Median-polish Kriging method. Choose Auto (default), Exponential, Gaussian, Linear, Power, Rational or Spherical interpolation models. The Auto setting allows Manifold to choose which of the interpolation models it thinks will work best in this case. Linear, Power, Rational or Auto choices will appear only if the optional Surface Tools extension has been installed.

Use only Voronoi neighbors
Interpolate over each location using only those neighbors that would be adjacent in a Voronoi diagram. This helps achieve a balance between a too-smooth interpolation achieved with a high number of neighbors and a too-coarse interpolation achieved with a low number of neighbors. Using this option will increase processing time.

Use radius
Appears when using the Gravity, Kriging or Median-polish Kriging method. The distance in the given units from any data point over which an interpolation can extend. Not checked by default to allow Manifold to choose the radius.

Save error surface as
Appears when using the Kriging or Median-polish Kriging method. Allows saving of an error surface using the given numeric type.

Set corner values to
Appears when using the triangulation method. Optionally set the values in the corners of the computed surface to the given values. If this option is used, the entire surface (to the full rectangular extents) will be interpolated using the corner values as anchors. If this option is not used, those regions outside the convex hull of the existing data points will remain...
Trimming Unwanted Surface Extensions

Data pasted as a surface rarely fits into a rectangular box. Normally, the interpolation radius parameter will deal with this automatically. For example, suppose we have a drawing showing county centroids in the United States with a "population" field for each county. If we paste these as a surface, the data within the borders of the US will be real but there will be no data beyond the borders of the US. In that case, the interpolation radius will render invisible all pixels in the surface beyond the region where data points exist. When using the triangulation method, the **Set corner values** option allows us to force Manifold to fill in all invisible pixels outside the convex hull of the surface to form an interpolated rectangular surface.

Another option is to simply select the unwanted surface pixels and delete them. The easiest way to make a surface conform to some desired area in a drawing is to select the area and transfer the selection to the surface. Use **Edit - Invert Selection** to select all other pixels and delete them. Next, use the Selections pane to select invisible pixels, invert the selection once more and then use the transform toolbar to **Crop** to the selection.

Creating Tables from Surfaces

Surfaces may be copied and then pasted as tables. See the Editing Surfaces topic.

Unexpected Results in Surfaces

When creating surfaces from tables or drawings at times we may see unexpected results in the surface. For example, a regular pattern or other visual artifact might appear superimposed upon the surface as seen in the illustration below.

The illustration above shows a surface interpolated from a table of 641 records providing elevations near Portola Valley, California. The table was copied and then pasted using default settings for pixel size into a surface. Using default resolution creates a surface with 102,400 points which means that 99.4% of the points are interpolated using a Kriging algorithm.

For smoother results it would be better to paste the table using larger pixels, for, say, 1600 points with approximately 60% being interpolated…

…or perhaps somewhat smaller pixels to get 6400 points with approximately 90% being interpolated:
Both of the above illustrations show the full surface, of which the first illustration shows the upper right corner. Pasting tables or drawings as surfaces where the surface contains much more than 90% interpolated points will produce highly unreliable results.

It is always tempting for newbies to want to interpolate data to "fill in the gaps" between a data set that has too few data points. It is also easy to forget the simple arithmetic that creates from such innocuous sounding numbers as a 320 x 320 (X pixels by Y pixels) the huge number of 102,400 points. Between the desire to have data where there is none and a forgetfulness about how many pixels are involved in even medium-resolution surfaces it is easy to fall into the trap of trying to stretch a rather small data set into a very large surface. If we want to create a finely detailed, high-resolution surface from a table the only solution is to have a reasonably large number of data points (records) with which to begin.

**Example**

In this example we will create a surface from a grid of points.

We begin with a map that shows a drawing containing a grid of points superimposed upon the example Montara Mountain surface (created from the USGS 1:24K-scale SDTS DEM showing a region just south of San Francisco, California). The grid was created by creating a blank drawing and then using the Grid command to create a grid of points spaced every 1000 meters. Points in the grid that did not appear above the surface were deleted. Using the Transfer Heights command we placed the value of the height of the surface into the Height column for each point.

We now have a drawing that contains points with height values for each point. Many data sets from which we would like to create a surface will be in this form, as a drawing of points where each point has a height value. Although many such data sets will have the points in a regular arrangement, a regular arrangement of points is not necessary to create a surface from such points. In this example, the points are regularly arranged because
that was the easiest way to create points for the example, by using the Grid command. All that is necessary to create a surface from points is that the points are reasonably dense in areas of interest. Obviously, if some regions have very many data points while in other regions there are very few points then the accuracy with which a surface may be interpolated will be lower in regions with fewer points.

To create a surface, in the project pane we Copy the drawing containing points and Paste As a surface.

In the Paste As Surface dialog we choose to make each pixel 100 meters in size in X and Y directions. Since our original data set had a point every 1000 meters, this means that we will create a surface for which ten surface pixels will be interpolated between each data point. We have also checked the Save error surface box to create an error surface.
Viewing the result, we can see that the surface is clearly of much lower resolution than the original. Even so the surface reproduces the general topography, at least as much as can be represented given that the surface heights were sampled only every 1000 meters (the spacing of the grid points). Note that the only way to completely reproduce the original surface would have been to lay down a grid of so many points that each pixel of the original surface could be sampled.
Opening the error surface we can see the regions of higher error by applying the spectrum palette in the View - Display Options dialog, arranged so that regions of higher error show red and those of lower error show blue and purple. Note that the regions immediately surrounding the data points used to interpolate the surface show relatively low error while those regions surrounding rapidly changing terrain elevations (such as the higher altitude peaks) show greater error.

**Notes**

Images that represent raster data such as elevations, temperatures and other factors are often very interesting to visualize as surfaces.

Because Manifold can paste tables directly into surfaces, one can take a table of elevations created from, say, a GPS and paste it immediately as a surface. One could also take a table of any value (such as pollution levels, temperature, etc.) and paste it as a surface.

If a field named `z`, `elevation`, `elev`, `e`, `height`, `hgt` or `h` (case insensitive) exists in the drawing or table, Manifold will offer that by default as the field in the **Height** box. When pasting tables, fields named `longitude`, `latitude`, `lon`, `long`, `lat`, `x` or `y` (case insensitive) will be offered as the **X / long** or **Y / lat** box fields by default.

Attempting to create a surface larger than 16 million pixels (4,000 x 4,000) will trigger a confirmation dialog that will ask "Surface size is (x dimension) x (y dimension) pixels. Paste anyway?"

**See Also**

See the Displaying Data in a Gradient Map topic for an example that shows demographic data displayed in a continuously varying gradient throughout the United States using a surface.
Transform Toolbar - Surfaces

The Transform toolbar makes changes throughout the entire surface. If a selection is present it will operate only on those pixels in the selection. If no selection is present it will apply to all pixels in the surface.

The Transform toolbar consists of three boxes, from left to right: a target box, the operator box, and a parameter box.

- **Target box**: The pixels that will be affected, altered or which will control the operation. The target box will be pre-loaded with either [All Pixels] or with [Selection] depending on whether a selection is present or not.

- **Operator box**: The function to be applied. The operator box is context sensitive and will show only those operations that make sense for surfaces.

- **Parameter box**: The value to be used. Depending on the operator, this may be another pixel set or a value entered by the user. Many operators, such as Crop, do not require a parameter. The parameter box will not be enabled for such operators.

We use dark blue, black, and violet bold face fonts in this topic to distinguish the three boxes to make examples and explanation more clear. In real life Manifold uses the same black font color in all three Transform toolbar boxes.

**Using the Transform toolbar**

1. Click on the map layer or surface that contains the target pixels.
2. Make a selection if the operation is to be applied just to the selection.
3. Choose the desired operator in the operator box.
4. Choose or specify a value in the parameter box, if this operation requires it.
5. Press Apply.

**Target box**

The left-most box specifies the target pixels. These are the pixels that will be affected, altered or which will control the operation. The example above shows that there is no selection present, so the Transform toolbar will apply the Transform function to all of the pixels in the surface. If we make a selection, the target box would switch to [Selection] to show that whatever operation we apply with the Transform toolbar will act only on those pixels that are part of the current selection.

The target box is not enabled for changes when used with surfaces because the scope of the operation (All Pixels or Selection) is automatically determined by whether there is a selection present or not. When used with Tables, where the scope (which fields) can be user selected, the target box will be enabled for changes.

**Operator box**
Choose a function from the long list of operators available in the operator box. The example shows Add Noise, which will add random noise pixels to the surface. Note that many operators in the Transform toolbar's operator box are simplified versions of more flexible operators in the Surface menu. The Transform Operators - Surfaces topic lists operators available for use with surfaces. Many of these operators are the same as or directly analogous to transform operators used with images.

**Parameter box**

Many operators do not require any parameters. For these functions the parameter box will be disabled. Other functions will require specification of an additional parameter. This may be another pixel set (such as [All Pixels], [Selection] or the names of saved selections), or more frequently it could be a parameter that is entered by the user. To enter a parameter, click into the parameter box, enter the value using the keyboard and then press Enter.

**Examples**

[All Pixels] Rotate -90 - Rotate the surface counter-clockwise 90 degrees.

[Selection] Crop - Crop the surface to the minimum enclosing rectangle of the selection.
Transform Operators - Surfaces

Many transform operators used with surfaces are the same as or directly analogous to transform operators used with images. See the Transform Operators - Images topic for a guide to operators used in images, including links to topics that illustrate many of the concepts used in transforms that are similar to those in surfaces. The hyperlinks in the table below will usually jump to the images version of the command.

- **Add Margin** Add to the rectangular size of the surface by the given number of pixels at the margin.
- **Blur** Blur image by fixed amount. Blurs both features and elevations. For a "blur" effect that does not mix elevations, use the Median filters.
- **Blur (parameter)** Blur image by the number of pixels given in parameter. This blur is implemented as a matrix operator where the value of the parameter is the weight of the center pixel with weights of all other pixels set to 1. Increasing the parameter therefore produces a lesser blur.
- **Crop** Normally used with [Selection] as the scope. Crop surface size to the selection.
- **Crop Margin** Crop the rectangular size of the surface by the given number of pixels at the margin.
- **Difference East** Detect and emphasize edge transitions to the East. See the Filters topic for general discussion of convolution matrix filters like this one.
- **Difference North** Detect and emphasize edge transitions to the North.
- **Difference North-East** Detect and emphasize edge transitions to the North-East.
- **Difference North-West** Detect and emphasize edge transitions to the North-West.
- **Difference South** Detect and emphasize edge transitions to the South.
- **Difference South-East** Detect and emphasize edge transitions to the South-East.
- **Difference South-West** Detect and emphasize edge transitions to the South-West.
- **Difference West** Detect and emphasize edge transitions to the West.
- **Flip Horizontally** Flip surface left / right to mirror surface.
- **Flip Vertically** Flip surface top / bottom to upside down surface.
- **High Pass 1** Emphasize rapid transitions between pixels. Good edge detection with horizontal and vertical lines.
- **High Pass 2** Stronger emphasis on rapid transitions between pixels with strong edge detection on lines of all angles.
- **High Pass 3** Edge detection with crisp vertical and horizontal and fuzzy lines at other angles.
- **Interpolate** Fill in invisible pixels by interpolation. Set the invisible pixel to the average value within the smallest rectangular box centered at given pixel that contains at least one visible pixel. If all pixels in the surface are invisible, the operator makes no changes.
- **Interpolate (Parameter)** Fill in invisible pixels by interpolation. Set the invisible pixel to the average value within the rectangular box of a given radius centered at given pixel, and leave the pixel invisible if the box contains no visible pixels. Depending on the size of the parameter, this operator can be extremely slow although if the radius parameter is chosen to incorporate many pixels it is the most accurate. Slight increases in the radius parameter can...
result in geometrically slower operation, so scale up carefully when using this operator.

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Interpolate Row</td>
<td>Fill in invisible pixels by interpolation. Set the invisible pixel to the weighted average of the visible pixels to the left and right of the given pixel in the same row, and leave the pixel invisible if its row does not contain any visible pixels. This operator is faster but not as accurate as the other interpolation operators.</td>
</tr>
<tr>
<td>Invert</td>
<td>Invert pixel values so that 0 becomes 255 and 255 becomes 0.</td>
</tr>
<tr>
<td>Laplace 1</td>
<td>Good edge detection with emphasis on horizontal and vertical changes.</td>
</tr>
<tr>
<td>Laplace 2</td>
<td>Strongest changes at point of intersection of horizontal and vertical lines, resulting at a small X pixel pattern at the point of intersection; fuzzy detection of linear features at other angles.</td>
</tr>
<tr>
<td>Low Pass 1</td>
<td>Strong blur, with strong suppression of large pixel to pixel changes.</td>
</tr>
<tr>
<td>Low Pass 2</td>
<td>Blur, with medium suppression of large pixel to pixel changes.</td>
</tr>
<tr>
<td>Low Pass 3</td>
<td>Blur, with least suppression of large pixel to pixel changes. Removes graininess in some surfaces.</td>
</tr>
<tr>
<td>Median Cross</td>
<td>Evens out elevation tending to preserve horizontal and vertical features. A &quot;blur&quot; that ignores perfectly horizontal and vertical linear features.</td>
</tr>
<tr>
<td>Median Square</td>
<td>Evens out elevation looking at a 3 x 3 matrix surrounding each pixel. A &quot;blur&quot; effect that preserves prevailing elevation.</td>
</tr>
<tr>
<td>Median Square 5</td>
<td>Strong evening out of elevation looking at a 5 x 5 matrix surrounding pixels of elevation differing greatly from surrounding pixels. A stronger &quot;blur&quot; effect that preserves prevailing elevation.</td>
</tr>
<tr>
<td>Rotate</td>
<td>Rotate surface given number of degrees. Negative degrees are taken as counter-clockwise rotation.</td>
</tr>
<tr>
<td>Sharpen</td>
<td>Emphasize transitions to give images a sharper appearance.</td>
</tr>
<tr>
<td>Sharpen (parameter)</td>
<td>A Sharpen with selectable parameter value for degree of sharpness. This sharpen is implemented as a matrix operator where the value of the parameter is the weight of the center pixel with weights of all other pixels set to 1. Increasing the parameter therefore produces less sharpening.</td>
</tr>
<tr>
<td>Sharpen More</td>
<td>Enhanced sharpness compared to standard Sharpen.</td>
</tr>
<tr>
<td>Threshold Lower</td>
<td>Resets all pixel values below the elevation given in the parameter to that elevation value.</td>
</tr>
<tr>
<td>Threshold Upper</td>
<td>Resets all pixel values above the elevation given in the parameter to that elevation value.</td>
</tr>
<tr>
<td>Tile</td>
<td>Divides surface into square tiles of given extent and then averages pixel values within the tiles. This is used for aggregating and interpolating surfaces into larger tiles and for creating &quot;pixelated&quot; artistic effects.</td>
</tr>
</tbody>
</table>
| Tile Median       | Equivalent to Tile command, but uses a median computation to derive the elevation to be used from the tile from only those elevations that already exist in the surface. Useful to assure elevations of tiles will be round numbers if only round numbers had previously existed in
the surface.
Transform - Surface - Interpolate Operators

The interpolation transform operators discussed in this topic are enabled when the optional Surface Tools extension has been installed and the focus is on a surface window. If you have not activated the Surface Tools extension with a valid serial number the capabilities in this topic will not be available.

Manifold provides three interpolation operators that are used to fill in invisible pixels within surfaces.

- **Interpolate** sets the invisible pixel to the average value within the smallest rectangular box centered at given pixel that contains at least one visible pixel. If all pixels in the surface are invisible, the operator makes no changes.

- **Interpolate (Parameter)** sets the invisible pixel to the average value within the rectangular box of a given radius centered at given pixel, and leaves the pixel invisible if the box contains no visible pixels. Depending on the size of the parameter, this operator can be extremely slow. Slight increases in the radius parameter can result in geometrically slower operation, so scale up carefully when using this operator.

- **Interpolate Row** sets the invisible pixel to the weighted average of the visible pixels to the left and right of the given pixel in the same row, and leaves the pixel invisible if its row does not contain any visible pixels. This operator is faster but not as accurate as the other interpolation operators.

Note: The Interpolate transform usually provides the best results overall. The Interpolate (Parameter) transform has been provided for the use of experts who want precise control of the interpolation process.

**Example**

Suppose we begin with a surface that has some missing pixels, represented by invisible pixels.

Normally, of course, it would be unusual to have a surface with such relatively large swaths of missing pixels. The usual case is to have a few pixels missing, perhaps as a result of noise.
The **Interpolate** transform operator does a good job of filling missing pixels. The smaller the region of invisible pixels the better the result.

Using **Interpolate (Parameter)** with a parameter of 50 (meaning a radius of 50 meters) results in an overly-even interpolation.

The **Interpolate Row** operator results in lengthwise striations since it interpolates by row. This command is very fast, but it is best used in "flat" regions.
**Tech Tip**

The **Interpolate** transforms operate on selected pixels, but both selected and unselected pixels will be used to compute the interpolation required for the effect upon selected pixels if unselected pixels also are within range of the interpolation.
Transform - Surface - Tile Operators
Divides surface into square tiles of given extent and then averages pixel values within the tiles. This is used for aggregating and interpolating surfaces into larger tiles and for creating "pixelated" artistic effects.

Example

The surface on the left was tiled into the surface on the right using tiles of 10-pixel size.

Setting up the transform toolbar as seen above and pressing Apply will tile the surface into tiles of 10-pixel extent. Note that if the accompanying terrain is open it too will be tiled.

Before tiling the terrain is seen from the position marked in the surfaces above.
After tiling the terrain is rendered based on the square, even tiles that now make up the surface.

Comments

The terrain used is the Montara Mountain, California, 1:24K-scale SDTS DEM downloaded from USGS. The view in the terrain shows San Andreas lake in the valley of the San Andreas Fault just south of San Francisco.

Tile will find exact mathematical values for the elevation of each tile. These will often not be round numbers. If the surface originally used elevations that are round numbers (such as whole feet or meters) use Tile Median to preserve such round number values.

Surface Tools

Surface Tools

The Surface Tools package is an optional extension to Manifold System that provides additional commands for working with surfaces. The extension adds functionality in several areas:

- The Surface - Transform command dialog allows arbitrary transformation of surfaces, including computations that involve multiple surfaces such as subtracting one surface from another. A very rich collection of operators allows many different types of tasks to be accomplished.
- The Surface - Watersheds command works with a surface and optionally a drawing to find watersheds in the surface (regions sharing a common drainage) as well as streams in the surface or upstream areas in the surface from points in a specified drawing.
- The Transfer Heights command enables rapid transfer of surface values from surfaces to points.
- The Visible Area command shows areas that are visible from given points. The height of viewing points may be automatically adjusted from a height field.
- New options in surface generation allow creating surfaces from drawings and tables using Gravity interpolation, Median-polish Kriging and triangulation. See the Project Pane - Paste as Surface topic.
- Expanded model choices for Krige interpolation include Linear, Power, Rational and automatic model choices.
- New transform toolbar operators for interpolation of missing pixels, Interpolate, Interpolate (Parameter) and Interpolate Row. See the Transform - Surface - Interpolate Operators topic for details.
- Surface Tools adds the ability to work with new Profiles and Elevations components that show cross-sectional cuts through a given path over a surface.
- Expanded programmatic access to surface operations.
If you do not have the optional **Surface Tools** package enabled you will not have the above capabilities enabled within Manifold System. This documentation describes these commands but they will not be enabled if you do not have the **Surface Tools** package enabled.

### Installing Surface Tools

The **Surface Tools** package is built into your Manifold System installation and becomes enabled for use when activated. Activate it by providing a **Surface Tools** serial number and Activation key that turn on **Surface Tools** functionality. The process of activating the **Surface Tools** extension is very similar to that used to activate Manifold System. See the Activation Keys and Serial Numbers topic and the Installing and Activating a Manifold Extension topic for details.

Some Manifold product options, such as Universal Edition or Ultimate Edition, use a single serial number and Activation key to enable permanent installation of both Manifold System as well as extensions. If you have activated Universal Edition or Ultimate Edition you do not need to individually turn on **Business Tools** or **Geocoding Tools** or **Surface Tools**. Activating Universal Edition or Ultimate Edition will also automatically turn on all three extensions.

### Turning on Surface Tools

If you have licensed Universal Edition, you do not need to turn on **Surface Tools**. The **Surface Tools** extension is automatically enabled with a Universal Edition serial number.

If you have not licensed Universal Edition and you wish to add **Surface Tools** functionality to your installation, begin by acquiring a **Surface Tools** license from manifold.net, which will provide you with a **Surface Tools** serial number.

2. Launch Manifold System. Close any projects that may be open.
3. Choose Help - Activate Extension
4. Enter the **Surface Tools** serial number. Enter it exactly as it was issued to you by manifold.net. Do not change upper case to lower case. Do not replace hyphens with space characters or make any other changes to the serial number. If desired, you may also enter an Activation key for the serial number as well. Press Accept.
5. Manifold will then exit. When re-launched, the Surface Tools package will be enabled.
6. Using the serial number alone the **Surface Tools** package may be run for 30 days from the date the serial number was issued. After that, an Activation Key must be fetched and provided to the Help - Activate Extension dialog together with the serial number. Once an Activation Key and a serial number have been provided to the Help - Activate Extension dialog the extension will be permanently installed. Don't forget to login as Administrator when permanently activating the **Surface Tools** extension.

### Status of Extensions

The Help - About dialog shows all extensions that have been installed. If a serial number only has been used to install an extension, the number of days left before an Activation key is also required will be shown.

Transforming Surfaces

Surfaces may be transformed in Manifold using several main methods:

- Transform Toolbar - The transform toolbar may be used for simple, one-line manipulation of surfaces. The transform toolbar for surfaces is available in all Manifold editions. The optional Surface Tools extension adds new interpolation commands discussed in the Transform - Surface - Interpolate Operators topic.
- Surface - Transform Dialog - The Transform dialog allows sophisticated manipulation of surfaces via the evaluation of formulas. Formulas can be simple expressions, such as adding one surface to another, or they can include sophisticated program logic using a host of different operators. The Transform dialog is available only if the optional Surface Tools extension has been installed.
- Surface menu commands - Commands such as Surface - Resize may be used to alter surfaces.
- Scripting - By writing scripts or other programs surfaces may be changed.

This topic discusses operations using the Surface - Transform dialog. The Surface - Transform menu selection is enabled when the optional Surface Tools extension has been installed and the focus is on a surface window. If you have not activated the Surface Tools extension with a valid serial number you will not be able to use the Surface - Transform command and the capabilities in this topic will not be available.

Many functions in the Surface - Transform dialog can use NVIDIA CUDA for nearly instantaneous computation if our systems are so equipped. See the NVIDIA CUDA topic for details.

The Surface - Transform Dialog

![Surface - Transform Dialog](image)

To launch the Transform dialog, open the surface that is to be transformed and choose Surface - Transform in the main menu. The Transform dialog allows us to choose the scope in the upper combo box and to enter a formula into the lower pane. The dialog also includes a Surfaces pane that lists all surfaces in the project. We can double click on a surface in the list to add it to the Formula pane and thus save ourselves the effort of manually entering the name of a surface.

The scope specifies the pixels that will be affected by the transformation, and can be [All Pixels], [Invisible Pixels] or any selection or saved selection made in the surface. Formulas can contain numbers, names of surfaces (names of surfaces must be enclosed in square brackets [] if the name contains a space character), arithmetic operations and functions. Formulas are case insensitive. When we press the OK button, each pixel in the surface in the scope will be replaced with the value of the formula for that pixel.

If we would like to preserve the original surface unmodified we can check the Save result as new component box and the system will create a new surface (a copy of the surface which had the focus when the dialog was launched) and put the results of the formula there. The Save result as new component also allows us to
surface transformations on a surface that is a read-only component, such as perhaps a surface that has been linked into a project from an Enterprise storage using the Enterprise Edition of Manifold System.

Suppose we have three surfaces named A, B and C. If we open A and invoke Surface - Transform we can enter

\[ A + B \]

into the Formula pane and press OK. This will set all heights in A to the sum of A + B. If we had entered a formula using the Max() function (one of many Transform Dialog Functions and Operators that may be used) as follows:

\[ \text{Max}(A, B + C + 1) \]

we would have set the height of each pixel in A to either the value of that pixel in A or the value of B + C + 1, whichever is larger.

When evaluating formulas, Manifold automatically handles coordinate system conversions so that a surface in lat/lon and a surface in UTM projection may be used together in a formula. Manifold will also automatically handle type conversions so that a surface with floating-point values for height may be used in a formula together with a surface using integer values for heights.

Invisible pixels are also automatically handled. A formula consisting of just "A" makes all pixels that are visible in A visible in the result, and it makes all pixels that are invisible in A invisible in the result. The formula "A + B" makes all pixels that are visible in both A and B visible in the result, and makes all pixels that are invisible in either A or B invisible in the result.

**Example**

Suppose we have two surfaces that show the intensity of the downwind chemical plumes from two different releases of a hazardous chemical:

Suppose the releases happened on different days from different positions so that because of changes in wind and release position and amount of chemical released the plumes have different orientations and show different intensities. The two surfaces are called Plume A and Plume B. These surfaces are correctly georegistered to a true location on Earth, so that the inclined rectangle that is the area of interest is exactly at the same location for both surfaces.
Dark green shows zero chemical detected, while brighter green shading to beige to darker colors to white shows increasing levels of exposure. Our task is to sum the two surfaces so we can see what are the values of combined exposure to the two plumes in the area of interest.

This is easy. We first duplicate Plume A and rename it to Combined Plumes. We do this so that the original surface will not be altered when we do a transform.
With the focus on the Combined Plumes surface, we choose Surface - Transform and enter

\[[\text{Plume A}] + [\text{Plume B}]\]

into the Formulas pane. We can save time keyboarding by double clicking on the names of the surfaces in the Surfaces box to add them to the formula instead of typing out them out manually. We press OK.

The surface is transformed so that each pixel now has a value that is the value of that location in Plume A plus the value of that location in Plume B. We can immediately see where the cumulative effects of the plumes are creating “hot spots” not immediately obvious from a visual examination of only Plume A or Plume B.
Note that the pixels that were invisible in both Plume A and Plume B continue to be invisible in the combined result. If we turn on the Layers pane and turn on the Border we can see that a considerable part of the surface is invisible pixels.

Can we use the Transform dialog to make these invisible pixels visible? That also is easy.

We launch the Transform dialog once more and choose [Invisible Pixels] as the scope. In the Formula pane we enter 0. This terse expression simply means to put the value zero into all pixels in the scope, that is, into all pixels that are invisible pixels.
When we press OK the invisible pixels will be filled in with the value 0 so they will be colored the same dark green as all the other zero pixels.

If we combine the surfaces in a map with a drawing of roads we can see where the chemical plumes have combined to generate regions of higher exposure. The illustration uses partial transparency in the surface layer.
We can also add invisible pixels using the **Null** constant with an expression like that above, which converts all pixels with a value of 100 or less into invisible pixels.

The bright green zone in the combined plumes corresponds to a value of **100 so the formula used renders invisible all pixels except those in the plumes themselves, stripping out the zero-valued dark green pixels.**
This may be a more useful effect when combined with other surfaces in a map. The map above shows the surfaces using partial Layer Opacity for each for a better effect.

This is a somewhat contrived example, but it shows the ease with which the **Surface - Transform** dialog may be used to perform calculations using multiple surfaces.

**Example**

The **Surface - Transform** dialog may be used for a variety of utility operations, such as interpolating regions of missing (invisible) pixels.

Suppose we have a surface called **Montara** that shows the terrain in the region of Montara Mountain, California. The surface has portions with no data, represented with invisible pixels.
We may use the Surface - Transform dialog with the Interpolate(s) function to fill in the missing pixels as seen above. Note that the name could have been cited as simply (Montara) because there are no spaces in the name. However, the example uses ([Montara]) with square brackets [ ] because the name was added by double clicking on the surface name in the Surfaces pane to save having to manually enter the name.

The result is imperfect, but better than having invisible pixels. See the Interpolate Operators topic for additional examples.

Example

Open the Montara Mountain sample surface. Launch the Surface - Transform dialog, check the Save result as new component option and run the following formula:

```
FlowAccum(FlowDir(FillSinks([Montara])))
```

This will create a flow accumulation surface. Rename the resulting surface Montara Flow.
The following query counts the number of pixels with flow exceeding 10000:

```sql
SELECT Count(*) FROM [Montara Flow] WHERE [Height (I)] > 10000;
```

The following query finds the coordinates of the top 10 maximum flow pixels:

```sql
SELECT TOP 10 * FROM [Montara Flow] ORDER BY [Height (I)] DESC;
```

See the Watersheds topic for additional information on flows.

**Available Expressions in Formulas**

Formulas may use +, -, *, / as arithmetic operators (addition, subtraction, multiplication and division). Pi (3.1415926...) and Null are the only available constants. Null is used to create invisible pixels.

A vast number of functions and operators are available, and are listed in the Transform Dialog Functions and Operators topic.

**Merging Surfaces**

It may be tempting to use the Surface - Transform tool to attempt to merge two or more overlapping or non-overlapping surfaces into a single surface. However, this is not something done with the Surface - Transform tool. The Surface - Transform tool takes a surface and sets its pixels to values possibly taken from other surfaces, and then perhaps saves the result as a new surface. It never attempts to enlarge or reduce the surface.

For example, given two surfaces A and B where B is a larger surface that partially overlaps A, the expression A + B operating on surface A will not expand the bounding box of A to include a larger B surface. It will simply set the pixels of the resulting surface (which will be the same size as A) to the sum of values in A and B and make pixels at locations that do not belong to either A or B invisible.

To merge a pair of surfaces together, select all pixels in the first surface, copy them and paste the pixels into the second surface. Make sure the Confirm expanding images or surfaces when pasting option in the Tools - Options - Miscellaneous dialog is turned on.

**Short Examples**

Given surfaces A, B and C with surface A in feet and surfaces B and C in meters, we may execute the following formulas on surface A:

```sql
A + 1
```

Increases the height of all visible pixels in A by 1.

```sql
A * 0.3048
```

Converts the heights of all visible pixels in A from feet to meters.

```sql
IIf(B > 2000, Max(A, B/0.3048), A)
```

Makes pixels in A at least as high as those in B in regions where the height of B exceeds 2000 meters.

```sql
LowPass1(B) + HighPass1(C)
```

Creates a composite surface (in meters) taking low frequencies from B and high frequencies from C.

```sql
A + B/0.3048
```
Increases the height of all visible pixels in A by the height of the respective pixels in B. Makes pixels in A that are invisible in B invisible.

\[
\text{IIf(HasValue(B, 0, 0), A + B/0.3048, A)}
\]

Increases the height of all visible pixels in A by the height of the respective pixels in B. Leaves pixels in A that are invisible in B intact.

\[
\text{IIf(A < 1000, Null, A)}
\]

Makes all pixels below 1000 invisible and leaves all other pixels intact.

**Tech Tips**

- In case of disaster, single-step **Undo** works to undo the results of the **Transform** dialog.

- The **Transform** dialog remembers the previous formula. This is very useful together with **Undo** to make adjustments to formulas that create unexpected results.

Transform Dialog Functions and Operators

The functions and operators discussed in this topic are available in the Surface - Transform dialog's Formula pane. The Surface - Transform menu selection is enabled when the optional Surface Tools extension has been installed and the focus is on a surface window. If you have not activated the Surface Tools extension with a valid serial number you will not be able to use the Surface - Transform command and the functions in this topic will not be available for use with that command.

Surface - Transform functions taking a drawing name as an argument will also accept the names of drawing tables or theme components.

Many functions in the Surface - Transform dialog can use NVIDIA CUDA for nearly instantaneous computation if our systems are so equipped. See the NVIDIA CUDA topic for details.

Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Abs(x)</td>
<td>Returns the absolute value of x.</td>
</tr>
<tr>
<td>ACos(x)</td>
<td>Returns the arccosine of x in the range of 0 to pi radians.</td>
</tr>
<tr>
<td>ASin(x)</td>
<td>Returns the arcsine of x in the range of -pi/2 to pi/2 radians.</td>
</tr>
<tr>
<td>Aspect(s, w)</td>
<td>Returns the aspect of s in the range of -180 to 180 degrees, computed over a window of specified size (1 for 3x3, 2 for 5x5, etc). CUDA enabled.</td>
</tr>
<tr>
<td>Atn(x)</td>
<td>Returns the arctangent of x in the range of -pi/2 to pi/2 radians.</td>
</tr>
<tr>
<td>Atn2(y, x)</td>
<td>Returns the arctangent of y/x in the range of -pi to pi radians.</td>
</tr>
<tr>
<td>AvgValue(s, w)</td>
<td>Returns the average value of s in a window of specified size (1 for 3x3, 2 for 5x5, etc). CUDA enabled. With CUDA, the maximum window size is 31.</td>
</tr>
<tr>
<td>Blur(s)</td>
<td>Returns the value of the Blur filter. CUDA enabled. Example: Blur([Plume A])</td>
</tr>
<tr>
<td>Ceil(x)</td>
<td>Returns the smallest integer that is greater than or equal to x.</td>
</tr>
<tr>
<td>Cos(x)</td>
<td>Returns the cosine of x.</td>
</tr>
<tr>
<td>CurvGauss(s, w)</td>
<td>Returns the Gaussian curvature of s, computed over a window of specified size (1 for 3x3, 2 for 5x5, etc). CUDA enabled.</td>
</tr>
<tr>
<td>CurvMean(s, w)</td>
<td>Returns the mean curvature of s, computed over a window of specified size (1 for 3x3, 2 for 5x5, etc). CUDA enabled.</td>
</tr>
<tr>
<td>CurvPlan(s, w)</td>
<td>Returns the plan curvature of s, computed over a window of specified size (1 for 3x3, 2 for 5x5, etc). CUDA enabled.</td>
</tr>
<tr>
<td>CurvProfile(s, w)</td>
<td>Returns the profile curvature of s, computed over a window of specified size (1 for 3x3, 2 for 5x5, etc). CUDA enabled.</td>
</tr>
<tr>
<td>Deg2Rad(x)</td>
<td>Converts x from degrees to radians.</td>
</tr>
<tr>
<td>DifferenceE(s)</td>
<td>Returns the value of the DifferenceE filter. CUDA enabled.</td>
</tr>
<tr>
<td>DifferenceN(s)</td>
<td>Returns the value of the DifferenceN filter. CUDA enabled.</td>
</tr>
<tr>
<td>Function</td>
<td>Description</td>
</tr>
<tr>
<td>------------------</td>
<td>-----------------------------------------------------------------------------</td>

<tr>
<td>Diversity(s, w)</td>
<td>Returns the number of different values of s in a window of specified size.</td>
</tr>
<tr>
<td>DiversityIndex(s, w)</td>
<td>Returns the diversity index of s in a window of specified size as a value</td>
</tr>
<tr>
<td>Exp(x)</td>
<td>Returns the exponent of x.</td>
</tr>
<tr>
<td>FillSinks(s)</td>
<td>Fills depressions in s.</td>
</tr>
<tr>
<td>Fix(x)</td>
<td>Removes the fractional part of x rounding towards zero</td>
</tr>
<tr>
<td>Floor(x)</td>
<td>Returns the largest integer that is less than or equal to x.</td>
</tr>
<tr>
<td>FlowAccum(dir, den)</td>
<td>Computes flow accumulation using flow directions (dir) and optional flow</td>
</tr>
<tr>
<td>FlowAreas(dir, str)</td>
<td>Computes watersheds using flow directions (dir) and streams (str) by</td>
</tr>
<tr>
<td>FlowDir(s)</td>
<td>Computes flow directions for s. Returns true degrees between -180 to 180</td>
</tr>
<tr>
<td>FlowStream(dir, x, y)</td>
<td>Computes a stream starting at a given location using flow directions (dir),</td>
</tr>
<tr>
<td>FlowStreams(dir, acc, thr)</td>
<td>Computes streams using flow directions (dir) and flow accumulation (acc). Streams with accumulation lower than the threshold (thr) are ignored. Returns a unique stream ID for each pixel belonging to a stream whose accumulation is higher than or equal to the threshold, and 0 for all other pixels. Note that there are two variants of the FlowStreams function, one of which takes a drawing as an argument and one that does not.</td>
</tr>
<tr>
<td>FlowStreams(dir, drawing)</td>
<td>Computes streams for all points in a given drawing using flow directions (dir). Returns a unique stream ID for each pixel belonging to a stream, and 0 for all other pixels. Note that there are two variants of the FlowStreams function, one of which takes a drawing as an argument and one that does not.</td>
</tr>
<tr>
<td>FlowUpstreamArea(dir, x, y)</td>
<td>Computes an upstream area for a given location using flow directions (dir). Returns 1 for pixels belonging to the upstream area, and 0 for all other pixels.</td>
</tr>
<tr>
<td>FlowUpstreamAreas(dir,</td>
<td>Computes upstream areas for all points in a given</td>
</tr>
</tbody>
</table>
drawing) drawing using flow directions (dir). Returns the ID of the point object for each pixel belonging to its upstream area, and 0 for all other pixels.

Gravity(drawing, column, neighbors, model, voronoi) Interpolates objects in the given drawing using the given column as the height. Line objects participate as sets of their coordinates. Area objects are ignored. Setting the number of neighbors to -1 will use the default number of neighbors. The model argument should be a blank string. The voronoi argument is a boolean (if true, only Voronoi neighbors are used). All arguments except the first two are optional.

HasValue(s, dx, dy) Returns True if surface s has a visible pixel at current position offset by dx and dy and False otherwise.

Height(s) Returns the number of rows in surface s.

HighPass1(s) Returns the value of the HighPass1 filter. CUDA enabled.

HighPass2(s) Returns the value of the HighPass2 filter. CUDA enabled.

HighPass3(s) Returns the value of the HighPass3 filter. CUDA enabled.

Ilf(a, b, c) Returns b if a is True and c otherwise.

Interpolate(s, p) Returns the value of s at the current pixel if it is visible and the interpolated value if it is invisible. The interpolated value is computed as the average value of s in the smallest box centered at the current pixel that contains at least one visible pixel. If all pixels in s are invisible, the function returns Null. The optional parameter p allows specification of an interpolation radius over which interpolation occurs. See the discussion for the Interpolate (Parameter) transform operator.

InterpolateRow(s) Returns the value of s at the current pixel if it is visible and the interpolated value if it is invisible. The interpolated value is computed as the value of the straight line segment between the nearest visible pixels in the same row of s. If all pixels in the current row of s are invisible, the function returns Null. Overall, this function works much faster than Interpolate but is also less accurate.

Int(x) Returns the largest integer that is less than or equal to x (same as Floor(x)).

Kriging(drawing, column, neighbors, model, voronoi) Interpolates objects in the given drawing using the given column as the height. Line objects participate as sets of their coordinates. Area objects are ignored. Setting the number of neighbors to -1 will use the default number of neighbors. The model argument is a case-insensitive string, e.g., "spherical" or "gaussian". The voronoi argument is a boolean (if true, only Voronoi neighbors are used). All arguments except the first two are optional.

KrigingMedianPolish(drawing, column, neighbors, model, voronoi) Interpolates objects in the given drawing using the given column as the height using the median-polish kriging interpolation method. Line objects participate as sets of their coordinates. Area objects are ignored. Setting the number of neighbors to -1 will use the default number of neighbors. The model argument is a case-insensitive string, e.g., "spherical" or "gaussian". The voronoi argument is a boolean (if true, only Voronoi neighbors are used). All arguments except the first two are
optional.

**Laplace1(s)** Returns the value of the Laplace1 filter. CUDA enabled.

**Laplace2(s)** Returns the value of the Laplace2 filter. CUDA enabled.

**Latitude()** Returns the latitude of the current pixel in standard lat/lon coordinate system (lat/lon, WGS84).

**Log(x)** Returns the natural logarithm of x.

**Log2(x)** Returns the binary logarithm of x.

**Log10(x)** Returns the decimal logarithm of x.

**Longitude()** Returns the longitude of the current pixel in standard lat/lon coordinate system (lat/lon, WGS84).

**LowPass1(s)** Returns the value of the LowPass1 filter. CUDA enabled.

**LowPass2(s)** Returns the value of the LowPass2 filter. CUDA enabled.

**LowPass3(s)** Returns the value of the LowPass3 filter. CUDA enabled.

**MajValue(s, w)** Returns the most frequently occurring value of s in a window of specified size (1 for 3x3, 2 for 5x5, etc). In case of a tie, returns the lowest of the most frequently occurring values. CUDA enabled. With CUDA, the maximum window size is 31.

**Max(x, y)** Returns the maximum value of x and y.

**MaxValue(s, w)** Returns the maximum value of s in a window of specified size (1 for 3x3, 2 for 5x5, etc) or the maximum value of s overall. CUDA enabled. With CUDA, the maximum window size is 31.

**MedianCross(s)** Returns the value of the MedianCross filter. CUDA enabled.

**MedianSquare(s)** Returns the value of the MedianSquare filter. CUDA enabled.

**MedianSquare5(s)** Returns the value of the MedianSquare5 filter. CUDA enabled.

**MedValue(s, w)** Returns the median value of s in a window of specified size (1 for 3x3, 2 for 5x5, etc). CUDA enabled. With CUDA, the maximum window size is 31.

**Min(x, y)** Returns the minimum value of x and y.

**MinValue(s, w)** Returns the minimum value of s in a window of specified size (1 for 3x3, 2 for 5x5, etc) or the minimum value of s overall. CUDA enabled. With CUDA, the maximum window size is 31.

**Mod(x, y)** Returns the remainder of the division of x by y. y must not be equal to 0. Examples: (Mod(5.2, 1.0) = 0.2; Mod(5.2, 0.3) = 0.1).

**PixelArea(unit)** Returns the area of a single pixel in the context surface in the given units.

**PixelHeight(unit)** Returns the height of a single pixel in the context surface in the given units.

**PixelWidth(unit)** Returns the width of a single pixel in the context surface in the given units.

**Pow (x, y)** Returns the value of x raised to the power of y.
Surfaces and Terrains

Rad2Deg(x)  Converts x from radians to degrees.
Rnd()       Returns random value between 0 and 1.
Sgn(x)      Returns the sign of x (-1 if x is negative, 1 if x is positive, 0 if x is 0).
Sharpen(s)  Returns the value of the Sharpen filter. CUDA enabled.
SharpenMore(s) Returns the value of the SharpenMore filter. CUDA enabled.
Sin(x)      Returns the sine of x.
Slope(s, w) Returns the slope of s in the range of 0 to 90 degrees, computed over a window of specified size (1 for 3x3, 2 for 5x5, etc). CUDA enabled.
Sqr(x)      Returns the square root of x.
SumValue(s, w) Returns the summary value of s in a window of specified size (1 for 3x3, 2 for 5x5, etc). CUDA enabled. With CUDA, the maximum window size is 31.
Tan(x)      Returns the tangent of x.
Tile(s,x)   Returns the value of the Tile filter for surface s and tile size x pixels. CUDA enabled.
TileMedian(s,x) Returns the value of the TileMedian filter for surface s and tile size x pixels. CUDA enabled.
Triangulation(drawing, column, corners) Interpolates objects in the given drawing using the given column as the height using the triangulation interpolation method. Line objects participate as sets of their coordinates. Area objects are ignored. The corners argument is the height to use for corners and can be omitted.
TriangulationContours(drawing, column, corners) Interpolates objects in the given drawing using the given column as the height using the contour triangulation interpolation method. Line objects participate as sets of their segments, with intersections between segments being resolved automatically. Area objects are ignored. The corners argument is the height to use for corners and can be omitted.
Value(s, dx, dy) Returns the value of surface s at current position offset by dx and dy.
Width(s)    Returns the number of columns in surface s.
X()         Returns the X coordinate of the current pixel in coordinate system of the target surface.
Y()         Returns the Y coordinate of the current pixel in coordinate system of the target surface.

s as an argument indicates the function takes the name of a surface (within square brackets []) if the name has a space character in it) as an argument. x and y as arguments are numeric arguments. CUDA enabled operators will execute automatically within NVIDIA CUDA multiprocessor hardware, if available and enabled. See the NVIDIA CUDA topic.

The filter functions in the above are analogous to the convolution matrix filters used in image transformation via the image transform toolbar. See the Transform Operators - Images for a short description of each filter.

Operators
In Boolean operators, a value of 0 is considered to be False, and all other values are considered to be True. All Boolean operators return either 0 or 1.

The following Boolean operators are available:

- **x And y**: Returns True (1) if both x and y are True, returns False (0) otherwise.
- **x Eqv y**: Returns True (1) if both x and y are True or False, returns False (0) otherwise.
- **x Imp y**: Returns True (1) unless x is True and y is False, returns False (0) if x is True and y is False.
- **Not x**: Returns True (1) if x is False, returns False (0) otherwise.
- **x Or y**: Returns True (1) if either of x and y is True, returns False (0) otherwise.
- **x Xor y**: Returns True (1) if one of x and y is True and another is False, returns False (0) otherwise.

**Constants**

Pi (3.1415926...) and Null are the only available constants. Null is used to create invisible pixels. See the Transforming Surfaces topic for examples.

Transforming Surfaces
Visible Area

The Drawing - Visible Area menu selection is enabled when the optional Surface Tools extension has been installed and the focus is on a drawing layer in a map window that also includes a surface layer. If you have not activated the Surface Tools extension with a valid Surface Tools serial number you will not be able to use the Drawing - Visible Area command.

The Visible Area command works with a surface and a drawing to find all parts of the surface that are visible from one or more locations in the drawing marked by points. This function in other GIS systems may be called a viewshed function or visibility zones function. This function is bi-directional in that it may also be used to find all locations from which the tops of one or more towers are visible from the surface.

The Visible Area command creates a new area object within the target drawing that shows the region of the surface that is visible from the designated points.

Launching the Visible Area command in the Drawing menu launches the Visible Area dialog. The dialog above uses a surface called Montara Mountain and a target drawing called Drawing (not a very original name, but descriptive).

Controls

- **Source**: Choose the surface for which visibility is to be analyzed.
- **Target**: Choose the drawing from which viewing point locations will be taken and within which the visible area will be created.
- **Scope**: [All Objects in drawingname] or the selection or a saved selection, if one exists.
- **Height**: The data field to be used for heights of observing points. Choose [None] if no height field is to be used, in which case the observing points will be taken to lie upon the surface.
- **Relative Heights**: If unchecked, interpret the height field to mean an absolute altitude. If checked, interpret the height field to mean a relative height above the surface at that location.
- **Compute area visible from all locations**: If unchecked and multiple points are given the created area will be the region visible from any one of the locations. If checked, the area will represent only that part of the region that is simultaneously visible from all of the locations.

Using Heights

If [None] is specified in the Height field, Manifold will compute the regions of the surface visible from each location assuming that the observer's eye is located at ground level. That usually is not a realistic choice since a
literally ground level view will easily be obstructed by slight rises that would not impede the view even from the height of an average person's eye.

It is much more frequently the case that we would like to know areas that are visible from a person's eye or from a tower or other structure. In such cases the eye of the observer is elevated to some height above the surface. The **Height** option allows us to specify the name of a column in the drawing's table that provides the heights of each viewing location.

At times the height of the viewing location is known in absolute terms (such as the height of an aircraft observer) and at times the height of the viewing location is known in relative terms (such as the height of a tower above ground level). The **Relative heights** option box allows us to choose which is the case for the height values in our drawing's table. Check this option box to use relative heights, for example, the height of a tower above ground level.

**Example**

This example computes the area visible from five towers in the region of Montara Mountain, California. It uses a drawing of five points and a surface taken from part of the Montara Mountain USGS SDTS DEM data set.

Imported into the project the components appear in the project pane as seen above. The drawing (called **Drawing**) and the surface (called **Montara Mountain**) appear together in a map (called **Map**).

Opening the map we see that the drawing contains five points.
Opening the drawing's table, we see that each point has a **Height** value ranging from 100 to 10. The points have been thematically formatted in the drawing so that the color of each point varies from yellow (the 10 point) to purple (the two 100 points located on ridges).

The drawing represents five towers ranging in height from 10 feet to 100 feet that are located in various parts of the Montara Mountain region.

To find the visible area we click on the drawing tab in the map and launch **Drawing - Visible Area**.

In the **Visible Area** dialog we choose **Montara Mountain** as the Source, **Drawing** as the Target, [All Objects in Drawing] as the Scope and **Height** for the Height field. We check the **Relative heights** box because the height for each tower is given as the height above ground level at that position. Press **OK**.
The result is that a new area is added to the drawing. We have taken a moment to format the area in yellow color so that it is easy to see. Any location on the surface within that area is within sight of the top of one of the five towers. Because there are five towers and three of the towers are high towers, much of the surface is visible from at least one of the towers.

Suppose we would like to determine the visible area from only a subset of towers? That’s easy to accomplish.

Let’s suppose we are interested only in the area that is visible from either of the two tallest towers. We delete the new area created in the previous step, and then we select the two tallest towers (the purple dots).
We launch the Visible Areas dialog as before except this time the Scope is set to [Selection in Drawing]. Press OK.

The result is a new area that shows all parts of the surface that are visible from one of the two selected towers. Although it is a smaller area than is visible from all five towers, nonetheless it covers a large part of the surface because the two selected towers are tall towers that are located on high ridges.

So far we have looked at two cases where the visible area is visible from any one of the towers. Suppose we would like to find those regions that are visible from both towers at once?
We could delete the visible area created in the previous step, select the two tall towers and then re-run the Visible Areas dialog. This time we can check the Compute area visible from all locations box.

The result is a new area that shows all parts of the surface visible to both of the two selected towers at the same time. Because line of sight is bi-directional, if we stood at any of the locations marked by the yellow area we would be able to see the tops of both towers.

If we like, we can see which area is visible from all five towers simultaneously.
To do so we launch the **Visible Area** dialog using **[All Objects in Drawing]** for the **Scope** and we check the **Compute area visible from all locations** box.

The result shows that very few locations can be seen from all five towers at the same time. In general, it is only portions of the highest ridges that may be seen from all five towers at once. If we stood at any location within the yellow area we could see all five towers at once.

**Notes**

Only one area object is created by the **Visible Area** command. The area is a branched area object so that even those parts of the area that appear disconnected from other parts of the area all belong to the same area object. Clicking on any one part of the area using touch selection will select the entire area.

Strictly speaking, if we want to consider the visibility of a 100-foot tower we should add some value for the height of the individual who is viewing. One way to do this is to add some average amount, say, 5.5 feet, to the height of each tower.

Line of sight is bi-directional. Every spot that may be seen from the top of a tower is also a spot from which the top of a tower may be seen. The **Visible Area** command not only lets us find all locations that are visible from a given location, it also allows us to find all areas from which the given location is visible. This function is very
useful in determining whether or not towers or other structures can be seen. For example, if we would like to
determine the areas from which a cellular telephone antenna may be seen we can determine the visible area from
the cellular antenna's location using the height of the antenna. Anyone standing within the visible area will be
able to see the antenna.

This command is very useful for planning any line of sight task. For example, it can be invaluable when planning
the location of monitoring instruments (such as seismic sensors on volcanoes) that connect to central stations via
microwave or laser communications links, the location of observation posts for borders or secure installations or
even the location of defensive positions in military installations.

Computing visible areas can be a highly computationally intensive task that can take a long time to accomplish
with large surfaces or with many viewing points.

**Surface Tools**
Profiles and Elevations

Profiles and Elevations are supplementary components that are available within a Manifold project when the optional Surface Tools extension has been installed. If you have not activated the Surface Tools extension with a valid serial number you will not be able to use Profiles or Elevations.

A profile is a Manifold component created by copying a line from a drawing and then pasting it as a profile, choosing a surface to which that profile will be bound. The line in the profile shows a path over the surface. By themselves, profiles have little utility except that they are used to create elevations.

An elevation is a Manifold component that is a chart showing the height of a surface plotted along the length of a profile path. The appearance of an elevation is controlled by opening the elevation and then choosing View - Display Options. There can be more than one elevation bound to the same profile. For example, we can right click on an elevation in the project pane, choose Duplicate and then open that new elevation and change the Display Options for that elevation. This would provide two elevations bound to the same profile but showing the results in different ways.

Profiles are normally created by showing a surface in a map together with one or more drawing layers. A line for a profile may be chosen by selecting an existing line in a drawing, or by creating a new line in a drawing. Because Manifold already has a wide range of tools for creating and editing lines in drawings, we can use a drawing to create whatever line we want for the profile.

Once the line is created, we can copy it and then paste it as a profile. When a profile is created, it appears in the project pane beneath its parent surface. An elevation is automatically created under its parent profile as well.

Profiles may participate within maps as layers, they may be re-projected, and they can appear within print layouts. Profiles may have control points and may be georegistered, and they support use of the layers and views panes. Profiles may even participate in web pages via the IMS File - Export Web Page command. Grids and graticules may be used within a profile. Elevations may appear within print layouts as well. Profiles and Elevations may be immediately printed using File – Print.

Profiles and elevations may be copied and pasted within the project pane. Copying a profile and pasting it will bind it to the same surface. Copying and pasting an elevation will bind it to the same profile. We can copy and paste drawings to profiles and vice versa. When copying a drawing and pasting it as a profile, if the drawing contains no lines the paste operation will fail. If the drawing contains more than one line, the profile will be created from the first line encountered within the drawing's internal ID list of lines. If the first line is a multi-branched object containing more than one branch the profile will be created from the first branch.

Surfaces and their profiles and elevations are dynamically updated. Changes made in the surface will automatically appear in the surface's profiles and elevations. Changes made in an elevation (for example, by relocating or changing the shape of the profile line) will automatically appear in the profile's elevations.

Profiles may be navigated using the standard navigation toolbar to zoom, center, pan with the grabber or measure distances with the tracker tool. Profiles may also be navigated using hot scroll. Elevations present a fixed view of the elevation chart that is always scaled to fit the available window.

Example

Suppose we are working with a surface called Montara Mountain, using the example Montara Mountain 1:24K-scale SDTS DEM surface on the Manifold CD.
We can create a map that uses this surface as one layer and overlays upon it a drawing layer showing roads in the region.

If we are interested in the changes in elevation along a given road, we can select one of the road lines as seen above and then create a profile. To create a profile, we Copy the line and then right click into the project pane and Paste as a profile.

The Paste Profile dialog allows us to choose which surface will be the parent for the resulting profile.

We press OK and see that a new profile is added to the project as a component under the parent Montara Mountain surface. Under the new profile is an elevation component.
If we click open the new profile component we see that it shows the line that was pasted as a profile, with all coordinates defining the line marked. The surface is shown in the background with partial transparency to provide visual orientation. The last coordinate in the profile is displayed using a solid black diamond icon to show the direction of the profile line.

If we click open the new elevation component we can see that it shows a chart of elevations along the path of the profile. The elevation chart reads from left to right from the beginning of the profile line to the end of the profile line. The vertical axis labels use even breaks of altitude. The elevation line will be dotted where it crosses any regions of invisible pixels in the underlying surface.

If we prefer to see the profile with full color background, we can drag and drop the profile into the map as a layer. When profiles are used as a layer within maps their faint background is not used and just the profile line (with coordinate handles) appears.
**View - Display Options**

We can change labels and other options in the elevation using the **View - Display Options** dialog.

For example, the display above has the **Label Surface Breaks** option checked so that height axis labels are automatically taken from the interval breakpoints that define the palette used to color the parent surface. The above illustration also has the **Include zero height** option checked so that the full range of altitudes is visible and not just those traversed by the profile.

Profiles also have a **View - Display Options** dialog, which is used to:

- Specify whether the coordinates defining the profile line are displayed as small edit handles.
- Set the number of decimal digits used when reporting the average, minimum and maximum heights for the profile in the **info** pane.

### Display Options for Elevations

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Shade background</strong></td>
<td>Color the background of the elevation using the same palette (if any) used to color the parent surface. On by default.</td>
</tr>
<tr>
<td><strong>Display coordinates</strong></td>
<td>Display dots at the location of each coordinate that defines the line used as a profile.</td>
</tr>
</tbody>
</table>

#### X axis (distances)

- **Label coordinates**
  - Draw vertical lines and label the X axis at each coordinate that defines the profile line. Off by default.
- **Label even values**
  - Draw vertical lines and label the X axis at even values of distance. On by default.
- **Decimal digits**
  - The number of digits past the decimal point to show in labels on the X axis. The default value of **0** results in no digits past the decimal point.

#### Y axis (heights)

- **Include zero height**
  - Show the entire range of elevations for the surface, from zero to the highest in the elevation display. Off by default, so that the full range of the elevation display is used to show the heights within the elevation only.
<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Label coordinates</td>
<td>Draw horizontal lines and label the Y axis at each coordinate that defines the profile line. Off by default.</td>
</tr>
<tr>
<td>Label minimum / maximum</td>
<td>Draw horizontal lines and label the Y axis at the minimum and maximum values of height that occur in the profile line. Off by default.</td>
</tr>
<tr>
<td>Label surface breaks</td>
<td>Draw horizontal lines and label the Y axis at the numeric values that define interval breaks in the palette used to color the surface. Off by default.</td>
</tr>
<tr>
<td>Label even values</td>
<td>Draw horizontal lines and label the Y axis at even values of height. On by default.</td>
</tr>
<tr>
<td>Decimal digits</td>
<td>The number of digits past the decimal point to show in labels on the Y axis. The default value of 0 results in no digits past the decimal point.</td>
</tr>
</tbody>
</table>

Ok: Accept the current display option settings and update the Elevation display.

Cancel: Exit the dialog without making any changes.

**Editing Profiles**

The shape of profiles may be changed by **CTRL-ALT** clicking the profile line within the profile and then dragging the coordinate edit handles to new locations. **CTRL**-dragging an edit handle will move the entire profile line. This is a handy way of seeing the elevation along different paths if the profile's elevation window is kept open while dragging profile edit handles around to new locations: as soon as the edit handle is moved, the elevation window will show the new elevation automatically.

For example, suppose we start with a profile like that seen above, a straight line defined by just two coordinates. Note that the ending coordinate is shown with a solid black diamond icon.
The elevation for that profile shows the heights traversed by the profile line. The ending coordinate is shown with a solid black diamond icon so that we may easily relate the direction of the elevation to the direction of the profile line. Note the flat sections where the profile line crosses over Pilarcitos Lake.

To select the profile line for editing we **CTRL-ALT** click on it.

Edit handles will appear at each coordinate defining the line. We can then click and drag an edit handle to move it.

Dragging the edit handle automatically reshapes the line.

When we release the drag at a new position the elevation will automatically be recomputed.
If we keep the elevation window open while editing the profile we can immediately see the different altitudes traversed by the new profile line.

Profile lines may also be edited by CTRL-ALT clicking the line to select it for editing and then right clicking onto the line and choosing a function from the Coordinate context menu choice. Coordinate - Add, Coordinate - Delete and Coordinate - Duplicate commands may be used to add, delete and duplicate coordinates (and their editing handles) which may then be dragged to new locations as desired. Note that as edits are made any elevation window for that profile that is open will be dynamically updated. For examples of editing using the Coordinate context menu, see the Changing the Shape of Objects section in the Editing Objects topic.

Edits to profiles support single step Undo and Redo. That is the editing command just performed may be undone or redone.

**Invisible Pixels**

Where a profile crosses a region of invisible pixels in the surface the profile line will be shown in the elevation using a dotted style.

For example, suppose some pixels were deleted from the Montara surface as seen in the profile above.
In the elevation for that profile, the elevation line will be drawn using a dotted line style for the portion of the profile that crosses the region of invisible pixels.

**Saving Elevations as Images**

The Tools - Make Image command captures the current scene displayed in an elevation window as an image. Images made of elevation windows are captured at screen resolution.

**Info Pane and Profiles and Elevations**

When the focus is on a profile or elevation window or on a profile layer in a map, the info pane will report the average height for the profile as well as the minimum and maximum height in the profile.

**Use in Layouts**

Profiles and elevations may be used as elements in print layouts just like other components, either as their own elements or as a layer in a map that appears as an element in the print layout. When an elevation element is used in a print layout, if it is selected for editing the font used may be changed using the layout's format toolbar.

Text entries in a print layout that are bound to profiles and elevations can use [**Average Height**], [**Minimum Height**], and [**Maximum Height**] escape sequences to automatically incorporate these numbers into the text.

**Example**

We can create a print layout using an elevation, or we can drop an elevation element into an existing layout.

In the illustration above the page setup uses landscape orientation and the elevation element has been resized and moved to the left of the page.
We can insert text into the layout using the **Insert Text** button. Click on the **Insert Text** button and then draw a text box in which the text will be located.

In the **Insert Text** dialog, enter the text that is desired. We have used the **[Average Height]**, **[Maximum Height]**, and **[Minimum Height]** system generated expressions to add these values to the text automatically. See the **How to Print** topic for a detailed example of adding text to a layout.
The new text appears in the layout.

If we zoom into the layout we can see how the numbers for average, maximum and minimum height are automatically generated and substituted into the text element. Note that if we change the profile line or surface, the resultant elevation will also change and the reported numbers for average, maximum and minimum values will also automatically change.

**Note**

The foreground and background colors of profiles can be set in **Tools - Options - Colors**.

Although we may edit the profile line in simple ways within the profile, for more complex editing we can use the full roster of editing tools within drawing windows to create and edit lines as desired to use for profiles.
Analysis

Manifold provides a wealth of analytic capabilities. These include a full range of tools from simple measurement to complex statistics or network-analytic measurements. Analytic capabilities are distributed throughout the system where they are needed during various tasks. Highlights include:

**Transform Toolbar**
Transform toolbar operators provide numerous analytic functions. In drawings, these include spatial analytic functions such as the creation of Buffer Zones or Voronoi tilings or many other functions. The transform toolbar operators for images and tables likewise provide many analytic functions, including numerous statistical functions for tables.

**Decision Support System**
The Decision Support System allows analysis through queries using flexible criteria. It also provides the fuzzy inference engine used to power the "More like this" analytic capabilities built into Manifold tables.

**Active Columns**
Use formulas within active columns to add automatically computed measurements to tables. For example, we can create an active column titled "Perimeter" that contains a simple formula that reports the perimeter of the object for each record.

**ViewBots**
ViewBots provide a one-line analysis bar that is aimed at a window and which reports some analysis based on the contents of that window. ViewBots are used to perform simple statistics, queries, and other functions, including measurement functions such as the total area of selected objects.

**Queries**
Manifold SQL provides many analytic functions, including measurements, spatial relationships, and statistics.

**Spatial Overlay**
Spatial overlays provide a way of combining data between areas, lines and points that is often used in analyses.

**Surfaces Display Options**
Display options for surfaces can provide Height, Slope and Aspect analyses.

**Tracker**
Use the Tracker tool to interactively measure distances and areas by clicking with the mouse.

**Scripts**
Scripts may be written within Manifold to provide any analytic function.

In addition to the above major areas, there are numerous "implied" analytic capabilities throughout the system. For example, the Threshold function with images provides an embedded analytic capability that creates a histogram of pixel values. This histogram can then be used to set ranges for forcing pixels to white or black values.

Many types of implied analysis appear in the presentation capabilities of Manifold as well. For example, when creating a thematic format we have many choices as to how data fields will control the formatting. Some of these choices involve analysis, such as a natural breaks grouping of intervals used for thematic coloring.
Measurement

Measuring distances, areas and other quantities in Manifold is easy. There are several ways to make measurements in Manifold System:

**Tracker** Use the Tracker tool to interactively measure distances and areas by clicking with the mouse.

**Active Columns** Use formulas within active columns to add automatically computed measurements to tables.

**ViewBots** ViewBots provide a one-line analysis bar that is aimed at a window and which reports some analysis based on the contents of that window. ViewBots are used to perform simple statistics, queries, and other functions, including measurement functions such as the total area of selected objects.

**Queries** Manifold SQL provides many measurement functions.

**Scripts** Scripts may be written within Manifold that provide custom measurement functions.
Tracker

The tracker tool provides interactive distance and area measurements. To use the tracker, click on any start location. As the mouse is moved, the status bar will provide a distance from the starting point to the current position of the cursor.

If we click the tracker at several locations the distance reported will be through the polyline distance from the starting point to the current cursor location. Right click or press the ESC key to clear the tracker so it may be clicked at a new starting point.

For example, if we wish to know the distance from the Oakland Estuary around Treasure Island, back to the City front and then up to Sausalito we can begin by clicking the tracker cursor just outside the Estuary. We can then click a few more times to form a line going around Treasure Island and back to the City. At all times the status bar measurement readout will report the distance through the resultant line from the starting point to the current position of the cursor.

When we move the cursor up towards Sausalito we can see the distance over the indicated path is about 21671 meters.

To measure exact distances between specific locations, we will often use Snap together with the tracker tool to snap to an exact location, such as a point. Use the TAB key to jump the cursor to the nearest snap location as specified by the current Snap To modes.

By default, the tracker tool will report distances using the unit of measure used in the native coordinate system (projection) of the drawing. Pressing CTRL will shift the unit of measure to the units set in the Tools - Options dialogs. When using CTRL, distances will be computed over the Earth ellipsoid in use and reported in linear measurement units even if the drawing has not been projected.

Autoscroll

The tracker tool is a "live" cursor that is attached to the mouse cursor. Moving the cursor out of the active window after the first tracker click will cause an autoscroll. To avoid unintended autoscroll, remember to use ESC or a right click to end tracker scrolling before moving the mouse cursor out of the active window.

Press CTRL to Change Units and Computation

Press and hold down the CTRL key at any time to switch the tracker read out between native units and the default measurement unit specified in Tools - Options.

For example, in maps using Latitude / Longitude projection the native units are degrees. If we would like to see tracker distance in miles or kilometers we would hold down the CTRL key. The tracker in CTRL mode will show measurements in either English (miles and feet) or metric (kilometers and meters) depending on the setting of the Use English measurement units option in Tools - Options. Small distances will automatically use the smaller units (feet or meters) with the display jumping to larger units (miles or kilometers) for larger distances. Very small values will be reported using millimeters or inches.

Using CTRL also shifts the formulae used within Manifold to compute distance. The default tracker measurement uses plane geometry on the assumption that the component is seen in whatever projection is desired. By default, the tracker tool reports simply Euclidean distance in whatever units define the native, planar coordinate system of the drawing. Pressing CTRL shifts the computation to a full ellipsoidal trigonometric computation of the arc distance of the geodetic curves involved for length or areas.
The difference may be seen sometimes when using metric units so that the default tracker might report a distance of 50017 meters while a CTRL tracker reports, for example, 49.92 kilometers. The difference between the two is the difference between an Euclidean computation on a plane and an ellipsoidal computation on the Earth ellipsoid in use.

**Accuracy**

Normally, if a projection is well chosen for the region of interest the difference between the two computations (using or not using CTRL) will not be that great. A large difference between the two computations indicates either an error in georegistration or the inappropriate use of a projection. For example, GIS newbies sometimes attempt to combine data from multiple UTM zones into a single UTM zone, applying the single UTM zone to geographic regions far beyond where that particular zone's projection will be accurate. In such cases, there will be a significant difference between the value reported in native units as a result of a planar Euclidean computation and the value reported in default measurement units as result of an ellipsoidal trigonometric computation.

For highest accuracy first make sure that the component is correctly georegistered and second make sure that the projection used for the image is one that is scale-invariant and centered exactly upon the region of interest.

Because no projection is perfect at representing the curved surface of the globe, when measuring very large regions of the Earth there is likely to be a significant difference between the ellipsoidal trigonometric computation done with CTRL and the Euclidean computation done by default, even if the projection is well chosen. In such cases the CTRL computation is the more accurate one.

At times the difference between Euclidean and ellipsoidal calculations will be great even over relatively small regions. For example, when using the tracker tool with Mercator projections (which do not preserve distances accurately away from the Equator) there will be great differences between the tracker and the CTRL-tracker measurement. This effect may be very noticeable when using image servers to provide linked images in Mercator projection. When making measurements in such cases use the CTRL-tracker numbers.

**Measuring Perimeter and Area with SHIFT**

The tracker may also be used to measure area. The tracker reports the area within the closed region formed by connecting the starting point to the current position of the mouse. Press the SHIFT key at any time when using the tracker and the area denoted by the tracker path so far will be closed and a computed area will be reported to the status bar.

The SHIFT and CTRL keys may be combined to show areas in different units.

**Example**

The illustrations below show a drawing with three points. The drawing is in unprojected Latitude / Longitude so the native units used are degrees. We have set Snap To Points and have clicked on the tracker.

We first click on the uppermost point. As the cursor moves near the middle point the snap function will snap the square secondary cursor onto that point and…

![Image](image-url)

... the status bar will report the length of that segment in kilometers. At the scale used kilometers are a better match than meters. We can change the default units between metric and English (miles) units in Tools - Options.

Pressing the CTRL key while operating the tracker will toggle the units shown between native units (degrees, in this case) and "real" units (miles or kilometers).
We can click to anchor that tracker segment on the middle point. Now, when we move the tracker cursor near the third point the *snap* function will snap / extend the tracker line to the third point.

With the square cursor box on the third point the status bar will read the overall length of the tracker line, which now consists of two segments.

At any time we can press the *SHIFT* key to temporarily close the tracker line back to the originating point. In the above illustration, we’ve positioned the mouse cursor near the third point so that the tracker line snaps to the third point, but we have also pressed the *SHIFT* key so that the tracker line closes the figure back to the first point.

The result in the status bar is the length of the entire tracker perimeter as well as the area in square kilometers.

**Scroll Wheel**

When using a mouse with a scroll wheel we can use the scroll wheel to zoom in and out. This works even in the middle of commands such as the tracker tool. By default the zoom will be centered on the mouse position. Holding the *CTRL* key while operating the scroll wheel will force the zoom to be near the center of the opened window.

**Notes**

Keep in mind that projected maps use linear measures such as feet or meters as their native units. Toggling the tracker tool using *CTRL* may therefore in some cases toggle between the native unit and "real" units that in both cases may be meters.

In addition to using a right click or the *Esc* key to cancel tracker function, the *ALT-Tab* key combination may also be pressed if some non-Manifold program or information dialog (such as a "download complete" notification when downloading files in background) has snatched context away from the Manifold window.

When used with layouts, the tracker tool will report in either English (inches) or metric units depending on the setting of the *Use English measurement units* option in *Tools - Options*.

Tracker computations depend upon correct georegistration of the component being measured. If the component has not been correctly imported and georegistered the *CTRL* computation cannot be accurately done.

**Advanced**

See the Dialog Mode and Visual Tools topic for a parameter or value oriented way of specifying a tracker path or shape.
ViewBots

ViewBots are one-line analytic instruments used to dynamically compute a statistical or comparative measure over a subset of records and are extremely useful for analyzing tables. They are one of the most popular functions in Manifold for experienced users. When a ViewBot is configured for a drawing's table it continues to function when the drawing has the focus. For example, if we configure a ViewBot to show the average of a given field for selected items it will continue reporting the average of the selection whether or not we select items from a drawing's table or by using mouse selection commands to select objects in the drawing.

Turn on the ViewBots pane with a \texttt{SHIFT-ALT-B} ("B" for "ViewBot") or with a \texttt{View - Panes - ViewBots} command.

The ViewBots above, for example, report on those operations they have been told to conduct on the table in view. ViewBots are bound to the tables for which they were created. When a drawing window is active, the ViewBots pane will list all ViewBots created for the drawing's table. When a drawing layer in a map is active, the ViewBots pane will list all ViewBots for the active drawing's table.

To Create a ViewBot

1. Open the ViewBots pane and press the \texttt{New ViewBot} button. A new ViewBot line will be added to the ViewBots pane.
2. Double click onto the saved ViewBot fields to choose analytic functions and the scope of the ViewBot.
3. Press the \texttt{Refresh} button to update the results in that ViewBot if the ViewBot autorefresh option is not on in \texttt{Tools - Options}.

To Make a Selection using a ViewBot

1. Click on the target component to make it active. Open the ViewBots pane.
2. Click on the desired ViewBot to highlight it.
3. Click on one of the ViewBot pane's selection command buttons to combine the object set picked out by the ViewBot with any selection that is currently made. For example, clicking on the \texttt{Subtract from Selection} button will take the set of objects picked out by the ViewBot and will subtract the objects it contains from the current selection.

To Delete a ViewBot

1. Click on the desired saved ViewBot to highlight it.
2. Press the \texttt{Delete ViewBot} button.

To Edit a ViewBot

1. Double-click on the ViewBot to be edited, or
2. Click on the ViewBot to highlight it and press the \texttt{F2} key.
ViewBots Pane Toolbar Commands

Use the New ViewBot and Delete ViewBot buttons to create and to remove ViewBots from the pane. Use Refresh and Refresh All to update the calculation in the highlighted ViewBot or in all ViewBots.

Five selection command buttons are arrayed at the top of the ViewBots pane. These commands apply to whatever set of objects is picked out by the highlighted ViewBot. If we click on a ViewBot to highlight it and then press one of these buttons, the object set picked out by that ViewBot will be combined with whatever is the current selection in the image. The selection commands allow us to use object picked out by a View ViewBot to replace the selection, to add to the selection, to subtract from the selection, to invert with the selection and to intersect the selection. For example, if we have a ViewBot that reports the number of objects for which the Elevation is greater than 100, the set of all objects picked out by this ViewBot will be combined with the existing selection with the selection command buttons.

- **Move Up** - Move the active layer up one position in the layer stack.
- **Move Down** - Move the active layer down one position in the layer stack.
- **Replace Selection** - Replace the existing selection with the objects picked out by the highlighted ViewBot.
- **Add to Selection** - Add the objects picked out by the highlighted ViewBot to the existing selection.
- **Subtract from Selection** - Subtract the objects picked out by the highlighted ViewBot from the existing selection.
- **Invert with Selection** - Deselect what is in the objects set picked out by the highlighted ViewBot that was already in the existing selection and otherwise add the ViewBot's object set.
- **Intersect Selection** - Select only the region of overlap between the highlighted ViewBot's objects and what is in the existing selection. If there is no overlap, nothing will be selected.
- **Refresh** - Update the highlighted ViewBot.
- **Refresh All** - Update all ViewBots in the pane.
- **New ViewBot** - Create a new ViewBot line in the ViewBots list.
- **Delete ViewBot** - Delete the highlighted ViewBot.

Add ViewBot Dialog Controls

- **Scope** - The objects upon which the ViewBot operates: all objects (or records, pixels, etc), the selection, or the name of any saved selection.
- **Column** - The name of the field to use. Optional for some operations. For example, Number of Areas or Center X don't require a field.
- **Operation** - The ViewBot operator to be employed.
- **Argument** - Arguments, if required for the operator.
- **Ignore Case** - Treat upper and lower case letters the same in strings.
Used with text operators.

**Ignore leading and trailing whitespace**
Ignore any space or tab characters in strings. Used with text operators. "This" would be treated the same as "This".

**Ignore interior whitespace**
Ignore any space or tab characters within strings. Used with text operators. "Th is" would be treated the same as "This".

**Caption**
String to display for ViewBot results. Can include escape sequences in square brackets:

- **[Argument]** - Replace with argument in use.
- **[Column]** - Data field in use.
- **[Operation]** - Replace with the operation in use.
- **[Scope]** - Replace with scope in use, such as the name of a saved selection.
- **[Scope Size]** - Replace with the number of items in the scope.
- **[Time]** - Estimated time to compute the ViewBot. Normally used when **Autorefresh** is turned off to warn users of computationally intensive ViewBots that should not be casually refreshed.
- **[Value]** - Repeats the value computed and displayed in the **Value** column. Normally redundant.

The default **Caption** string of **[Column] [Operation] [Argument] in [Scope]** creates a reasonably comprehensible sentence for most ViewBots.

**Autorefresh viewbot**
Command ViewBot to self-refresh on any changes in the subject component. If this value is not checked, a **Refresh** or **Refresh All** command in the ViewBots pane will be required to update the value of the ViewBot on any changes.

**Selection and ViewBots**

Some ViewBots such as the maximum value of a column allow selection from the ViewBot and some (such as the average value of a column) do not.

**Examples**

We will open the **Order Details** table from the sample **Nwind.mdb** database.
For simplicity, we will hide all columns except Order ID and Unit Price. In the illustration above we’ve opened the ViewBots pane using View - Panes - ViewBots and have positioned it over the table so we can make screenshots of both at the same time.

To create a new ViewBot we press New ViewBot in the ViewBots pane.

The Add ViewBot dialog opens up. We will choose Unit Price for the Column and Average for the Operation, using defaults for all other choices.

In particular, we will leave the caption string to the default settings. We press OK and a new ViewBot is created.

We can press Refresh All at any time to re-compute the ViewBot if Autorefresh viewbot is not checked. The Value column for the ViewBot reports that 24.71998… is the average of unit price values in the table.
To see how the Caption string is generated, recall that the Caption box in the Add Viewbots dialog contains the default string:

\[[Column] \[Operation] \[Argument]\] in \[Scope\]

The result in the ViewBot Caption column is the text seen above.

When the ViewBot is recomputed, the values of the various escape phrases in \[] square brackets are replaced with the relevant text. There is no \[Argument\] used in this ViewBot so it is replaced by nothing.

Let's add another ViewBot. Once again we press the New ViewBot button.

We will use the same settings as before, but this time we will change the Scope to \[Selection\]. The Scope setting specifies upon which objects (records) the ViewBot will operate. By changing the Scope to \[Selection\] we are telling the ViewBot to look only at records that are selected.
We can press **Refresh All** again (or, simply check the **Autorefresh ViewBot** box when creating the ViewBot) to see the new values. There is no value for the second ViewBot because we have not selected anything in this table.

If we make a selection as seen above and press **Refresh All** we see that the average of unit price for the selected records is **23.3**. Note that we can simultaneously see the average for all records and for those only in the selection.

Suppose we had previously made a selection representing new orders we've received and that we've saved this selection in the Selections pane under the name **New Orders**. We could create a third ViewBot using **New Orders** in the **Scope** box (all saved selections will appear as choices in the **Scope** box).

We would then be able to see how the unit price average for all records compares to the unit price average in the **New Orders** saved selection as well as in any current selection we care to make. We could also have query panes or use other methods to make selections and the ViewBots will faithfully report the latest figures based on the current selection if that is the **Scope** specified. The "live" ability of ViewBots to dynamically report values based on the current selection is an analytic and data discovery instrument of great power.

We can get rid of the third ViewBot by clicking on it to highlight it and then choosing **Delete ViewBot**.

**Using ViewBots to Make Selections**

Operations like **Average** are aggregate operations that calculate a number without identifying any specific record. Many ViewBot operations can identify specific records. We can then use the ViewBot to select those records. We will add two more ViewBots that can be used for selection.
First we add a ViewBot that finds records where the Unit Price is greater than 50.

The resulting ViewBot informs us there are 191 records that are priced higher than 50.

We will add one more ViewBot that finds records where the Unit Price is less than 50.

This ViewBot tells us the table contains 2630 records that are priced lower than 50.
To make a selection using a ViewBot, we click on it to highlight it and then we press one of the Selection Commands at the top of the ViewBots pane.

For example, we can click on the greater than 50 ViewBot and press Replace Selection.

Instantly, all those records with unit price greater than 50 are selected. In the table in view, we see only one such record (the others are scrolled out of sight). Note also that the ViewBot showing the average unit price in the selection has also been recomputed. We now know that the average unit price for products priced higher than 50 dollars is 100.86. What is the average unit price for products that are priced lower than 50 dollars?

To find out, we click on the lower than 50 ViewBot and press Replace Selection once more.
Instantly, all records with unit price less than 50 are selected. We can now see from the second ViewBot that the average price for products that sell for less than 50 dollars is 19.13.

**ViewBot Uses**

ViewBots can be used for a very wide variety of purposes. In the example above we could have added ViewBots that reported the total number of items in the selection and then tried different ViewBots at different price levels to find average, maximum and minimum values.

We can use ViewBots for selection. Suppose we have a mailing list that needs to have duplicates cleaned. We could open a ViewBot that finds all duplicates except the first. If we select records with that ViewBot we can then delete the selected records.

Suppose we have a customer database for a store where we would like to find all customers who have purchased refrigerators who are not on credit hold. If our database has a "notes" field that contains the word "refrigerator" for anyone who has purchased a refrigerator, and if it also has a field for credit hold, we can create two ViewBots. One ViewBot finds all records where the notes field contains "refrigerator." The other ViewBot finds all records where credit hold is true. To create a list for mailing, we use Replace Selection with the refrigerator ViewBot to select all records with refrigerators. We then use Subtract from Selection with the credit hold ViewBot to remove the credit hold records from the selection. The resulting selection is only those people with refrigerators who are not on credit hold.

**Example: Using ViewBots with Drawings**

ViewBots are a great way to see a report of information from a drawing. In this example we import and use the mexico_eg.mif sample drawing that is on the Manifold CD. This drawing shows provinces in Mexico and provides demographic data for each province.

Begin by importing the drawing. Open the drawing and turn on the ViewBots pane with a SHIFT-ALT-B or with a View - Panes - ViewBots menu command.

Click the New ViewBot button to create a new ViewBot.
Configure the Add ViewBot pane as seen above. In the example drawing the POBL_1990 field gives the population in 1990 for each province. We will create a ViewBot that reports the sum of population in all selected provinces. Although Manifold will offer a suggested caption based on the scope and operation in use, we will provide our own caption, “Total Population in Selection.” Note that the Autorefresh viewbot checkbox has been checked. This updates the ViewBot on any changes.

The initial result in the ViewBots pane is an empty ViewBot. The Value will not appear until we select something, either in the drawing or in the drawing's table.

If we select three provinces in the drawing the ViewBot will update.
Now it reports a total population of **5763591** for the three provinces.

If we pop open the drawing's table we can see the values of `POBL_1990` that are in the selected provinces do indeed add up to **5763591**.

If we make a different selection in the drawing the ViewBot will update the value.
We can see that this selection has a much higher total population (because, of course, it includes the provinces surrounding Mexico City).

See the Selection topic for examples of *Replace*, *Add*, *Subtract*, *Invert* and *Intersect* selection command usage.

ViewBot Operators for lists of operators that may be used within ViewBots.

See the Show Area of a Parcel in Acres topic for an example that uses ViewBots to show acreage of selected parcels.

ViewBot values are displayed using the format of the underlying column, if appropriate. See the Formatting Columns topic for information on setting formats.
ViewBot Operators

ViewBot operators work with fundamental Manifold data types: binary, Boolean, date, numeric and text fields. URL fields are text fields. Currency, latitude, longitude and percentage fields are numeric fields. Operator results are selectable unless otherwise noted.

ViewBot Operators for All Field Types

- **Duplicates**: The number of duplicated values.
- **Duplicates Except First**: The number of duplicated values less one for each unique value. Example: a 2-2-2-3-3-4-4 sequence of values yields 4 and a 2-2 sequence yields 1.
- **Uniques**: The number of unique values.

ViewBot Numeric, Date and Text Operators

- **Maximum**: The maximum value that occurs.
- **Minimum**: The minimum value that occurs.
- **Median**: The median of all values in the scope.
- **Less than**: The number of values less than the given value.
- **Less or Equal to**: The number of values less than or equal to the given value.
- **Equal to**: The number of values equal to the given value.
- **Not Equal to**: The number of values not equal to the given value.
- **Greater than**: The number of values greater than the given value.
- **Greater or Equal to**: The number of values greater than or equal to the given value.

ViewBot Text and URL Operators

- **Duplicates**: The number of duplicated values.
- **Duplicates Except First**: The number of duplicated values less one for each unique value. Example: a 2-2-2-3-3-4-4 sequence of values yields 4 and a 2-2 sequence yields 1.
- **Empty**: Number of empty values.
- **Uniques**: The number of unique values.
- **Maximum**: The maximum value that occurs.
- **Minimum**: The minimum value that occurs.
- **Median**: The median of all values in the scope.
- **Less than**: The number of values less than the given value.
- **Less or Equal to**: The number of values less than or equal to the given value.
- **Equal to**: The number of values equal to the given value.
- **Not Equal to**: The number of values not equal to the given value.
- **Greater than**: The number of values greater than the given value.
Greater or Equal to  The number of values greater than or equal to the given value.
Starting with The number of values starting with the given substring.
Ending with The number of values ending with the given substring.
Containing The number of values containing the given substring.
Matching The number of values matching the given regular expression pattern.
Sounding Like The number of values sounding like the given word.
Starting with Token The number of values that start with the given token.
Ending with Token The number of values that end with the given token.
Containing Token The number of values that contain the given token.
Starting with Match The number of values that start with a match to the given regular expression pattern.
Ending with Match The number of values that end with a match to the given regular expression pattern.
Containing Match The number of values that contain a match to the given regular expression pattern.

Comparison operators such as Greater than will work with text, binary, coordinate system and geometry columns as well as with numeric columns. When used with non-numeric columns a comparison operator will compare data going byte-by-byte stopping on the first different pair of bytes.

ViewBot Numeric Operators

Choose Not with some operators (such as Equal to) to create the "not" form.

Duplicates The number of duplicated values.
Duplicates Except First The number of duplicated values less one for each unique value. Example: a 2-2-2-3-3-4-4 sequence of values yields 4 and a 2-2 sequence yields 1.
Bottom Identify the lowest $N$ values where $N$ is given by the argument. Does not return a value for the ViewBot but enables selection of the lowest $N$ values.
Uniques The number of unique values.
Maximum The maximum value that occurs.
Minimum The minimum value that occurs.
Median The median of all values in the scope.
Less than The number of values less than the given value.
Less or Equal to The number of values less than or equal to the given value.
Equal to The number of values equal to the given value.
Not Equal to The number of values not equal to the given value.
Greater than The number of values greater than the given value.
Greater or Equal to The number of values greater than or equal to the given value.

Printing and Layouts

Printing

Manifold provides two paths to printing:

- The contents of any component window may be printed in a default way using the File - Print command.
- More sophisticated layouts may be composed using a Print Layout, which may then be opened and printed using File - Print. The layout will be based on whatever settings (paper size, orientation, etc.) specified in the File - Page Setup dialog. Layouts are used to print maps at a specific scale. See the Layout topic.

Note that printing items with a layout is a three-step process: create the layout, adjust the elements of the layout to taste, and then print the layout.

Page Setup

The page setup dialog allows us to set paper orientation (portrait or landscape), paper size, printer properties and borders. Page setup options will be applied to any print job.

Layouts

Layouts are used to provide more sophisticated control over printing jobs. A layout may be created using a single component or none at all. Additional components that are to appear in the layout may be dragged and dropped into the layout and then resized, moved and adjusted as desired. We can change the characteristics of components that appear within a layout by right clicking on them and choosing Properties. This allows us to change the component to use a view or to show embellishments such as a North arrow or scale bar. We can use layout tools to add text or border lines. We can then print the layout.

The most sophisticated print layouts will normally feature a main compositional element that is a map. This map will consist of many drawing, image and labels components to create the visual effect desired. Because maps provide very rich editing capabilities they are the natural "console" within which to work when creating desired effects involving many layers.

Experienced Manifold users will therefore often put most of their compositional efforts into arranging the main map as desired. They will then use that map as the main element in a layout and will add other components to the layout rather sparingly. It is often a matter of taste and convenience whether a particular compositional element is placed within a map or is dropped into the layout as a separate element.

Suppose for example we have a map of wetlands that is to be printed and we wish to have a title block that includes a main text title hovering over a corporate logo. We could create the entire ensemble with both the wetlands drawings and the text labels and image used as the title block as a set of layers in one map. Such a complex composition is shown at the end of the Layers topic using the splash screen for Manifold as an example. Once a complex composition is created as a map, it could then be dropped into a print layout that consists of just that one component.

Alternately, we could create a map showing the wetlands and then create another map that just consisted of a few labels and image layers that made up the title block. We could then drop the wetlands map into a layout and also drag and drop the title block map into the layout. We would then print the layout that now is made up of two components.

The former approach allows creating everything within the same map window so that all layers are immediately at hand to allow adjustment of any visual aspect of the map. The second approach allows us to create a standard title block that could be recycled into other print layouts. Production print jobs could well include a combination of the two methods.

Layouts also support use of layout templates which allow us to create standardized arrangements for layouts. It is very important to master the use of layout templates when engaged in repetitive layout work or when creating layouts that must share the same look and feel.

Print Toolbar Button
As is the case in standard Windows applications the Print toolbar button prints directly to the default printer. In contrast the File - Print command called from within the main menu will display a Print dialog that allows choice of which printer to use.

Printer Drivers

Printer drivers vary widely in their ability to provide rapid and efficient printing. The printer vendor normally provides printer drivers. A well-written driver will allow faster printing with less data passed between Manifold and the printer. A poorly written driver may result in slow print jobs or very large amounts of data in temporary printing files. Printer drivers with very serious defects may not print jobs correctly.

When a layout is printed, Manifold sets up the print job and passes it to Windows, which then passes the job to the printer driver. Two key options found in the printing page of the Tools - Options dialog help control how Manifold interacts with Windows and thus the printer driver.

- **Optimize printing of images and surfaces**
  - When on, the system avoids rendering image and surface components in full resolution during print job setup, deferring final rendering to the printer driver, provided the image or surface can be rendered with either no re-projection or with simple scaling and shifting. This makes the size of the print job smaller and offloads the task of scaling raster images to the printer driver. Most printer drivers can automatically re-scale images and surfaces within the driver for better performance and reduced print job size. Some drivers cannot do so and will so cause the job to be printed more slowly than if Manifold renders images and surfaces. By default the option is turned on since most modern printer drivers can automatically render and re-scale. If the print job is slow or if the printer or plotter in use is suspected to be Windows unaware, try turning this option off and see if performance improves.

- **Print using GDI+**
  - On by default. If unchecked, prints using GDI mode instead of GDI+ mode. GDI is an earlier Microsoft technology. Provided for use in case of a buggy or incomplete printer driver. Printing in GDI mode does not support antialiasing or transparency for drawings. See the Layer Opacity topic for information on transparency. Curved (rotated) or labels aligned to lines cannot be printed n Windows 9x systems if the Print using GDI+ option is turned off.

The Tools - Options dialog includes other options related to printing, but the above options have by far the largest impact on the process of printing.

If your printer driver provides poor performance or causes errors, try changing the default settings of the above two options. Make sure you have installed the most recent version of the printer driver available for your Windows operating system. Printer vendors will frequently provide new editions of printer drivers on their web sites that are more recent than the versions delivered with the printer or bundled into Windows.

It is always possible in the case of older printers or plotters that the printer vendor no longer provides driver updates, or that the only printer drivers available do not support recent Windows editions. In that case, the only choice may be to upgrade to a new printer that is supported with drivers that fully support current Windows editions.

**Tech Tip: Printing a Layout to PDF**

There are two ways to create a PDF file from a layout: exporting a layout to a PDF or "printing" the layout via File - Print using a PDF virtual printer driver, which mimics a printer to capture any printing activity as a PDF.
Printing a layout to a virtual printer driver that produces PDF feeds the layout through an ordinary GDI / GDI+ rendering pipeline, which issues "dumb" printing commands that are then captured by the driver. Exporting a layout directly as a PDF feeds the layout through the Manifold PDF rendering engine, which optimizes printing commands. In general, the results of exporting a layout as a PDF will almost always be better than the results of printing the same layout to a virtual printer driver.

Note also that printing a layout to a via File - Print exposes you to the risk of whatever that PDF printer driver vendor has in mind. For example, it could easily produce different results depending on the installed version of Acrobat if that is what is used for a PDF printer driver. In contrast, exporting a layout to a PDF via File - Export - Image will be consistently the same.

See Also

File - Print - Many components can be most easily printed by clicking open the map, drawing or image window and choosing File - Print.

How to Print - For a step by step example of creating and printing a layout.

Exporting Layouts
Layouts

Layouts are components that allow us to design printing jobs. When opened in a layout window, a layout allows us to drag and drop components such as drawings, images, maps, surfaces, tables, palettes and labels components into the layout. Charts, comments, queries and scripts can also appear in layouts. We can then resize or reposition those items to arrange the appearance of our printed page. Items in layouts may be copied and pasted within the layout. Layouts may be based upon layout templates to use standardized arrangements.

Layout windows are scaled so that the layout shown looks exactly like the printed page that will be created. Choosing View - Zoom To - 1:1 will zoom the layout to a 1:1 view that shows it on the monitor exactly as it will be printed. If we are working with US Letter sized paper in landscape orientation and we have a monitor that can show a display 11 inches by 8.5 inches, we will see a literal image of exactly how the printed page will appear.

Layouts will automatically be configured to show the printed page as it would look given current Page Setup settings for the printer selected. Layouts save their last-used printer settings when the project is saved. To change margins in the layout, use the Page Setup dialog. The Page Setup dialog uses inches or millimeters depending on the setting of the Use English Measurement Units checkbox in the Tools - Options dialog.

Layouts are not only used for printing, they may be used to create images of arbitrary DPI resolution using the Tools - Make Image command and are also used to save an image of the layout in graphics file formats such as .emf, .ps or .pdf.

Creating a Layout

Layouts may be created in two ways. The first way is to create a layout based on a particular component, such as a drawing, and to then add any other components to the layout. The second way is to create a blank layout and to then drag and drop components into the layout.

The first method will automatically scale the component that is used to create the layout to fill an entire page or, in the case of text components like tables or comments, the layout will be expanded to a multipage layout to allow the entire component to be printed. This component will automatically be the main component so that addition of any system generated text expressions will use this component. The first method is convenient when one main component will be the subject of the layout.

The second method may be more convenient when several components will be the subject of the layout, or when a layout is being created for use as a standard layout with many different projects.

To Create a Layout

1. Click on the project pane and create a new layout with File - Create - Layout. If the layout is to be based upon a particular component, choose that component in the Create Layout dialog.
2. In the Create Layout dialog, if a template is to be used check the Template box and choose a template. If the layout is to be blank, check the No parent box and no component will be loaded into the layout by default.
3. Open the new layout.
4. Verify paper size and other overall options are correctly specified in File - Page Setup.
5. Drag and drop components that are to appear from the project pane into the layout.
6. Insert any objects such as vertical or horizontal lines, text labels, etc.
7. Edit the component elements in the layout to change size, position, views to be printed, etc.
8. Use File - Print to print the layout.

Creating a layout based upon a non-text component, like a drawing, will automatically scale the component to fit the entire component on a single, full page. Creating a layout based upon a text component such as a table, query, script or comments component will automatically invoke the multipage layout capability to use as many pages as are necessary to show the entire component in the font size that is used.

Dragging and Dropping

We drag and drop items into a layout from the project pane. Begin by double clicking on the layout component to open it in a project pane. We can now click on an item in the project pane and drag and drop it into the layout window. Components that are dragged and dropped into a layout will at first appear as a fairly small layout.
element so they do not obscure other elements in the layout. Click on the component that's just been dropped to select it and then resize and reposition the element as desired.

Text Components in Layouts

Text components such as queries, scripts or comments are printed as text. Creating a layout based upon a comments, query or script component will adjust the number of pages vertically so the entire component is visible. Dragging and dropping a text component into a layout will create the usual small element that can be resized and repositioned as desired.

Text components (comments, queries and scripts) will always be printed with left alignment and will be word-wrapped to fit within the width of the layout element. Each tab will be replaced by four spaces. The default font used for the text component will be taken from the Tools - Options - Fonts page.

Selecting a text component in a layout for editing by **CTRL-ALT** clicking it will allow changing foreground color, background color and font using the format toolbar.

Inserting Items with the Tools Toolbar

The tools toolbar for layouts allows us to insert additional design elements into a layout. When a layout is the active window, the tools toolbar will change to show tools used with layouts.

<table>
<thead>
<tr>
<th>Insert Horizontal Line</th>
<th>Create a horizontal line in the layout. Default line size is 1/20th of a point.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Insert Vertical Line</td>
<td>Create a vertical line in the layout. Default line size is 1/20th of a point.</td>
</tr>
<tr>
<td>Insert Box</td>
<td>Create a rectangular box with a click and a drag. Boxes have foreground and background color and line thickness that can be set by selecting the box and using the format toolbar. Default line size is 1/20th of a point.</td>
</tr>
<tr>
<td>Insert Box on Center</td>
<td>Create a rectangular box centered on initial mouse click. Default line size is 1/20th of a point.</td>
</tr>
<tr>
<td>Insert Text</td>
<td>Add a text box, such as a caption, copyright notice or title, to the layout. Click on the text box to select it and then use the format toolbar to format the text. Double-click a text box in the layout to edit the text it contains.</td>
</tr>
<tr>
<td>Insert Legend</td>
<td>Add a legend to the layout, based upon a component used in the layout.</td>
</tr>
<tr>
<td>Insert North Arrow</td>
<td>Add a North arrow to the layout, based upon a component used in the layout.</td>
</tr>
<tr>
<td>Insert Scale Bar</td>
<td>Add a scale bar to the layout, based upon a component used in the layout.</td>
</tr>
</tbody>
</table>

When inserting horizontal or vertical lines, it is usually best to turn on the grid with View - Grid and to then use **Snap to Grid** to position layout element such as vertical and horizontal lines.

To add text, legends, North arrows and scale bars, click the tool and then click and drag open a horizontal box in the layout showing where the item is to appear. Inserting a legend, North arrow or scale bar will raise a dialog asking upon which component the item is to be based. If the layout does not contain any components for which a legend, North arrow or scale bar can be created, these buttons will be disabled.
The default line size of both horizontal and vertical lines is 1/20th of a point. Since this is a thinner line than can be displayed in one pixel on most monitors, keep in mind that the line will print more thinly than it appears on the monitor.

Creating Images from Layouts

Layouts have a special role in creating images because they capture and unify scale information for all of the elements that are used in them. This makes it possible to use layouts to create a single image at a specified resolution even though the layout is composed of drawings or other non-image elements.

To create an image from a layout, open the layout and use the Tools - Make Image command and specify the resolution desired (the default will be the resolution of the screen display, usually 72 or 96 DPI). This will create an image in the project. If an image file is desired, the image may then be exported to any image format supported by Manifold.

Another way of creating an image from a layout is to use File - Export - Image to save the layout as a .emf, .ps or .pdf file. When saving a layout via File - Export - Image we must specify the desired Pixel resolution and the Vector resolution of the file.

Pixel resolution (screen resolution by default) is used to save images and surfaces that are in the layout. Vector resolution (300 DPI by default) is used to save drawings and labels as well as layout elements such as text or horizontal and vertical lines. If saving to PDF for subsequent work in some other program before printing choose a Vector resolution setting that is the same as the resolution of the printer that will be used. If printing to a 600 DPI printer, for example, use 600 DPI. Pixel and Vector resolution must be at least 1 DPI and cannot exceed 7200 DPI.

See the How to Print topic for an example of saving a layout to a .pdf file.

Example

In this example we create a new layout from a drawing.

We begin with a drawing of Mexico. We would like to print this drawing using a layout.
In the project pane toolbar we click on the **Create** button down arrow for a pull-down menu of project pane components that may be created.

![Create button](image)

We choose a **Layout**. This will pop open the **Create Layout** dialog.

![Create Layout dialog](image)

The **Create Layout** dialog displays a list of all components in the project. This project only has one component, the Mexico drawing. We click on **Mexico Drawing** to highlight it and then press **OK**. If we wanted our new layout to be named something other than "Layout" we could have specified a new name as well. We will not use a template. See the Layout Templates topic for information on templates.

![Project pane](image)

In the project pane a new layout is created underneath the parent **Mexico Drawing** component. To open the layout, we double-click on it.
The default layout will show the entire component on whatever is the default page size and orientation defined for our printer. Since most people use Letter or A4 sized paper in a portrait orientation it is quite likely the layout will look like that above. The light gray lines bordering the drawing show the extent of page margins that have been set for this printer.

Given the East - West extent of Mexico, our drawing would look better if printed on the paper in landscape orientation.

To change the paper orientation we choose **File - Page Setup** and click on **Landscape**, then we press **OK**.
The layout will be redisplayed using landscape orientation for the paper. If we like, we can print the layout now with File - Print.

To continue this example we will resize and move the layout element that shows the Mexico drawing component. Before editing the layout we will first change the selection style used. Manifold can show selections in different styles, with the Dense Dots style being the default. It may be more convenient to show selections in layouts using the Border style.

To change the selection style we click on the down arrow of the Selection Style button in the selection toolbar.

We then choose Border.

We can now continue with the example.
Layouts can contain more than one component. When a layout is created from a component as we have done above, it will contain that component as the initial design element in the layout. To select the layout element we **CTRL-ALT** click on it.

The selected element will appear with a red border with editing handles. We can resize the element by clicking on an editing handle and dragging. Dragging on a corner will resize both the horizontal and vertical sides at the same time. We can also resize vertically and horizontally using the vertical and horizontal edit handles.
The resize action will be shown with a moving preview box as we drag the mouse.

Release the drag to finish the resize. The component seen in the layout will also be resized to fit in the maximum vertical or horizontal extent that it can fit.
To move a selected element, click on it and drag.

A preview box will appear as we drag the mouse to a new location.
Releasing the drag will move the element to the new position.

Clicking outside the selected element will deselect it.

**Selection in Layouts**

We normally use smart mouse selection within layouts, although of course the regular selection commands will work as well. Edit menu selection commands such as **Select All**, **Select None** and **Select Inverse** may be used. The **Selections** pane may be used to save selections. Selection styles may be altered. For example, many users will use the **Border** style within layouts.

To edit a layout element, use a **CTRL-ALT** click to select the element for editing. This will make the element the **primary selected** element.
Formatting operations (such as changing the font of a text element or the size of a line) will be applied to the primary selected element if there is more than one element selected. For convenience, if only one element is selected the formatting toolbar will work for that element. This allows rapid clicking on an element to select it followed by formatting.

Rotating a Layout Element

Layout elements are shown “North Up” by default. An element may be rotated by selecting it for editing and then pressing the **Element Rotation Angle** button in the format toolbar.

Consider a layout element that’s been selected for editing.

> We click the **Element Rotation Angle** button to rotate the element.

This calls up a menu of common choices for rotation angle. If we want to specify an angle not in the menu, we choose **More** for a dialog that allows us to specify an exact angle. We choose **40** to specify 40 degrees clockwise rotation.
The element is rotated 40 degrees clockwise. Note that the selection frame and editing handles also rotate. We can drag the editing handles in the new, rotated angular directions.

If we click outside the element to deselect it, we can see it has been rotated 40 degrees clockwise.

**Properties for Drawings and Maps**

How an element appears in a layout is controlled by its properties. Right click on the element and choose **Properties** in the context menu to call up a **Properties** dialog, or simply double click the element. Right click on a text element and choose **Edit** to edit the text.

The **Properties** dialog for a layout element showing a drawing has many properties:
**Properties**

**Scope**  Choose *entire component*, *layer*, *locked rectangle*, *locked center / scale*, *saved selection*, *selection*, or *view* to specify the contents of the element. If views or selections have been saved, choosing *view* or *saved selection* will enable the choice box to the right with all of the views or saved selections available.

**Paging**  Controls the printing of this component within multipage layouts:

- **continuous** - Spread output evenly across the entire range of pages they appear on.
- **individual** - Confining output to only that portion of a page on which the component appears and replicate this output likewise on all pages. Used to create overview maps with a printout repeating on all pages.

**pages or page ranges**  Used with multipage layouts to control which page this element appears in. Enter a series of page numbers or page ranges separated by commas. White space is ignored and reverse ranges are interpreted correctly. For example, we could enter 1, 2, 5-8 or 1, 2, 8-5 and get the same results. See the Multipage Layouts topic.

**Background**  Show the background color for this component, or change it in the layout. Choose *auto*, *custom* or *none*. *custom* allows choice of a custom background color in the adjacent color well.

**Control points**  Display any control points embedded in this component. Choose *auto*, *hide* or *show*.

**Graticule**  Display a graticule overlaying this component. Choose *auto*, *hide* or *show*. A graticule will not be displayed in the layout unless the user has explicitly configured it in the component's window using *View - Graticule*.

**Grid**  Display a grid overlaying this component. Choose *auto*, *hide* or *show*. A grid will not be displayed in the layout unless the user has explicitly configured it in the component's window using *View - Grid*.

**Legend**  Display the legend defined for this component. Choose *auto*, *hide* or *show*. 
North arrow  Display the North arrow defined for this component. Choose auto, hide or show.

Scale bar  Display the scale bar defined for this component. Choose auto, hide or show.

Border  Show a border for this component. By default, no border is shown. Borders are drawn using the color shown in the adjacent color well, black by default. Choosing coordinates, coordinates (graticule) or coordinates (grid) for a border style will print labels along the edges of the border. The default font is set by the Border entry in the Tools - Options - Fonts dialog.

[color well]  Choose a color for the border.

ABC  Enabled when using a coordinates border style. Double-click to choose the font to be used for labels.

Size  Enabled when using a coordinates border style. Specify the width in points of the border margin in which coordinate labels are shown.

Interval  Enabled when using a coordinates border style. The stepping between label values and the unit of measure to be used.

Rounding  Enabled when using a coordinates border style. A formatting option that rounds values for the coordinate labels as specified. For example, rounding to 1 digit will round down to the nearest ten with values like 115 rounded to 110 and 95 rounded to 90. The main usage of this formatting option is to suppress unwanted trailing zeros in minutes and seconds when using degrees - minutes - seconds format. Setting the Interval to a fractional value such as 1.5 will automatically adjust Rounding. Choosing arc minute or arc second as the unit in Deg-min-sec format will also change Rounding automatically so that the specified units will appear with full precision.

Deg-min-sec format  Enabled when using a coordinates border style. Toggle between decimal degrees and degrees, minutes and seconds format when degree coordinates are used. Currently enabled only when the layout component is in Latitude / Longitude form. The default is to use decimal degrees format.

Resolve Overlaps  Enabled when using a coordinates border style. Automatically clip labels when so many are specified that they would overlap.

Border each page  Enabled when using a border style, for use when working with continuous style paging in multipage layouts. When checked, draws a border for each individual page as would be used for map books. When not checked, draws a single continuous border as would be used when the multipage printout is intended to be tiled together into a single large print.

Accessory visual elements such as legends, North arrows or scale bars are defined within the component shown in the layout. The Properties dialog allows us to specify how (and if) these will appear in the layout.

auto  Show if the item is turned on in the component window, otherwise hide.

hide  Always hide the item.

show  Always show the item.
For example, we might not have a scale bar turned on in a drawing when we open it in a drawing window but we might want to have the scale bar turned on in a layout. In that case, we would choose show to show the scale bar in the layout whether or not it is turned on in the drawing window.

**Labels on Borders**

A common task is to place labels along the borders of a layout element that show the latitudes and longitudes of locations within the element.

This is a two-step process in Manifold: first a graticule is configured for the element within its own window and then the graticule is used to guide the creation of labels in the layout window. Graticules are used to guide the placement and values of border labels because graticules provide a simple, visual way of choosing reasonably even intervals at which to show latitudes and longitudes.

**To create latitude / longitude labels on the border of a layout element:**

1. Suppose layout element in question is a drawing. Open the drawing in its own window.
2. Use View - Graticule to turn on a graticule and to configure it as desired.
3. In the layout window, right click on the drawing and choose **Properties**.
4. In the **Properties** dialog, choose **coordinates (graticule)** for the **Border** style.
5. Check the **deg-min-sec format** box if degrees, minutes and seconds format is desired.
6. Press **OK**.

Labels will appear along the border of the element at intervals and values aligned to the graticule lines. The labels will appear when the **coordinates (graticule)** option is selected in the **Border** style box. The graticule lines themselves will appear or not appear depending on the setting of the **Graticule** option. It is possible, therefore, to show latitude / longitude labels on the border based on the graticule while choosing **hide** for the **Graticule** option and thus not showing any graticule lines.

Graticule and grid labels will not be displayed in a layout unless a graticule or grid has been explicitly configured within the component’s window using the **View - Graticule** or **View - Grid** commands.

When using **coordinates (graticule)** the graticule labels will be placed along all four edges of the layout entry as needed whether they are latitudes or longitudes. Note that latitude labels might appear on either upper and lower edges or, if need be, on the left or right edge of the layout.
With some projections as shown in the illustration above meridian lines will cross an upper or lower border edge as well as a left or right edge. It is possible in such cases to have one label for a meridian at the top edge of a layout and another label for the same meridian at the right edge of the layout. Manifold will automatically place graticule labels correctly in such cases.

When overlap resolution is turned on, vertical edges give priority to latitudes and horizontal edges give priority to longitudes. The locations of graticule labels in layouts for projected components are accurate to approximately 1/300th of a page.

See the Graticule Labels in a Print Layout example topic for creation of graticule labels.

**Border options**

In the Properties dialog for a layout element such as a map, drawing, image, labels component or surface the following options are available for Border styles:

- **coordinates** Print border labels using the native coordinates of the component. Projected drawings, for example, using projections with meters as units of measure will have labels in meters. Lat/lon drawings will have labels in degrees.

- **coordinates (graticule)** Print border labels with position and values aligned to graticule lines. Requires configuring a graticule first for the component in the component's window using View - Graticule. The preferred way of creating latitude and longitude border labels.

- **coordinates (grid)** Print border labels with position and values aligned to grid lines. Requires configuring a grid first for the component in the component's window using View - Grid. The preferred way of creating border labels at even intervals using native coordinates in projected drawings.

- **none** Do not show a border.

- **thick** Show a rectangular border using a thick line.

- **thin** Show a rectangular border using a thin line.

See the Graticule Labels in a Print Layout example topic for use of the above options.

**Properties for Text Elements**
Some layout components will have a simpler **Properties** dialog. For example, a text element will have just a few options in its **Properties** dialog:

<table>
<thead>
<tr>
<th>Properties</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bound to</td>
<td>The component from which this text element takes its system-generated text expressions.</td>
</tr>
<tr>
<td>Page filter</td>
<td>Used with multipage layouts to control which page this element appears in. Enter a series of page numbers or page ranges separated by commas. White space is ignored and reverse ranges are interpreted correctly. For example, We could enter 1, 2, 5-8 or 1, 2, 8-5 and get the same results. See the Multipage Layouts topic.</td>
</tr>
<tr>
<td>Border</td>
<td>Show a border for this component. By default, no border is shown. Borders are drawn using the color shown in the adjacent color well, black by default.</td>
</tr>
</tbody>
</table>

When a new text element is inserted into a layout that contains only one component element, the text element will automatically be bound to that component. If there are several components already in the layout the text element will be bound to none.

**Views in Layouts**

When the scope of a layout element is set to **View**, the layout element will use the view to guide what is displayed within the layout element. A view specifies a central point and a scale, but views themselves are limitless in extent. How much of the view is seen depends on the size of the layout element. If the element is resized smaller, less of the view will be seen. If the element is resized larger, more of the view will be seen.

**Tables in Layouts**

Layouts may be created from tables, and tables may also be dragged and dropped into a layout. See the Printing Tables topic for a discussion of tables and layouts.

**Layouts with multiple elements**

More than one component can be dragged and dropped into a layout.
Suppose we've created a layout using a drawing of Europe. We CTRL-ALT click on the Europe element in the layout to select it for editing.

We can now resize it by dragging the edit handles in the corners and the sides. For example, we could resize it by dragging on the lower right corner's edit handle to make the element smaller.
For example, we could resize it so that it fits into the upper left corner of the page. Click anywhere else in the layout to deselect the drawing.

To add another component we drag and drop the component from the project pane into the layout. For example, suppose we have the sample Bronze image in our project. We can click on it and drag it from the project pane into the layout.

When dragging into the layout the Bronze image will be dropped where we release the drag.
The image appears in the layout where we drop it. It appears using a default size. We **CTRL-ALT** click on the image to select it for editing.

We can now resize the image by dragging the upper left corner edit handle.
We can then click and drag the image to move it to the upper right corner of the layout.

Click on any empty space to deselect the image.
Suppose our project also contains the Schloss sample image. We can add it to the layout by dragging and dropping it from the project pane into the layout.

As before, the element is dropped into the layout at the point we release the mouse button on the drag. The new image appears in a default size. We will CTRL-ALT click on the Schloss image to select it for editing.
We can now resize the image by dragging any of the edit handles.

After resizing, we can move this image by dragging it to a new location.
In the illustration above, we've moved the Schloss image so that it partially overlaps the Bronze image in the layout.

If desired, we can move the Schloss image below the Bronze image so that the Bronze image is not partially covered up. To do so, we right click on the Schloss image and from the context menu choose Order - Move to Bottom.

This will move the Schloss image to the bottom of the layout element stack so that it no longer covers up part of the Bronze image.

**Aligning Items in Layouts**

Items may be aligned in layouts by selecting them and then using the alignment toolbar to invoke commands that align those items. The alignment toolbar is turned off by default. To turn it on, open a layout, choose Tools - Customize and check the box for the alignment toolbar. Alignment toolbar commands allow us to line up items in the layout with each other, to resize them, to center them and otherwise place and size them as desired.
Suppose we have a print layout with two elements, a drawing and an image. We clicked on the drawing to select it and then SHIFT-clicked the image to also select it as the primary selected item.

Clicking **Align Bottom** in the alignment toolbar will align the drawing to the bottom of the image. The alignment controls work by aligning all other selected items to the **primary** selected item (the one with the edit handles). See **Smart Mouse Selection** for quick moves to designate an item the primary selected item. See the Align Items in Layouts example topic.

Commands from the alignment toolbar are repeated in the **Layout** menu **Align, Center, Space, Resize Full** and **Resize Same** commands. The **Layout** menu appears when a layout window has the focus.

**Repositioning Multiple Items in Layouts**

Clicking and dragging the primary selected item in a layout will move that item. **SHIFT** clicking and dragging the primary selected item in a layout will move that item and will also move all other selected items as well.
Creating Frames and Borders with Lines

Use the horizontal line and vertical line tools to create borders and frames to visually organize other elements in the layout.

**Insert Horizontal Line**
Create a horizontal line in the layout. The default line size is 1/20th of a point.

**Insert Vertical Line**
Create a vertical line in the layout. The default line size is 1/20th of a point.

**Insert Box**
Create a rectangular box with a click and a drag. Boxes have foreground and background color and line thickness that can be set by selecting the box and using the format toolbar. The default line thickness is 1/20th of a point.

**Insert Box on Center**
Create a rectangular box centered on initial mouse click.

To assure lines start and stop at exactly desired locations, use a grid and **Snap to Grid**.

Choose View - Grid to launch the Grid dialog. Check the Show grid box to turn on the grid. Grids are created on a 1-centimeter spacing for layouts by default. Choose the X (horizontal) and Y (vertical) spacing and units desired and press OK.

The result is that a grid of dots appears within the layout.
Turn on Snap to Grid by first showing a grid with the View - Grid command and then pushing the Snap to Grid button or by choosing Edit - Snap to - Grid from the main menu. When Snap to Grid is on, the mouse cursor will move only between grid points on the form. Lines may therefore be created with end points that are snapped exactly to locations marked by grid points. See the Edit - Snap To topic for additional details and extra commands.

We can then use Insert Vertical Line and Insert Horizontal Line to draw lines for borders and other boxes.

Seen without the grid turned on, this is a typical artistic arrangement for printing, where the subject of the map is in the upper area and the three bordered boxes along the lower edge might be filled, for example, with a logo, the title of the map and some additional information.
Seen zoomed in, we’ve added a map component and have added a text element with two lines in it.

The **Snap To Elements** button causes the cursor to snap to the corners of existing elements in the layout. This is a convenient way of aligning or resizing elements to match exactly the dimensions or edges of other elements.

**Transparent Colors**

Layout elements use transparent color by default for a background color, thus giving a “floating” effect so that whatever items are in the background can be seen through the element’s “white space.” Transparent background color is often used with text labels in layouts. Exceptions are vertical and horizontal lines, which do not have a background color and which do not allow transparent foreground color.

**The Layers Pane and Layouts**

When a print layout window has the focus the Layers pane will show each item in the layout as a layer. Available commands include:

- Checking a box will turn the layout element on and unchecking the box will turn the layout element off. Hiding an element by unchecking its box will prevent it from being clicked, selected or printed.
- Moving “layers” up and down in the layers pane will move the layout elements up and down relative to each other within the layout.
- Double clicking onto a text label in the layers pane will allow immediate editing of the text in the box directly from the layers pane.
- The **Delete Layer** button in the layers pane toolbar will be enabled when any layer except the main layer is clicked. Deleting a layer will remove this element from the layout.
- The **Properties** button in the layers pane toolbar will open the properties dialog for any component-based element in the layout.

The layers pane is a key control when working with complex layouts.
In the example above we see a layout together with the layers pane. The layout is based on a main element that is a drawing of Europe. Below it is a text element that consist of the phrase "Copyright 2002" repeated several times in an outline font using a light gray color. Above the main element is another text element giving the title, "Europe," and two images, the example Bronze and Schloss images. The Background layer is turned off, so behind the layout page we see the checkerboard pattern used in Manifold when there is no background.

Note that the layout elements added with layout tools, such as text, are shown in the layers pane with special "layout element" icons. Text elements will be named using the initial characters of their text. Components will be shown with their scope, so that if a component is used more than once with different scope (for example, with different views) it is easy to tell which element is which in the layers pane.

With many overlapping elements in a layout we can use the layers pane to turn off upper elements if we want to select or otherwise work with lower elements.

**Layouts in the Layers Pane with other Components**

When a drawing or map or other component from which a layout has been created has the focus the layers pane will show layouts as "layers" in the layers pane. Checking the box for one of these print layout layers will cause a layout rectangle to appear in the component that shows the region covered by the layout.
In the illustration above the drawing has four layouts that show different parts of Mexico. Three of the layouts have been checked in the layers pane causing three layout preview rectangles to appear in the drawing.

The preview layout rectangles will be automatically adjusted if we change the scope of the layout.

For example, suppose we open a drawing window and a layout window for the same drawing and show the layout in the drawing window by checking the layout layer's checkbox. We select an area in the drawing by clicking on it with Select Touch. The scope of the layout (set by right clicking the layout in the layout window and choosing Properties) is set to entire component.

If we now change the scope of the layout to be the selection, the layout will show only the selected objects (one area, Germany, in this illustration) and simultaneously the drawing window will be updated to show the new region covered by this area.

Right clicking onto the hatched border of one of the layout rectangles in the drawing will cause a context menu to appear with controls based on that layout rectangle. For example, we can Zoom to a given layout rectangle, Print it or change its Properties. If a layout is empty (for example, if the layout scope is set to selection and nothing is selected in the parent component) zooming to the layout will do nothing.

Use Tools - Options - Colors - Layout Rectangle to change the color in which layout rectangles are shown. The default color is black.
We can insert text into the layout using the **Insert Text** button. Click on the **Insert Text** button and then draw a text box in which the text will be located. In the **Insert Text** dialog, enter the text that is desired. See the How to Print topic for a detailed example of adding text to a layout.

After creating a text element in a layout we can later edit the text by double clicking on the text element.

**System Generated Expressions for Text**

The **Insert Text** dialog includes an upper pane that lists a hierarchy of available expressions that may be used to automatically insert system-generated text into a text element. Double-click onto an expression to add it to the text element. Values for the text element, like scale, are taken from the main element in the layout.

The **Trim numbers** option will automatically trim numbers generated by the system to the specified number of decimal digits. This is very useful when creating latitudes, longitude or other numbers and many digits to the right of the decimal point are not desired.

Let’s consider an example. We will work with a project that has been saved in a file called *Eurasia.map*. We would like to add the name of the file to a layout.

To do so we add a text element to the layout. We then click into the **Insert Text** dialog’s lower pane and enter “Hello, my name is ”. In the upper pane we can click on the **Project** folder to expand it for a list of available expressions related to the project.
If we double-click onto the [Filename] expression it will be added to the text being assembled in the lower box. We can then click into the lower pane and add a period "." to finish the sentence.

If we double-click onto the [Filename] expression it will be added to the text being assembled in the lower box. We can then click into the lower pane and add a period "." to finish the sentence.

Hello, my name is [Filename].

After we click OK we can see how the text appears in the layout. Note that [Filename] has been replaced with Eurasia.map, the name of the file.

The following expressions may be inserted into text elements. They will be replaced automatically with the corresponding text whenever the layout is refreshed. The values are taken from the parent component of the text element. To change the parent component of a text element, right click on the text element, choose Properties and then choose the component desired in the Bound to box.

Note: The names of the system-generated expressions are case sensitive. For example, [date] does will not work as a substitute for [Date].

Component

[Average Height] Available for text elements bound to Profiles and Elevations elements in the layout. Gives the average height over the surface for the profile line. Profiles and elevations are optional components that are available when the Surface Tools package is installed. See the Profiles and Elevations topic for more information.

[Component] The name of the parent component in the project.

[Coordinate System] The coordinate system in use for the parent component (same as [Projection]).

[Datum] Name of the datum in use in this projection / coordinate system.

[Description] The contents of the parent component's Description property.

[Extent English] Scale reported as horizontal extent in English units.
[Extent Metric] Scale reported as horizontal extent in metric units.

[Maximum Height] Available for text elements bound to Profiles and Elevations elements in the layout. Gives the maximum height over the surface for the profile line.

[Minimum Height] Available for text elements bound to Profiles and Elevations elements in the layout. Gives the minimum height over the surface for the profile line.

[Page Center] Center of the page in projected coordinates.

[Page Center LatLon] Center of the page in latitude, longitude coordinates.

[Page Center LatLon DMS] Center of the page in latitude, longitude coordinates using degrees, minutes and seconds notation.

[Page Center Latitude] Latitude coordinate of the center of page in latitude, longitude coordinates.

[Page Center Latitude DMS] Latitude coordinate of the center of page in latitude, longitude coordinates using degrees, minutes and seconds notation.

[Page Center Longitude] Longitude coordinate of the center of page in latitude, longitude coordinates.

[Page Center Longitude DMS] Longitude coordinate of the center of page in latitude, longitude coordinates using degrees, minutes and seconds notation.

[Page Center X] X coordinate of the center of page in native units.

[Page Center Y] Y coordinate of the center of page in native units of the component being printed.

[Projection] The projection in use for the parent component.

[Scale] Printing scale in absolute scale style, for example 1:10000.

[Scale English] Scale in English units using relative scale style, as in 1 ft : 100.00 miles.

[Scale Metric] Scale in Metric units using relative scale as in 1 cm : 100.00 km.

[Scale Numeric] Scale as a 1:N ratio, same as [Scale].

[Unit] Native unit used in coordinate system / projection.

**Date and Time**

[Date] Current date in short date format specified in Windows Regional Options setting. A typical Windows default is “8/27/2003”.

[Day] Current day in the month from 1 to 31.

[Hour] Current hour from 1 to 24.

[Long Date] Current date in long date format specified in Windows Regional Options setting. A
Printing and Layouts

typical Windows default is "Wednesday, August 27, 2003" format.

[Minute] Current minute, from 1 to 60.

[Month] Current month, from 1 to 12.

[Month Abb] Month as a three-letter abbreviation, such as "Aug".

[Month Name] Month name, such as "August".

[Second] Current second, from 1 to 60.

[Time] Current time in format specified in Windows Regional Options setting. A typical Windows default is "3:41:08 PM".

[Weekday Abb] Day as a three-letter abbreviation, such as "Wed".

[Weekday Name] Day name, such as "Wednesday".

[Year] Current year.

Layout

[Layout] Report the name of the layout.

[Layout Description] Report the description of the layout.

Print Job

[Computer] Windows name of the computer executing the print job.

[Page] Page number as printed.

[Page Above] In multipage layouts, the page number of the page above this page. If no page exists above this page, prints "none".

[Page Below] In multipage layouts, the page number of the page below this page. If no page exists below this page, prints "none".

[Page Left] In multipage layouts, the page number of the page to the left of this page. If no page exists to the left of this page, prints "none".

[Page Right] In multipage layouts, the page number of the page to the right of this page. If no page exists to the right of this page, prints "none".

[Pages] Total number of pages in the print job.

[Page X] When printing multipage layouts that are to be tiled together, the position from left to right of this page.

[Page Y] When printing multipage layouts that are to be tiled together, the position from top to bottom of this page.

[Printer] Windows name of the printer.

[Printer Port] Windows name of the printer port.

[User] User login running Manifold.
Project

[Filename] Name + extension of the project file. In a new project, will be empty until the project is first saved.

[File Path] Fully qualified name of the project file. In a new project, will be empty until the project is first saved.

[File Title] Title of the project (displayed in the main window title). Before a project is saved for the first time will be something like "Project1". After the project is saved, will be the same as the project file name without the .map extension.

Square brackets [ ] may be used in running text within text elements as long as the square brackets are not used exactly in one of the above escape sequences (in which case the escape sequence will be replaced by the information it contains. Therefore, one can create a text element in a Manifold layout such as

Figures shown as [123] values are elevations.

If we don't like the default [Date], [Long Date] and [Time] formats used by Windows we may easily change them using the Control Panel's Regional Options applet. For example, we can change from AM/PM designations to 24-hour time, remove the day of the week from the [Long Date] and so on.

Scale text is reported in either relative scale or horizontal extent styles similar to those available for use in the status bar scale report. Relative scale reports the ratio between one centimeter or inch and the scaled number of meters/kilometers or feet/miles as in, for example, 1 cm : 100.00 km. Horizontal extent shows the horizontal size of the main layout entry.

Note that in the hierarchical list of system-generated expressions, the component folder will only be available for text entries belonging to layouts that were created from a component in the first place; otherwise, it would be unclear what component is being referred to.

Multipage Printing

A layout can be expanded to use more than one page with Layout - Pages and specifying the number of pages in the horizontal (x) and vertical (y) directions. Elements in the layout cannot be resized across page boundaries, although a single element can cover the entire multipage layout.

Using Maps or Using Layouts

For sophisticated compositions there may be a choice as to whether to create the visual effect desired in the layout by first composing multiple layers in a map and then using that map in a layout, or composing multiple elements in a layout. We might use a combination of both approaches.

For example, one can create a title block either in a layout or in a map. Suppose we want to create a rectangular box that contains a main title. We could create this in a layout by inserting a box using the controls in the Tools toolbar and then using the Insert Label command from the toolbar to add a text element.

We could also achieve the same result by creating a map that had three layers consisting of two drawings and a labels component. For example, suppose we wished to print a map that included a title caption with the text "Europe" in a box.
We could create a map that provided this caption.

The map could consist of three layers as seen above. The bottom layer is simply a rectangular area colored white. If we drag and drop this map into a layout, the white rectangle will provide a blank white background for the title text no matter what is underneath in the layout.

This same caption could have been created using the print layout *Insert* tools described at the beginning of this topic. For simple captions we would no doubt create the title block using the layout. For more elaborate effects, such as the use of Gaussian drop shadows, we would use the map.

### Printing to Scale

Printing to scale is accomplished by first creating a view at the desired scale and then printing that view within a layout.

**To print at a given scale:**

1. Open the map you want to print. Make sure it is a projected map.
2. Use *View - Zoom To* for setting the desired scale, for example *1:3000000*.
3. In the Views pane, create a new view. Rename the view to a memorable name such as "New York 1:3000000".
4. Create a layout component. Open the layout window and drag and drop the map component from the project pane into the layout window.
5. Right-click the map image within the layout window and select *Properties*. Set *Scope* to *View* and select the view created in step 3. Press *OK*.

When printing to scale, make sure the view selected is centered upon the area of interest. The actual extent of the component visible in the layout element will be controlled by the scale and by the size of that layout element on the page.

### Status Bar and Scale in Layouts

The status bar for layouts will report mouse cursor position in either inches or millimeters depending on the value of the *Use English measurement units* option in *Tools - Options - User Interface*. Page numbers will be added if a multipage layout is used.

The scale readout in the status bar gives the scale of the layout (in actual paper size) relative to the screen display. If the scale readout is set to use absolute scale (as in "1:100") and the layout is zoomed using *View - Zoom to* into a zoom of 1:1, then the layout will appear on the monitor in exactly the size that it will be printed. The status bar readout will also be 1:1.
For example, suppose we have a layout that uses one sheet of Letter size (8.5 x 11 inches) paper in Landscape mode and we have a very large, high-resolution monitor. We can zoom in to 1:1 scale in the layout and it will appear as an 8.5 inch by 11-inch sheet on the monitor.

Note that the scale reported in the status bar is not the geographic scale of what is in the layout but rather the scale of the layout as it would be printed on real paper compared to what is shown in the monitor. To get the geographic scale of the component as it will be when printed, insert a text element and use one of the system generated text expressions, such as [Scale] to report a scale in the text.

**Using Layouts Templates for Repetitive Work**

If we create many print jobs we may want to use the same type of layout for more than one job, repeating standard border arrangements. The best way to accomplish this goal is to use layout templates. Layout templates are by far the fastest and easiest way of recycling the look and feel of layouts into other layouts. If you create a lot of similar layouts, it is wise to master the use of layout templates. See the Layout Templates topic for details.

**Copy and Paste**

If desired, we can use Copy and Paste to move layouts between different instances of Manifold. Launch Manifold and open the project in which a layout is saved. Launch a second instance of Manifold in which the working project will be done. Copy the layout from the first instance of Manifold and paste it into the second instance of Manifold.

When copying and pasting layouts between different instances of Manifold all layout elements for components along with all dependent legends, North arrows, scale bars and text elements bound to a specific component will be removed. Nonetheless, the copy and paste method is very useful for many types of simple layouts consisting of boxes and vertical and horizontal lines and generic text such as copyright notices, statements of legal policy and so forth.

Using Copy and Paste to make copies of layouts within the same project is a good way to avoid irreversible errors when altering complex layouts. When a layout gets to the point that an error would be inconvenient to reverse, make a copy of the layout and continue working with the copy.

**Layouts and Enterprise Edition**

When using Enterprise Edition layouts can be shared to an Enterprise server. The Share command is enabled even if the main component in the layout is not shared. However, when sharing a layout, the system will automatically share all components used by that layout to the same Enterprise server if they are not yet shared. Note that it is possible to have an unshared layout that includes a shared component but it is not possible to have a shared layout that includes an unshared component.

**Notes**

Layouts may be copied and pasted, and layouts may be imported from a different project by using File - Import - Component.

The example date used for the system generated date, Wednesday, August 27, 2003, marked the closest approach between Earth and Mars in approximately 73,000 years.

When used with layouts, the tracker tool will report in either English (inches) or metric units depending on the setting of the Use English measurement units option in Tools - Options.

**Tech Tip: Printing a Layout to PDF**

There are two ways to create a PDF file from a layout: exporting a layout to a PDF or "printing" the layout using a PDF virtual printer driver, which mimics a printer to capture any printing activity as a PDF.

Printing a layout to a virtual printer driver that produces PDF feeds the layout through an ordinary GDI / GDI+ rendering pipeline, which issues "dumb" printing commands that are then captured by the driver. Exporting a
layout directly as a PDF feeds the layout through the Manifold PDF rendering engine, which optimizes printing commands. In general, the results of exporting a layout as a PDF will almost always be better than the results of printing the same layout to a virtual printer driver.

Layout Templates

Layout templates are pre-defined arrangements of layouts that may be invoked when creating a new layout or applied to an existing layout.

- To use a template when creating a layout, in the Create Layout dialog check the Template box and choose a template.

- To apply a template after creating a layout, open the layout and use the Edit - Template - Apply command to use a built-in template or a template added to the system through customization, or use the Edit - Template - Apply File command to apply a template from a file.

- To create a new template, create a layout and then use the Edit - Template - Save command to save the layout to a file for use as a template.

- The Edit - Template - Apply command also allows us to use a layout in our project as a template to be applied to the current layout.

Standard Templates

There are two built-in templates:

- **Simple, Entire Component** - Shows the entire parent component with the component name as the main title and several information lines.

- **Simple, View + Overview** - Similar to the above, but shows a view named Layout in the parent component as the main element with an inset element showing the entire component to give an overview. If there is no view named Layout that has been saved in the Views pane for the parent component, then the main element will be blank.

Templates try to provide as much information as possible to duplicate the look and feel of a given layout arrangement. They remember the basic arrangement of elements including their colors and other format options such as borders used in text elements. They save element visibility and preserve Z order, that is, the order in which elements are stacked above each other.

Example

Consider a map of Mexico that’s been thematically formatted. To create a print layout, we right click on the drawing in the project pane and choose Create - Layout.
In the Create Layout dialog we check the Template option and choose Simple, Entire Component as the template we would like to use.
When we open the resulting layout we see that the result is a neatly-arranged layout that includes a view of the entire component with a North arrow, a main title and a block of additional text information.

The block of supplementary text information provides the projection in use, the central latitude and longitude and the current date.

Templates consist of pre-arranged elements for a layout. We can edit them just like any other element.
For example, if we are curious as to how the additional text information is created we can double-click on it to see its properties. As we can see from the above, it is simply a text element that has a variety of escape sequences in it to have text information automatically loaded from the parent component.

The **Simple, View + Overview** layout template works with drawings that have a previously-saved view called **Layout**. To see this template in action we begin by zooming into the Mexico drawing near the province of Durango.
In the Views pane we create a view called Layout. We right click on the drawing in the project pane and select Create - Layout. In the Create - Layout dialog we check the Template box and choose the Simple, View + Overview layout template.

In the project pane we right click on the Mexico drawing and select Create - Layout. In the Create - Layout dialog we check the Template box and choose the Simple, View + Overview layout template.
When we open the resulting layout we see it has a main element that shows the Layout view zoomed in to the province of Durango as the main element as well as an inset smaller element that shows the entire component to provide a contextual overview.

**Using Edit - Template - Apply**

The **Edit - Template - Apply** command allows us to apply either existing templates or existing layouts to a layout. Open the layout to be operated upon, choose the command and then choose either an existing template or an existing layout to apply to the layout.

**Example**

Let's create a generic layout and then use it as a template for a different layout.
We begin with the Mexico drawing illustrated in the examples above. We create a layout called **Layout 3** from the Mexico drawing. In the **Create Layout** dialog we don't use any other templates. It doesn't matter whether we do or do not use a template, but for the sake of this example we will create a very simple layout to show that what we create, even if we don't use another template, can be used in turn with another layout.
After some tinkering and editing we create the above layout. It shows the parent component within a box border. Large captions are above and below the main element with a small scale bar to the right.
So far, so good. We now change gears and import a drawing that shows congressional districts in the US. We create a simple layout for the drawing as seen above.

To apply an existing template or layout to this layout we choose **Edit - Template - Apply**. In the **Apply Template** dialog we check the **Apply a template** radio button and choose the **Simple, Entire Component** template. Press **OK**.
The result is that the layout showing congressional districts immediately switches to the arrangement specified by the Simple, Entire Component template. Excellent!

To change the arrangement again, we once more choose Edit - Template - Apply.

In the Apply Template dialog we check the Apply a layout radio button and choose the Layout 3 layout we created earlier. Press OK.
The result now is that the layout arrangement used in the Layout 3 component has now been applied to this layout. It is, of course, somewhat absurd to provide a title of "Mexico" to a layout that shows US congressional districts, but this helps to illustrate the idea of using one layout to specify the arrangement of a different layout. The Edit - Template - Apply command makes it very easy for us to recycle the work done to create clever templates.

Obviously, if we wanted to create a series of templates to provide a standardized look and feel for the print layouts we create we would take care to use escape sequences for things like component names, so that the resulting layouts are automatically customized with correct names for the components they show.

Note, by the way, that if we are going to use a scale bar in a template to be used with many different components it makes sense to think carefully how we specify the scale bar. In the above illustration a scale bar that was defined for use with Mexico doesn't work very well with the US.

**Conveniences**

Manifold will remember the last used layout template and will automatically select it as the default choice in the Create Layout dialog and in the Apply Template dialog. Manifold remembers the last used layout template between Manifold sessions as well.

**System Customization**
If we create a custom layout template `.xml` file and save it in our Manifold System `Config` folder the layout will become automatically available for use as a built-in template. On startup, Manifold will automatically load any custom layout templates found in `.xml` files in the `Config` folder.

**Programming**

The `Document` object includes means to create a new layout using a layout template. The `Layout` object includes means to apply a layout template to the layout, to generate a layout template from the layout and to save the layout as a layout template.

Specifying Views in Layouts

Manifold provides many ways of specifying the content of a given element in a layout. Once a layout has been created using a component such as a drawing, or if a new element has been dropped into an existing layout, the contents shown by that component are specified by the **Scope** setting in that element's **Properties** dialog.

Think of elements in a layout as viewports or windows that take their content from the component used to create that element. The scope setting tells Manifold what part of the component is to be displayed within that viewport.

The **Scope** setting allows choice of:

- **entire component** - Show the entire component within the element.
- **layer** - If a map is shown, show an entire layer within the map. Equivalent to using **entire component**, but guided by the extent of the specified layer.
- **locked rectangle** - Show a specified region, re-scaling the view as necessary so the region fits within the element.
- **locked center / scale** - Show as much of a region as can fit within the element given the scale used. This option is similar to a **view**, but can be specified without creating a view.
- **saved selection** - Show a saved selection, re-scaling the view as necessary so all items in the saved selection fit within the element.
- **selection** - Show the current selection, re-scaling the view as necessary so all items in the current selection fit within the element.
- **view** - Using the scale and center point of a view from the **Views** pane, show as much of the view as can fit within the element given the scale used.

The scope setting provides several options because sometimes we would like to display the contents of an element at a specified scale, as in printing to a desired scale, and sometimes we don't care what scale is used so long as a specific region of interest is displayed.

**Examples**

In the illustrations that follow we show a drawing window and a layout window next to each other. The drawing shows provinces in Mexico. The drawing has been projected into **Orthographic** projection so that scales and other values may be computed accurately.

The layout was created from the drawing using default settings as described in the Layouts topic. The **File - Page Setup** command was used to switch the orientation of the layout page from **Portrait** to **Landscape**.

**Entire Component**

When a layout is created from a component one element is created that fills the page. The default setting for the scope is **entire component** so that the full extent of the component is shown on the available page. If we resize
the element to be smaller the contents it shows will automatically be re-scaled so that the entire component is always in view.

For example, to resize the element we can **CTRL-ALT** click on it to select it for editing. We can then drag the editing handles, like the lower left handle, to resize the element.

No matter how we change the size of the element window, it will always show the entire *Mexico Drawing* component.

Here we have deselected the element after resizing it. We then right clicked on it, chose **Properties** and then chose a **thin** border for the element. The border makes it easy to see the size of the element without having to select it.
Views

A view in Manifold is defined in the views pane and is used to show a particular region at a particular scale. Views are handy ways of recalling a particular view of a region regardless of the size of the window that is being used.

We can create a view by panning and zooming the drawing window to show a view of the province of Durango.

After panning to the province of Durango and zooming in to approximately the desired view, we then opened the View - Zoom to dialog and zoomed to exactly 1:10,000,000 scale (one to ten million scale). At this scale, one centimeter on the monitor is equivalent to ten million centimeters, or 100 kilometers, in the real world.

Within the views pane we can create a new view, called Durango 1:10m scale to remind ourselves what the view is and what scale it uses.
To change the layout so that it uses this view instead of the entire component, we right click on the layout element and choose Properties. Within the Properties dialog we choose view and then choose Durango 1:10m scale as the view to use. Press OK.

Alternative: An alternate approach is to use locked center / scale instead of view as the scope.

To do so, within the Properties dialog we choose locked center / scale and press the Edit button.
Within the **Edit Center / Scale** dialog we choose the **Durango 1:10m scale** view and press **Apply** to apply the values of this view. **Note:** the **Scale** value shown at the bottom is the internal scale metric used by Manifold to convert from geographic units to dimensionless internal units. The internal metric works all of the time, even if a component has not yet been projected. It is not the same "scale" as meant by the geographic scale of 1 to 10 million.

Why would we use the roundabout method of choosing **locked center / scale** instead of **view**? In some cases, we might want to achieve the same effect as a view even if a view has not yet been defined for the drawing. In the current case, since we are using the **Durango 1:10m scale** view as a fast way of setting the desired center and scale values it does not make sense to use **locked center / scale**. It is faster in this case to simply use **view** as the scope.

The result in either case is that the element viewport in the layout shows the **Durango 1:10m scale** view. Note that more of the view can be seen within the element viewport than appears in the drawing window, because the element viewport on the sheet of paper is much larger than the drawing window on the monitor.

If we were to print out the sheet of paper in the layout and hold it up to the monitor, we would see that the size of the province of Durango is, in fact, the same size as it appears within the rather small drawing window on the monitor.

One way to see this is to zoom the layout window to **1:1 scale** using **View - Zoom To**.
If the layout window is zoomed to 1:1 scale what appears in the layout window will be the same size as it will be when printed out on a sheet of paper. We can see that the province of Durango is, in fact, the same size in the layout as it is in the drawing window.

Note: If we wanted to show in the layout only that part of the view that is visible in the drawing window we could use the locked rectangle scope option. See the discussion of the locked rectangle option below.

Saved Selection and Selection

These scope settings are used to show a component where the visible part is automatically re-scaled so that a given saved selection or the selection is visible.

Suppose we go Back one scene in the layout window (using the left arrow in the navigation toolbar) so that it is no longer zoomed 1:1 but instead the entire sheet of paper is visible, and suppose we go back one scene in the drawing window so that all of Mexico is visible as well.

Suppose we select Mexican provinces in the drawing that border the Sea of Cortez. Note that making a selection in the drawing will also appear in red selection color in the layout as well.
In the selections pane we can save these as a selection called Sea of Cortez.

To tell the element to show the saved selection, we right click on the element in the layout, choose Properties and in the Properties dialog choose saved selection as the Scope and choose Sea of Cortez as the saved selection to use.

The result is that the layout element automatically pans and zooms (re-scales) so that the given saved selection is visible. Note that also will be visible those other parts of the Mexico drawing that will fit within the element's view given the size and shape of the element.
Note also that the saved selection does not have to be chosen as the selection for the saved selection scope option to work. In the illustration above, we have deselected all items (so that there is no current selection), but we can still choose Sea of Cortez as a saved selection for the scope and achieve the same view in the layout.

**Locked rectangle**

Recall that when we used a view of Durango province that the layout element did show Durango at the specified scale, but that because the element viewport was much larger than the drawing window used to create the view much more of Mexico in addition to Durango was visible. Suppose our objective is to show just the province of Durango in the layout, and we really don’t care whether or not the scale remains fixed at one to ten million. We can accomplish this by using the locked rectangle option for scope.

To begin with, let’s reset the scope to entire component so that all of Mexico is visible in the layout element.

Next, we click on the drawing window to make it active and in the layers pane we check the box to show the Mexico Layout "layer" within the drawing window.
This displays within the drawing the size and position of the layout elements currently in use for this drawing. Because the layout element is currently set to *entire component*, it shows that all of Mexico is displayed within the layout element. We can right click on the hatched portion of the layout preview rectangle and choose **Properties** to launch the layout **Properties** dialog.

In the **Properties** dialog we choose **locked rectangle** for **Scope** and press **OK**.

![Properties dialog screenshot](image-url)
In the drawing, a black rectangle appears to show the extent of the locked region that will be displayed in the layout.

We can click and drag this black rectangle with the mouse to change its shape. [Unlike many such re-sizeable items in Manifold, the rectangle does not use edit handles but it still is re-sizable.]

Note that as the black rectangle is resized the contents of the layout element automatically change to show only what is inside the black rectangle. We are using the drawing window to control what is visible in the corresponding layout element in the layout window.

If we resize the rectangle to show only Durango province, that is what is seen in the layout.
Upon close examination it will be clear that the layout window shows a slightly larger region to the left and right of the Durango province than is indicated by the square black rectangle in the drawing window. The reason is that the element in the layout is a more elongated rectangle and so it shows more than the square black box indicated in the drawing window.

When using the locked rectangle option the system will make a best effort to match the display indicated in the locked rectangle in the drawing to the aspect ratio of the element rectangle; however, it could be that great differences in the aspect ratio will allow somewhat more of the region of interest to be displayed.

To see this effect, CTRL-ALT click onto the layout element to select it for editing and resize it so that it is an even wider rectangle with reduced height. Note that the system still positions Durango within the rectangle so that at least the height of both locked rectangle in the drawing and height of what is displayed in the layout are the same.

However, because the rectangle is much wider in aspect than the indicated locked rectangle there will be more of the regions to the East and West of Durango that are visible in the layout.

Note that the hatched area in the drawing shows a preview of the extent of the layout element compared to the black box of the locked rectangle. As the layout element is resized in the layout window, the hatched preview of the layout element in the drawing window will change.

We can deselect the layout element to see clearly the relationship between the extent of the layout element in the layout window and the previews of the layout element and the locked rectangle in the drawing window.

Note: The Edit buttons that appear when a scope of locked rectangle or locked center / scale is used allow specification of the dimensions of the locked rectangle or center / scale view numerically. The scale parameter given is an internal scale parameter expressed in native coordinate system units per point. Normally, the Edit dialogs are not used in favor of setting a locked rectangle visually within the component and setting a locked center and scale by choosing an existing view or object set.

Layer

The layer option for scope in layout elements is similar to the entire component option, except that only that part of the component needed to show the given layer would be shown.

Suppose we create a map, called Mexico Map using the Mexico drawing used earlier. In addition, we have added another drawing as a layer in the map, called Stations. This drawing shows a group of points indicating environmental monitoring stations within a particular region in Mexico. The points are shown using a yellow square box style, with a point size of 4. To continue the style of illustrations used in this topic, the Mexico Map window is shown above approximately the same size as the layout window.

Because the layout still has only one element, the element created from the Mexico Drawing component, we need to add a second element that shows the map. To do so, we drag and drop the Mexico Map component from the project pane into the layout window. We can then resize the new element to whatever convenient size we like.
When a new element is dropped into a layout by default the "white space" it contains is drawn with transparent color. To make the layout more clear, we have right clicked onto the new map element and within the Properties pane have set the element to use white background color and to be drawn with a border.

By default the new element uses entire component as the Scope, so that the entire Mexico Map component is shown. To use only one layer, we first right click on the element and choose Properties and then in the Properties dialog we change the Scope to layer. We choose Stations as the layer to use for the scope.
The element immediately changes so that it shows only that part of the Mexico Map component that is required to show all objects in the Stations layer. New users may be surprised to see that the points in the Stations layer appear much smaller than they do in the Mexico Map window.

They do so because the display in the layout window is a true "WYSIWYG" (What You See is What You Get) display that also functions as a print preview. Because it shows a full sheet of paper zoomed out so that it all fits within a small window, the rather small point icons used (only four printer's points in size) will appear quite small.

If we zoom into the layout using the Views - Zoom To command to a scale of 1:1 we can see that when printed full size the yellow points will be exactly the same size, four printer's points, on the full-sized printed sheet that they are in the map window on the display monitor.

**Printing to Scale**

As can be seen above, printing to scale in Manifold is easy. We simply create a view of the desired scale and then use it as the scope of a layout element.

**To print a drawing to scale:**

1. Open the drawing and pan and zoom so that the desired area of interest is centered in the drawing window. Make sure the drawing is a projected drawing.
2. Use the Views - Zoom to command to zoom to exactly the scale desired.
3. In the views pane, create a new view.
4. In the project pane, right click onto the drawing and choose Create - Layout to create a layout using that drawing.
5. Open the layout and right click on the element and choose Properties.
6. In the Properties pane, for the Scope use the view created above.
7. If desired, resize the element in the layout to show more or less of the view at the given scale.

New users are at times confused by the relationship between what is shown in a layout viewport and a desired scale. If we decide to show a map at a desired scale, such as 1 to 10 million, then the only way to control how much of it is shown is to vary the size of the element in which it appears. A larger element will allow more of the map to be shown.

Conversely, if we want a particular region to be shown with no more or less of the map being visible than that particular region, then we cannot constrain the display to a fixed scale. In this case the view shown by the element will have to be zoomed in or zoomed out (re-scaled) so that only the region desired is seen within the element.

Layouts
**Multipage Layouts**

Manifold can print a layout using more than one page. This capability is used in two ways:

- To print a layout using many pages that are then pasted or tiled together to create a single image at a larger size than a printer can ordinarily print.
- To create a “map book” that shows a layout in the form of multiple pages that are formed into a book.

In both cases, the **Layout - Pages** dialog is first used to specify the number of pages (that is, the number of sheets of paper) to be used.

**To create a multipage layout:**

1. Create a layout and open it.
2. Choose **Layout - Pages** to open the **Pages** dialog.
3. In the **Pages** dialog specify the number of pages in the horizontal X direction and the number of pages in the vertical Y direction. Press **OK**.
4. Drag and drop the component to be spread across the pages into the layout.

**Very important:** Multipage layouts in current Manifold releases are strongly page oriented, where the boundary of a paper sheet is an absolute boundary. Components can be used in layout elements either as tiled continuously across all pages or as appearing within individual, repeated layout elements on every page. However, layout elements cannot appear on only one or two pages of a multipage layout, partially on one page and partially on another, as if the multipage layout represented a single large sheet of paper.

**Example**

Suppose we have a map that shows Europe with major cities.

![Map of Europe](image)

We can create a layout showing the map as seen above. **Page Setup** has been used to show the page in letter sized paper in **Landscape** orientation. To use more than one paper sheet to print the layout, choose **Layout - Pages** to open the **Pages** dialog.
In the **Pages** dialog we enter the above values to create a layout that has three pages horizontally and three pages vertically.

If we right clicked onto the map element in the layout and chose **Properties** we would see that the **Scope** is set to **entire component** and the **Paging** option is set to **continuous**. This means that the entire component is resized to fit to the maximum size possible within the pages available for the layout.

If we were to print the layout, six sheets of paper would be printed. Each paper sheet will have the correct section of the map printed so they can be tiled together to form a much larger printout. We could cut the pages along their inner margins (the region where the printer cannot print) and glue them together in a mosaic that is three sheets by two sheets to form a single, large printout.
If we right click on the map element, choose Properties and then change the Paging option to individual. This changes the usage of the component within the layout so that it is repeated on each page. The main reason we use this paging option is to place a repeated element on each page of a series of maps, such as those in a map book. The element might be a logo, a copyright notice, or a text expression such as Page number [Page] that gives the page number of each page.

**Multipage Layouts and Views**

When a view is used as the Scope for a layout element the component will be shown in the layout at the same scale as the view. Recall that we create a view by opening a component window such as a map window, drawing window, image window or surface component and then panning and zooming until the view seen in the window is the view we want. We then save it in the Views pane.

If the component is projected, saving a view at a given zoom level is the same thing as saving a view at a given scale. If the Adjust display scale for monitor resolution option is set in the Tools - Options dialog, the view we see at the zoom/scale in use will be literally the same size as what will be printed out if that view is used in a layout.

Suppose in the Europe example map seen above we have created a view called Central that is a zoomed-in view of the central part of Europe.
Suppose we create another layout, also in Landscape paper orientation, using the Europe map. If we right click on the map element in the layout, choose Properties and then set the Scope to View and choose the Central view we might see a display like that above.

The view is displayed at the same scale that was used to create it. The command to use a view for the scope of a layout element is a command to Manifold to show as much of the view at the specified scale that will fit within the size of the layout element. In the illustration shown above the layout element fills the entire page so as much of the view as can fit at the given scale will be printed.

Now let's try something interesting: we will use the Layout - Pages dialog to change the layout to a multipage layout that is three pages by two pages in size.

The layout expands to three pages by two pages in size, but now instead of showing just the central part of Europe the layout shows almost all of Europe. Although this may seem not to be the right behavior at first glance, in fact it is the correct function because of what we have told Manifold to do.
Because we are using a View as the scope, the element is printed at the scale used for the view. Using the same scale means that the sizes of the countries are printed at a fixed size on the paper, at whatever is the right size for the scale being used. If we make the paper sheet larger, either by printing on a larger piece of paper or by having a multipage layout, the sizes of the countries will still be the same. Using a larger piece of paper simply means there is more space available to print a larger portion of the view.

In the example above, if we look at, say, the middle page in the lower row we can see that the countries are printed at exactly the same scale as they were in the preceding illustration where only one sheet was used. The view is centered upon the multipage layout and it extends across the multiple sheets as far as the map extends at that scale.

We can confirm this by changing the Paging option from continuous to individual, which results in the display above. In this case the view is still used, but it is repeated on each page. If we compare the size of any country in this display to the size of the country when one sheet was used in the layout or when continuous paging was used we can see that in all three cases the size of the country is the same. That happens because we are using a view and views are always printed at the scale used at the view.

Suppose our objective is to show just the central part of Europe, but spread across a page layout that is three pages by two pages in size. How should we accomplish that?
The solution is to open the map component, open the Views pane and create another, more zoomed in view, perhaps called Central2. We can then use that view in the print layout to create a scene like that seen above.

"Map Book" Resizing Behavior

A map book is a large map that has been tiled into individual sheets that can then be bound as a book. Many consumer road atlases are produced in this form so drivers need not fold and refold large, unwieldy map sheets. The continuous paging mode of a component in a multipage layout can be used to produce a map book. If margins are set to allow room for a binding on one side the individual sheets will print correctly and can be bound into a book.

At times we would like to resize the element in the layout so that it does not quite fill each available sheet. We can do this to leave some empty space on each sheet for inclusion of other graphic elements. Let's begin with the zoomed in Europe example from the previous illustration.

We click on the map element to select it. It fills the layout.
If we **CTRL-ALT-click** on the map element in one of the pages of the layout, the map element will be selected for editing. We can resize the region in which the element appears by an editing handle. For example, we can drag the editing handle in the lower right corner to make the region smaller.

The result is that all of the regions for this element on all of the pages of the multipage layout are resized at the same time. This happens because in **continuous** paging mode the layout element for this map extends across all pages within the region on each page it is allowed to occupy. We can click outside of the element to turn off selection. Any alterations to this selection frame will apply to the element on all pages. For example, when we resized it the "resize" operation was applied to the element on all pages.
The result at first is slightly baffling. It appears to show a map cut into portions. However, when we examine the
map more closely we can see that after allowing for the margins each portion fits against adjacent portions of the
map exactly.

This is the behavior we would like in a map book. Suppose we printed this layout and numbered the resulting
pages as numbers 1, 2, and 3 across the top row and then 4, 5 and 6 in the bottom row and then assembled the
pages into a book. If we began reading the book with the first page (showing part of England) it is clear that if we
wanted to continue in the map book into France we would go to page 4 and if we wanted to continue East we
would go to page 2.

Text Components in Multipage Layouts

A text component is a component such as a comments or script component that consists of text. Text
components have no properties page since they are always printed as continuous text through whatever
element boxes they appear in within the multipage layout.

Text Elements in Multipage Layouts

We can make it easier for map book users by adding a page number to each page using a text element.
In the layout, we zoom into the lower right corner of the first sheet, and then use the Insert Text tool to draw a box for a text element.

In the Insert Text dialog we construct a text line consisting of

Page [Page X], [Page Y]

using the built-in [Page X] and [Page Y] expressions. These give us the page number in the column and row of the page layout. Press OK.
The result is a page number printout that will be different on each page that is printed from this layout.

If we zoom into the page number that is on the first page in the bottom row we see that it is given as Page 1, 2. We can edit the appearance of a text element by CTRL-ALT clicking it and then using the format toolbar to change the font. Changing any of the text elements will change all of them on all of the pages.

Some users might not like the "grid" style of page numbering used. We can always put a simple page number on the page by double-clicking the text element and changing the text line to

Tile [Page X], [Page Y] on Page [Page]
This results in a text element like that seen above, shown on the middle page of the bottom row.

**Citing Adjacent Pages / Page Filters**

In a map book it is often convenient to place notations at the margin of a page stating on which page of the book the adjacent map sheet may be found.

Suppose we start with a multipage layout showing Europe in **continuous** paging mode where the Europe element has been resized to allow some additional white space on the edges of each map.

Using the **Insert Text** tool we can draw a text box.
When the Insert Text dialog opens we construct a text string consisting of To Page [Page Below]. The [Page Below] expression will be replaced automatically with the page number of the sheet that appears below this sheet in the multipage layout.

The result (with greatly enlarged font size so the text is readable in this small illustration) is that each page contains a text element that includes the page number of the sheet below it.
Using the Insert Text tool we can add a page number to the upper right corner of each sheet. The text string used is simply [Page] to provide the page number. Note how the text caption at the bottom of the map in the upper left corner sheet reads "To Page 4" and that the sheet adjacent (the continuation of France to the South) is indeed page 4.

Note also that since there are no sheets adjacent to the bottom edge of the bottom row of pages, the captions there all read "To Page none". To eliminate these we can use the Page filter property to specify which pages will be printed.

Right click on one of the text elements and choose Properties from the context menu. In the Properties dialog enter 1-3 for the Page Filter. This specifies the pages on which this text element will appear. The Properties dialog for a text element also allows choosing a border for the text box.
The result is a much cleaner display.

In a similar way, we could add a text element to the upper margin using the string To Page [Page Above] to automatically print the page adjacent to the top margin. In the illustration above we have used the Properties - Page Filter option to specify the upper text element is to be printed only on pages 4-6.
With a bit of tinkering we can add yet more text elements using the [Page Left] and [Page Right] expressions to automatically note which pages appear to the left and right of a given sheet.

Each arrow is a separate text element. They were created by using the Wingdings 3 Windows font, which prints a left arrow for a lower case "f" character and a right arrow for a lower case "g" character. To create a left arrow, insert a text element that contains "f". Next, select the text element for editing by CTRL-ALT clicking on it. In the format toolbar, change the font to Wingdings 3 (if we have it available on our system) and then change the size of the font to make the arrow the size desired.

Next to each arrow is a text element containing [Page Left] or [Page Right]. The page numbers in the upper right corner have been edited (by double clicking them) to contain Page [Page].

There are, of course, many possible ways of using Manifold’s text tools to create notes on adjacent pages. The illustrations shown here were designed mainly to show the method within the very small illustrations available within a Help file and could obviously be improved in a full size display.

**Borders and Multipage Layouts**

The Border each page option found in the Properties of a layout element controls how borders are printed for elements that use continuous style paging in a multipage layout. The option is enabled when using a border.
When the **Border each page** option is checked, Manifold draws a border for each individual page as would be used for map books. When the option is not checked, Manifold draws a single continuous border as would be used when the multipage printout is intended to be tiled together into a single large print.

**Printing Multipage Layouts**

Multipage layouts are printed just like any other layout with **File - Print**. However, if desired, the **Page Range** section of the **Print** dialog can be used to specify that only some pages of the layout are printed.

**Notes**

Some multipage layouts of large maps using white backgrounds may result in some pages with no printing on them because the page falls entirely within a "whitespace" area of the map. By default, all pages are printed even blank pages. To save paper, we can uncheck **Print blank pages in multipage printouts** in **Tools - Options - User Interface**.

Using fonts such as **Wingdings 3** to add graphics with text elements is fun, but not particularly portable. If we move the `.map` project to a different system that has not had **Wingdings 3** installed on it and we open the layout, the arrows will not appear. Instead, the "f" and "g" characters will probably appear in the best default font that the system has available.

On the other hand, portability will be retained when saving a layout to `.pdf` because Manifold writes fonts to such files as "curves" or "outline" fonts so there is no need to have the font available locally when the `.pdf` is viewed.
Legends, Scale Bars and North Arrows in Layouts

A print layout in Manifold can include more than one component, that is, more than one drawing, image, surface or map. Each component can have its own legend, scale bar and North arrow specified. As many legends, scale bars and North arrows as desired may be added, with each one controlled by one of the components in the layout.

Adding legends, scale bars and North arrows to layouts in Manifold is therefore a two step process:

- Open the component and configure the legend, scale bar or North arrow as desired.
- Add the component to the layout, right click on the component, choose Properties and set the desired display mode for the legend, scale bar or North arrow. The default mode is auto, which means that if the legend, scale bar or North arrow is visible in the component window it will be visible in the layout.

Alternately, the legend, scale bar or North arrow may be added to the layout first and then configured in its parent component:

- Open the print layout and use Insert Legend, Insert Scale Bar or Insert North Arrow to insert the legend, scale bar or North arrow desired. If there is only one component element in the layout the legend, scale bar or North arrow will automatically be bound to that component. If there is more than one component element in the layout, a dialog will pop up asking to which component element the legend, scale bar or North arrow should be bound. In the pop up dialog, specify the component that will control the legend, scale bar or North arrow.
- To configure the legend, scale bar or North arrow, right click it and choose Edit, or double click on it to open it for editing. This will pop open the standard configuration dialog that would appear in View - Edit, View - Scale Bar or View - North Arrow.

To add a legend to a print layout (Method 1)

1. Open the component to be added to the print layout.
2. Choose View - Legend and configure the legend as desired.
3. Open the print layout.
4. Drag and drop the component from the project pane into the layout.
5. Right click on the component in the layout, choose Properties and, if the legend is not visible, change the Legend setting to show.

To add a legend to a print layout (Method 2)

1. Assuming the layout already has a component that can control a legend, use the Insert Legend tool to draw a box where the legend is to appear.
2. In the pop-up dialog choose the name of the component that will control the legend.
3. Right click on the legend in the layout and choose Edit, or double-click on the legend to open it for editing.
4. Configure the legend as desired.

The main difference between the first method and the second method is that in the first method the legend is a part of the layout element that controls it, and it may not be moved beyond that layout element. In the second method, the legend is created as an independent layout element and may be moved anywhere in the layout.

The procedure for adding scale bars or North arrows is similar. For example, we can adjust the configuration (style, options, etc.) of the legend, scale bar or North arrow working in the component window. Next, we can use the second method above, using the Insert Legend tool, for example, to add the item to the layout and choose the component to control it. The legend, scale bar or North arrow will have the same appearance as configured in the component window.

Note that every component that can host a legend, scale bar or North arrow can have only one configuration for that legend, scale bar or North arrow. It doesn't matter if, for example, a drawing is opened in its own window and the legend configured as desired, or if a legend for that drawing is right-clicked in a layout and the Edit command is used to configure the legend. In both cases the legend will take on the same appearance whether it is in the print layout or in the drawing window.
**Properties Options**

Whether or not accessories such as a legend, scale bar or North arrow appear in a layout element depend on the Properties settings for that element. Each accessory can be configured to auto, hide or show as follows:

- **auto**: If the accessory is turned on (show) in the main component window it will appear in the layout. If it is turned off (hide) in the main component window it will not appear in the layout.
- **hide**: Always hide the accessory in the layout even if it is turned on in the main component window.
- **show**: Always show the accessory in the layout even if it is turned off in the main component window.

**Changing Legends, Scale Bars or North Arrows**

To delete a legend, scale bar or North arrow from a layout, right click on the element and in the Properties dialog change the accessory's display mode to hide. If the legend, scale bar or North arrow was inserted using a tool like Insert Legend, select it for editing by CTRL-ALT clicking it and press the Delete key.

To edit the appearance of a legend, scale bar or North arrow, right click on it and choose Edit, or simply double click on it to open it for editing.

Note that accessories may be configured either in their host component's window or in the print layout. For example, if we would like to change the style of a legend that has been added to a map element in a layout, we can open the map in its own window and change the style of the legend there, or we can edit the legend in the layout. In either case, any change made in the map window will appear in the legend in the layout window and vice versa. This is true of scale bars and North arrow changes as well.

**Example**

See the Adding a Legend example topic for a step by step example of configuring a legend and then adding it to a print layout.
Printing Tables

Tables may be printed using three methods in Manifold:

- Open a table window and choose File - Print.
- Create a layout from the table and then print the layout.
- Create a layout using other components, drag and drop the table into the layout and then print the layout.

Which method is used depends upon the purpose of the layout. Tables are often printed by themselves to provide a printed record of the data they contain. In that case it is usually easiest to create the layout from the table. Tables are often also used as elements within a layout that may contain maps or drawings to provide data attributes or other information related to the objects shown in the maps or drawings. When the layout has already been created from some other element the table can be dragged and dropped into the layout and then configured as desired.

Creating a Layout from a Table

The simplest way to print a table from a layout is to create a layout using the table to be printed.

Creating a print layout from a table:

1. Open the table.
2. Hide any undesired columns.
3. Right click onto the table in the project pane and choose Create - Layout.
4. Open the layout and configure the table within that layout as desired. CTRL-ALT click onto the table to edit it. Right click onto the table and choose Properties to configure the tables' properties, such as which columns are displayed.
5. Tables may be formatted (font, foreground and background color) by selecting the table element for editing with a CTRL-ALT click and then using the Format toolbar.

When a layout is created from a table it will automatically be created as a multipage layout, if necessary, to print the entire table. If all columns and records fit on one page of a layout the table will be automatically centered on the layout page.

See the Create a Print Layout from a Table example topic for a step by step example.

Adding a Table to an Existing Layout

Another way to print a table is to add it to an existing layout by dragging and dropping it into the layout. When dragging and dropping a component into an existing layout, Manifold will drop the component into the layout using an element that does not fill the entire page. This allows dropping a new component into a layout without obscuring any other components that might already be there.
For example, if we have an existing layout created using a drawing we can drag and drop a table into that drawing. The table will appear as a new layout element at the point it was dropped.

We can `CTRL-ALT` click on the table to select it for editing, which will enable us to resize the table element to allow more of the table to be visible. This particular table illustrated is the table from the `mexico_eg.mif` drawing on the Manifold CD.
To resize the table we can drag the upper left editing handle.

When the table is resized more rows and columns will be visible. Note that since table background color is transparent by default the drawing that was already in the layout can be seen through the transparent parts of the table.

**Table Properties in a Layout**

Right click on a table element in a layout and choose **Properties** to set the following options:

- **Scope**  
  Choose **Entire component, saved selection, selection, or view** to specify the contents of the table. If views or selections have been saved, choosing **view** or **saved selection** will enable the choice box to the right with all of the views or saved selections available. The **Scope** setting allows us to print the entire table or just a selection within the table.

- **Paging**  
  Controls the printing of this table within multipage layouts:
  - **continuous** - Spread output evenly across the entire range of pages they appear on.
  - **individual** - Confin output to only that portion of a page on which the component appears and replicate this output.
likewise on all pages. Used to create overview maps with a printout repeating on all pages.

**pages or page ranges**

Used with multipage layouts to control which page this element appears in. Enter a series of page numbers or page ranges separated by commas. White space is ignored and reverse ranges are interpreted correctly. For example, We could enter 1, 2, 5-8 or 1, 2, 8-5 and get the same results. See the Multipage Layouts topic.

**Columns**

Choose auto or custom. The auto setting will automatically show or hide columns in the table element in the layout as columns are shown or hidden in the table window. The custom setting enables the columns pane in the dialog to allow choice of columns by checking them.

**[Columns pane]**

Enabled when the Columns option is set to custom. When enabled, the background of the columns pane will change to white and the toolbar will be enabled.

**[Toolbar buttons]**

The column pane's toolbars are enabled when the Columns option is set to custom.

- **Select All** - Check all boxes to print all columns in the table.
- **Select Inverse** - Uncheck all checked columns and check all unchecked columns. A fast way to show all but one column: click Select None, check the one column not desired and then click Show Inverse.
- **Select None** - Uncheck all columns in the table so none will be printed.
- **Move to Top** - Move highlighted column to the top of the list. This places the column at the leftmost position of the table.
- **Move Up** - Move highlighted column up one position in the list. This moves the column one step to the left in the table.
- **Move Down** - Move highlighted column down one position in the list. This moves the column one step to the right in the table.
- **Move to Bottom** - Move highlighted column to the bottom of the list. This places the column at the rightmost position of the table.

**Border**

Show a border for the table. By default, no border is shown. thick or thin borders may be selected.

**Column headers**

Display the names of table columns in boldfaced column headings.

**Grid lines**

Draw grid lines to separate rows and columns in the table.

**Shade alternate rows**

Use a shaded background for alternate table rows.

When adding a table to a layout, by default the auto setting for the Columns property will cause the table to be printed in the layout showing the columns that were displayed the last time the table window was opened. Any columns that were hidden from display will not be printed. This may be changed in two ways:

- Open the table window and show or hide columns using the View - Columns dialog or by right clicking onto column heads in the table and choosing Hide.
- Right click onto the table, choose Properties and change the Columns setting to custom. Next, check and uncheck the columns as desired in the columns pane.
Changing Colors and Fonts

To change the foreground (text) and background color of a table or to change the font used, select the table element for editing by CTRL-ALT clicking it and then use the Format toolbar to change foreground and background color and font.

Import and Export

Import and Export

Drawings, images and terrains may be imported into a Manifold project from a very wide range of formats using menus under File - Import. Different formats and variations thereof amount to over one hundred different types of files that may be read by Manifold.

Manifold organizes importers by type of component. To import a file, choose File - Import and then the type of component desired in the sub-menu. For example, in the image below we are about to import an image.

In the Import dialog that follows choose the appropriate file type desired from the pull-down list available in the Files of type list box.

For example, in the screen shot above we have chosen JPEG file types. Note that some importers use the same file type choice for filenames that have similar, but different extensions. For example, the same JPEG file choice importer is used for image files that have .jpg as well as .jpeg extensions.

The Files of type choice acts as a filter for what is displayed in the browse pane in the Import dialog. Simple file types are imported directly from the Import dialog by choosing the desired type in the Files of type box. More complex imports from data sources such as databases are imported by choosing Data Sources () in the Files of type box and then using the Data Source dialog.

When importing a simple file type, browse over to the file desired and click on it and press Open to import it, or simply double click on the file in the browse pane to open it and commence the import. We can import several files at once by using CTRL-click to choose more than one file when browsing in the Import dialog. We can also click on one file and then SHIFT-click on another to highlight all the files in between if we wish to choose several files for import.

Some importers are designed for use with files that are saved from specific applications. For example, the MapInfo MIF importer is used to import MapInfo files saved to .mif/.mid format. This format uses two files, a .mif file and an accompanying .mid file, to save a GIS drawing. To use this importer we need choose only the .mif file.

A few importers, such as the VMAP and the TIGER/Line importers are designed to work with very complex formats that provide information in many layers or drawings within one or more files. VMAP for example, is an extremely complex format involving numerous subfiles that are indexed by a main DHT file. Such formats are normally imported as numerous drawings at one time and automatically organized into one or more maps within the project.
Some formats, such as .e00 may contain drawings, surfaces or images. .e00 importers therefore appear as choices within the import dialogs for drawings, surfaces and images.

**SDTS** format may contain either drawings or surfaces. Import both types of components using the **File - Import - Drawing** choice even if you know the SDTS contains a "DEM" surface. A surface will automatically be created if the SDTS contains terrain elevation DEM data.

Not all importers are documented within this Help file. Many importers (especially for images) have no options and are operated by simply choosing the file to be imported. Other importers import data from very complex formats that require documentation beyond the scope of this document. Please consult the originator of the format for documentation on features.

**Strings are Trimmed on Import**

An option set in **Tools - Options** by default trims leading and trailing white space from strings. This may be turned off if desired. The trim function trims white space so that strings like " a b cdef " (with spaces before the a and spaces after the f) are trimmed to "a b cdef". Internal whitespace is unaffected.

**Text Components Import / Export as ANSI Text**

Manifold supports imports and exports of text components such as comments, scripts and queries. All such imports and exports are accomplished using ANSI text, not Unicode.

Text components may be imported or exported using any file extension. For example, .hdr "header" files are often plain ASCII text files that provide information about other files being imported. These may be imported as text to create a comments component.

**Exporting Maps**

A map component may be exported as a .dxf file, in which case all drawing and label layers will be exported into .dxf layers. Maps may also be exported to **XML** or **KMZ** format.

Otherwise, the layers that form a map should be exported into appropriate formats, for example, images exported into image formats, surfaces into surface formats, drawings into GIS or CAD drawing formats and so on.

**XML Files Created upon Export and Used on Import**

Not all formats to which Manifold can export have the ability to correctly save projection information. As a safety measure to ensure that projection information is never lost, Manifold always writes an accompanying .xml file when exporting drawings, images, labels, maps or surface components to a file. The accompanying .xml file contains coordinate system information and some other metadata. The XML file is created for all formats, even those that correctly save coordinate system information.

When Manifold imports drawings, images, labels or surfaces, the system will check for an accompanying .xml file that might have been written by Manifold. If such an .xml file exists, Manifold will read it and use the information it contains to load a correct coordinate system.

See the XML Accessory File Format topic for details on the internal organization of this file.

**Important Note when Using 64-bit Manifold Editions**

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to **DB**, **HTML**, **MDB**, **XLS** or **WKx** format files. This includes no access to the **MDB** parts of Manifold **MFD** and MapInfo **TAB** imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the **Manifold System (32-bit)** shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the **Manifold System (64-bit)** shortcut.

Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

**Tech Tips**
At times we would like to fetch a component that's been saved in a .map project file for use in another project file. One way to do this is to open a second instance of Manifold and to open the saved .map project. We can then **Copy** components from that project file, switch to our current working instance of Manifold and **Paste** them into our current project. Another way is to use the File - Import - Component command to import a component directly from a .map project file.

Whenever importing projected data (drawings, images or tables) from formats that do not provide projection information, be ready to visit the Edit - Assign Projection dialog after the import to make any necessary adjustments. See the Import a Shapefile example topic for a simple example and the Import Drawing - SHP, Shapefiles topic for a more extensive example of using Edit - Assign Projection to adjust projection parameters after import. See Creating Drawings from Geocoded Tables for information on table imports and usage when the table contains geocoded projected or unprojected data.

XML Accessory File Format

Not all formats to which Manifold can export have the ability to correctly save projection information. As a safety measure to ensure that projection information is never lost, Manifold always writes an accompanying .xml file when exporting drawings, images, labels, maps or surface components to a file. The accompanying .xml file contains coordinate system information and some other metadata. The XML file is created for all formats, even those that correctly save coordinate system information.

When Manifold imports drawings, images, labels or surfaces, the system will check for an accompanying .xml file that might have been written by Manifold. If such an .xml file exists, Manifold will read it and use the information it contains to load a correct coordinate system.

Example

GeoTiffs don’t require an .xml file. A “GeoTiff” is simply a .tif file with internal tags that save projection information. However, even when writing a GeoTiff Manifold will also create an accompanying .xml file. The .xml file is created by Manifold for all exports, even those that don’t need it, in something of a “belt and suspenders” move to save people from inadvertently losing projection info.

Even in the case of a GeoTiff the creation of a redundant .xml file is a valuable idea. Consider the following scenario: we georegister an image and save it as a GeoTiff. So far, so good. Now, let’s say we edit the .tif using PhotoShop, which for all of its image editing prowess doesn’t understand the GeoTiff tags embedded in the .tif and won’t preserve them. After editing in PhotoShop the image is now a plain, ordinary .tif that’s no longer georegistered and has lost all projection info.

However, as long as we haven’t changed the size or rotation of the image or renamed the file, we can still open it in Manifold and Manifold will automatically recover the projection information from the auxiliary .xml file thoughtfully written by Manifold when we first exported the .tif. If PhotoShop had not erased the GeoTiff tags inside the .tif we wouldn’t have needed the .xml file, but clearly it is very useful to have the .xml on hand to recover from what otherwise might have been a disaster caused by the PhotoShop editing session.

XML File Format

This section provides details on the internal organization of the accessory .xml file created on export and read, if available, on import.

Note: in the tables listing tags below, such as those that may be used for parameters, it is understood that a <tag> is matched with a </tag>. Instead of writing <tag> ... </tag> in the tables to indicate a <tag> followed by some intermediate material and then closed with a </tag>, we simply write “<tag>”

XML File Format:

<?xml version="1.0" encoding="UTF-8"?>
<data>
  <coordinateSystem>
    ...  <!-- coordinate system data
  </coordinateSystem>
  ...  <!-- other data
</data>

Coordinate System Data Format:

Notes

All latitudes and longitudes are in degrees. All angles are in degrees. All heights are in meters.

The local coordinate system is used as follows:

Suppose we have a SHP file in UTM 13N. Given the xf:yf coordinates stored in the SHP file, xc:yc are the coordinates in UTM 13N:

\[ xc = xf \times \text{localScaleX} + \text{localOffsetX} \]
\[ yc = yf \times \text{localScaleY} + \text{localOffsetY} \]
Alert readers will note the above table does not include a listing of various national grids. National grids are merely customized versions of the standard projections. In an XML file for a national grid, the `<name>` tag will contain the name of the grid (for example, "Michigan ..."), the `<system>` tag will contain the name of the underlying projection (for example, "Lambert Conformal Conic" or "Transverse Mercator"), and all other tags will contain the parameters for the underlying projection.

See the XML files on the Manifold CD in the documentation/xml files folder for examples of XML files that specify various projections. See also the Custom Coordinate System (Projection) Presets topic.
Import Component

Choose File - Import - Component to import components from Manifold .map project files. Choose the .map file to be opened in the resulting Import dialog and then choose the components to be imported in the Import MAP File dialog that follows.

Select All - Check all fields. All data fields will be imported with this drawing.

Select None - Uncheck all fields. No data fields will be imported. Tech tip: Use this to uncheck all fields before checking those desired.

Select Inverse - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.

Any component may be imported from a previously saved .map file. Labels components that are bound to drawings will be imported as unbound labels components.

Tech Tip: Save Frequently Used Components in .Map Files or Databases

The .map format used to save Manifold projects automatically compresses the data contained in the .map file using techniques similar to those used by popular "zip" compression utilities. Therefore, there is no need to "zip" a .map file with utilities such as WinZip to save space or to speed up transfers over Internet - the .map file is already compressed.

We can keep collections of frequently used drawings or other components in .map files and then use File - Import - Component to import them from the .map file into the current project whenever desired.

Another way to save frequently used components is to keep them in a spatial DBMS and then import or link the component from the spatial DBMS. This does require installing a DBMS, but it can be a very fast way of retrieving frequently-used components and sharing them with multiple people.

One final way (requiring Enterprise Edition) to save frequently used components is in an Enterprise Server. This can be a fast and convenient way to keep components organized and to share them in different projects.

Import Drawing

Importing Drawings

Choose File - Import - Drawing to import drawings from formats used to save drawings. Such formats might be said to save "maps" in other GIS systems. Drawings may also be linked from database tables. See the Linked Drawings and the Geometry in Tables topics for more information on linking drawings.

The Files of type choice acts as a filter for what is displayed in the browse pane in the Import dialog. Simple file types are imported directly from the Import dialog by choosing the desired type in the Files of type box. More complex imports from data sources such as databases are imported by choosing Data Sources () in the Files of type box and then using the Data Source dialog.

Formats used to save drawings vary widely in their capabilities. Some formats save projection information and some, such as .dxf or many types of .shp files, do not. When a drawing format contains projection information, Manifold will automatically use that projection information.

When a drawing format does not save projection information, for GIS formats such as ESRI .shp files the drawing will be imported into Latitude / Longitude projection as if the units contained were degrees. Most people are sensible enough not to use .shp and similar formats to publish projected maps so this will usually work.

For drawings imported from non-GIS formats such as AutoCAD .dxf, the drawing will be imported using the same default Orthographic projection used for non-geographic images. Such drawings will always require manual adjustment of parameters in the Edit - Assign Projection dialog.
If a drawing format does not save projection information, that information must be added after import via the Edit - Assign Projection dialog.

**Use Folders to Organize Imports**

Some drawing formats, such as those used for VMAP, will result in numerous drawings, tables, text components and maps. It's best to first create a folder in the project and to click on the folder to highlight it before beginning import of such drawings. The resultant mass of components created will then be created within the folder.

**Strings are Trimmed on Import**

An option set in Tools - Options by default trims leading and trailing white space from strings. This may be turned off if desired. The trim function trims white space so that strings like " a b cdef " (with spaces before the a and spaces after the f) are trimmed to "a b cdef". Internal whitespace is unaffected.

**Typical Drawing Formats**

Manifold can import from many different drawing formats. Some are highly specialized formats that provide much data organized in a complex way. Precise description of certain specialty formats is beyond the scope of this document. In such cases, please refer to the originating agency or company for detailed documentation on their format.

Interested in support for a new format not listed below? See the Contacting manifold.net topic for information on suggesting a new format.

Notes on a few of the most popular formats are set forth in the following topics:

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>ADF</td>
<td>Import a drawing from ESRI .adf ArcGrid format.</td>
</tr>
<tr>
<td>ADO .NET Data Sources</td>
<td>Create a drawing by importing data from a table using an ADO .NET, ODBC or OLE DB data source. Imported using the Data Source dialog.</td>
</tr>
<tr>
<td>BNA</td>
<td>Atlas .bna format.</td>
</tr>
<tr>
<td>CSV</td>
<td>Create a drawing by importing data from a geocoded table from a text file using comma-separated value format. Imported using the Data Source dialog.</td>
</tr>
<tr>
<td>DB</td>
<td>Create a drawing by importing data from a geocoded table from a Borland Paradox file. Imported using the Data Source dialog.</td>
</tr>
<tr>
<td>DBF</td>
<td>Create a drawing by importing data from a geocoded table from a dBase or FoxPro file. Imported using the Data Source dialog.</td>
</tr>
<tr>
<td>DGN</td>
<td>Bentley MicroStation / Intergraph .dgn.</td>
</tr>
<tr>
<td>DLG</td>
<td>USGS DLG optional format.</td>
</tr>
<tr>
<td>DWG</td>
<td>AutoCAD drawing format.</td>
</tr>
<tr>
<td>DXF</td>
<td>AutoCAD exchange format.</td>
</tr>
<tr>
<td>DSN</td>
<td>Create a drawing by importing data from a geocoded table using a DSN file data source. Imported using the Data Source dialog.</td>
</tr>
<tr>
<td>E00</td>
<td>ESRI ArcInfo export format. Manifold will automatically detect and correctly import drawings, images, surfaces and labels within the .e00.</td>
</tr>
<tr>
<td>GDF</td>
<td>Import TeleAtlas MultiNet in GDF format. Also used to</td>
</tr>
</tbody>
</table>
Import and Export

import European GDF format.

Geocoding Database
Import drawings of US streets on a county basis from the Manifold Geocoding Database provided on the Manifold downloads site. Requires installation of the Manifold Geocoding Tools extension.

Geodatabase
Import or link drawings from ESRI geodatabase files. Use Database Console to connect (via the Data Source dialog) to the .mdb file hosting the Personal Geodatabase and then Manifold's spatial DBMS capability will automatically identify the contents of that geodatabase. We can then import or link drawings as desired. See the spatial DBMS topic.

GML
Geography Markup Language. A spectacularly inefficient format based on XML that is being touted as a "standard" in some circles. Used by the UK's Ordnance Survey.

HTML
Create a drawing by importing data from a geocoded table from an HTML file. Imported using the Data Source dialog.

KML, KMZ
An XML-based format used by Google Earth and others. KMZ is a "zip" compressed version of KML.

LULC
USGS Land Use and Land Cover format.

Etak MapBase
Create a drawing by importing data from a geocoded table from a Microsoft Access file. Also used to import or link drawings from ESRI geodatabase files. Imported using the Data Source dialog.

MFD
Manifold System 4.50 format. Will import objects from an .mfd even if the associated .mdb database file is not present.

MIF
MapInfo .mid / .mif format. Will import objects from a .mif even if the associated .mid database file is not present.

MWS
Manifold System 4.5 .mws format.

NTAD
Bureau of Transportation Statistics National Atlas Transportation Database (NTAD) and North American Transportation Atlas Data (NORTAD) files.

NTF
UK Ordnance Survey .ntf files. Will automatically import Land-Line vector data sets as drawings and DTM grids as surfaces.

ODBC Data Sources
Create a drawing by importing data from a table using an ODBC data source. Imported using the Data Source dialog.

OLE DB Data Sources
Create a drawing by importing data from a table using an OLE DB data source. Imported using the Data Source dialog.

S-57
A simple importer for vector data in S-57 format (used for nautical charts). Manifold's importer attempts to bring in as much data as possible, leaving it up to the user to format and organize the data. Should greater interest appear in this format and enough user requests are received (see the Contacting manifold.net topic), the S-57 importer can always be tuned to provide a higher degree of organization or formatting in support of particular S-57 data sets.

SDTS
US Federal Spatial Data Transfer Standard. Can include drawings, surfaces, tables and comments. The correct component will automatically be created based on the
contents of the SDTS files.

**SHP**
ESRI ArcView .shp ("shapefile") format.

**TAB**
MapInfo "table" format consisting of multiple files (usually 5) referenced by a controlling .tab file. Can result in drawings, labels, images and surfaces.

**TAIF**
TeleAtlas TAIF format. Choose the TAIF subtype (Level 1, Level 2, Multinet or Streetnet) and the module desired. Map fields between tables and Import Z are enabled only for Multinet. Same function as SDTS. Will create multiple drawings and map.

**TIGER/Line**
US Bureau of the Census TIGER/Line formats.

**IDRISI VCT**
IDRISI .vct. Import a vector drawing from IDRISI 32 without any data attributes. Does not import from IDRISI 16 format.

**UDL**
Create a drawing by importing data from a geocoded table from a Microsoft Universal Data Link file. Imported using the Data Source dialog.

**VMAP**
NIMA (www.nima.mil) VMAP 0, VMAP 1 and VMAP 2 format, based on .vpf. Choose coverages to be imported. Import fields will import all data attributes associated with a coverage. Import Z causes an additional drawing to be created filled with points each of which has a Z coordinate. Will create multiple drawings, labels and maps.

**WKx**
Create a drawing by importing data from a geocoded table from a Lotus file. Imported using the Data Source dialog.

**XLS**
Create a drawing by importing data from a geocoded table from an Excel file. Imported using the Data Source dialog.

**DB2 Data Sources**
Connect to IBM DB2 equipped with the DB2 Spatial Extender using IBM's native spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**Oracle Data Sources**
Connect to an Oracle data sources using the Oracle Call Interface (OCI), the native Oracle interface for exchanging data. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**PostgreSQL Data Sources**
Connect to PostgreSQL equipped with the PostGIS spatial extender using native PostgreSQL connection technology. Connections made using this data source will have any password required masked so that later usage will not inadvertently expose the password. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**SQL Server Data Sources**
Connect to Microsoft SQL Server 2008 spatial DBMS facilities using native SQL Server 2008 spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**Important:** Using a vendor's native spatial DBMS connection technology (like those above) provides better performance and allows using features, such as built-in spatial DBMS facilities, not exposed through generic database interfaces such as ODBC, OLE DB and ADO .NET. For example, exchanging data with Oracle data sources via OCI automatically maps geometry columns.
Import and Export

into Oracle SDO_GEOMETRY data and will likewise map geometry columns into the native geometry types used by DB2, PostgreSQL and SQL Server 2008.

Note: because the Database Console provides a more convenient user interface for browsing databases, we will almost always use the Database Console to import or link components from a database instead of using the File - Import or File - Link menu commands.

Importing Drawings from Geocoded Tables

Drawings may also be created from geocoded tables by using File - Import - Drawing and selecting Data Sources in the Files of type box to launch the Data Source dialog. See the Linked Drawings from Geocoded Tables topic for a general introduction.

In the case of imports a drawing of points will be created from the geocoded table but it will not be linked to the table. Linked drawings are read-only because their content is controlled entirely by the external table but a drawing imported from a geocoded table will be read / write because it is an ordinary drawing like any other in a project. Unlike a linked drawing, however, any change to the originating geocoded table will not be reflected in the imported drawing.

Formats from which geocoded tables may be read to create drawings include:

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>CSV</td>
<td>Comma separated values ASCII files, including files using .txt or .csv or other extensions.</td>
</tr>
<tr>
<td>DB</td>
<td>Borland Paradox.</td>
</tr>
<tr>
<td>DBF</td>
<td>dBase and FoxPro.</td>
</tr>
<tr>
<td>DSN</td>
<td>ODBC file data source that describes an ODBC driver to use.</td>
</tr>
<tr>
<td>HTML</td>
<td>Tables in web pages.</td>
</tr>
<tr>
<td>UDL</td>
<td>Microsoft Universal Data Link file that describes an OLE DB connection.</td>
</tr>
<tr>
<td>WKx</td>
<td>Lotus tables.</td>
</tr>
<tr>
<td>XLS</td>
<td>Excel tables.</td>
</tr>
</tbody>
</table>

ADO.NET Data Sources

A generic ADO.NET connection allowing use of a .NET DLL assembly, provider class and connection string (parameters).

ADO.NET ODBC Data Sources

Connect using the standard Microsoft .NET ADO.NET provider for ODBC.

ADO.NET OLE DB Data Sources

Connect using the standard Microsoft .NET ADO.NET provider for OLE DB.

ADO.NET Oracle Data Sources

Connect using the standard Microsoft .NET ADO.NET provider for Oracle.

ADO.NET SQL Server Data Sources

Connect using the standard Microsoft .NET ADO.NET provider for SQL Server.

ODBC Data Sources

Connect to a data source using ODBC drivers installed on this system.

OLE DB Data Sources

Connect to an OLE DB data source using an OLE DB provider installed on this system.
Oracle Data Sources

Connect to an Oracle data sources using the Oracle Call Interface (OCI), the native Oracle interface for exchanging data. Using the native interface provides better performance and allows using features not exposed through generic database interfaces such as ODBC, OLE DB and ADO.NET. Exchanging data with Oracle data sources via OCI automatically maps geometry columns into Oracle SDO_GEOMETRY data.

Note that the table used to create the drawing must be a geocoded table, that is, each record must contain latitude and longitude values for that record's position expressed in decimal degrees. By default, drawings imported from geocoded tables consist of points, one point for each record, although if the table's content permits lines also may be optionally created. See the Linked Drawings topic for more information.

Importing Drawings from a Spatial DBMS

A more sophisticated way of storing drawings in databases is to store actual geometry data within a spatial DBMS. Manifold supports the major spatial DBMS players directly, including Oracle Spatial, IBM DB2 with Spatial Extender, Microsoft SQL Server 2008 spatial, SQL Server 2005 with the Manifold spatial extender, ESRI SDE geodatabases, ESRI Personal geodatabases and just about any other DBMS using spatial DBMS capabilities conferred by Manifold through generic spatial indices.

To import drawings from such databases we use the Database Console dialog to connect to the data source (using the Data Source dialog) and then import by highlighting the desired drawing and clicking the Import button in Database Console.

Note that connecting to some spatial DBMS products, such as using a native OCI connection to connect to Oracle Spatial, requires Enterprise Edition or above. See the Oracle Spatial Facilities topic for additional information and examples.

XML Files Created upon Export and Used on Import

Not all formats to which Manifold can export have the ability to correctly save projection information. As a safety measure to ensure that projection information is never lost, Manifold always writes an accompanying .xml file when exporting drawings, images, labels, maps or surface components to a file. The accompanying .xml file contains coordinate system information and some other metadata. The XML file is created for all formats, even those that correctly save coordinate system information.

When Manifold imports drawings, images, labels or surfaces, the system will check for an accompanying .xml file that might have been written by Manifold. If such an .xml file exists, Manifold will read it and use the information it contains to load a correct coordinate system.

See the XML Accessory File Format topic for details on the internal organization of this file.

Important Note when Using 64-bit Manifold Editions

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKx format files. This includes no access to the MDB parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut.

Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

Tech Tip

For advanced users: Some transform toolbar operators in drawings must assure that there are no errors in object metrics before running, so they run a normalization/error correction on all objects that are not already marked "clean" by Manifold. This can result in an unexpectedly slow operation on a newly imported drawing the first time such operators are run. Some drawings may be imported from sources that do not maintain clean object metrics. Expert users may want to run Normalize Topology or Normalize Metric on newly imported drawings just after the import to be sure that all objects are marked "clean" for future passes by any operators.
Import Drawing - ADF
Import ESRI .adf format files. ESRI .adf is sometimes called ArcGrid format.

.adf files can contain raster data, ESRI TIN data or vector (drawing) data. The Manifold .adf importer will automatically configure itself to import either drawings or surfaces as applicable regardless of whether the importer was launched via File - Import - Drawing or via File - Import - Surface. For information on importing .adf files that contain TINs or raster data, see the Import Surface - ADF topic. This topic discusses import of drawings.

Importing a Drawing

Importing an .adf file that contains vector data allows importing fields (data attributes) via the following dialog options:

- **Select All** - Check all fields. All data fields will be imported with this drawing.
- **Select None** - Uncheck all fields. No data fields will be imported. Tech tip: Use this to uncheck all fields before checking those desired.
- **Select Inverse** - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.

(Fields pane) Check the data attribute fields to be imported.

- **Compose areas** - Create areas (checked by default). Not enabled when the file contains no areas. May be unchecked if areas are not needed. Importing areas is a computationally intensive process so not importing them speeds up the import process.
- **Import ticks** - Import ESRI tick marks.

See Also

Import Surface - ADF
Import Drawing - ADO .NET / ODBC / OLE DB

Manifold can create a drawing directly from data stored in a geocoded table. This capability is directly analogous to the creation of a linked drawing from a geocoded table except that instead of the drawing being linked to the originating table it is created as an independent drawing within the Manifold project.

Such imports are accomplished by choosing File - Import - Drawing and then choosing Data Sources () in the Files of type box to launch the Data Source dialog. The desired data source can then be configured and used in the Data Source dialog.

Drawings can be imported from geocoded tables using any of the data access methods, such as connection to an ODBC or OLE DB data source, provided by Manifold.

Dialogs used are the same as for creating a linked drawing from a geocoded table, except that linked drawings always invoke the Data Source dialog and the result of an import is an imported drawing rather than a linked drawing.

See Also

The Data Source Dialog
Importing and Linking Tables
Linked Drawings
Create a Linked Drawing from a Geocoded Table
Import Drawing - BNA
Import drawings in Atlas .bna format. The only option with this importer is which data fields should be imported from the Atlas drawing.

Select All - Check all fields. All data fields will be imported with this drawing.

Select None - Uncheck all fields. No data fields will be imported. Tech tip: Use this to uncheck all fields before checking those desired.

Select Inverse - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.

Fields pane Check the data attribute fields to be imported.
Import and Export

Import Drawing - CSV

Manifold can create a drawing directly from data stored in a geocoded table. This capability is directly analogous to the creation of a linked drawing from a geocoded table except that instead of the drawing being linked to the originating table it is created as an independent drawing within the Manifold project.

Such imports are accomplished by choosing File - Import - Drawing and then choosing Data Sources ( ) in the Files of type box to launch the Data Source dialog. The desired data source can then be configured and used in the Data Source dialog. Note that the CSV import choice includes files with any extension. For example, a .txt file that contains a table in comma-separated value format can be used with this importer.

Dialogs used are the same as for creating a linked drawing from a geocoded table, except that linked drawings always invoke the Data Source dialog and the result of an import is an imported drawing rather than a linked drawing.

Import Drawing - DGN

Bentley MicroStation Design File format (DGN) is also known as Intergraph DGN format due to Intergraph's sales of Bentley GIS products. Current editions of Manifold import Version 7 of DGN. Future editions will likely add support for Version 8.

Importing a drawing from DGN format allows two options:

**Threshold**  
Threshold expressed in whatever units are used within the .dgn. Within this threshold straight lines are used to approximate curved elements such as splines or circles.

**Import Z**  
Create an additional drawing with points that provide a Z coordinate.

Several formats in common use allow objects such as lines to be defined not just by X,Y coordinates but also by Z coordinates at each coordinate location that defines the line. Checking the Import Z box causes an additional drawing to be created filled with points, each of which has a Z coordinate taken from the accessory Z values in the coordinate sequences that define lines or other objects. This drawing can then be used to create a surface. Note: if there are several sets (layers) of objects in a original .dgn, all of the Z points will be created in one Z drawing. Use spatial overlays to select/filter only those Z points desired for a given set of objects.

Importing a DGN into Manifold will import splines as curved shapes.

Importing a DGN file with external references will cite the names of any reference files in the History pane.

**Note:** DGN files are not really geographic files but utilize an unusual internal coordinate system unique to MicroStation. Making sense of such data requires formidably expert skills in MicroStation. MicroStation experts advise a simpler path, writing MicroStation data to AutoCAD DWG, making sure to write the data out in master units and thus forcing MicroStation to write out in sensible XYZ coordinates instead of the bizarre internal coordinates used by MicroStation. One can then import the AutoCAD DWG file using the usual procedures when importing projected information from non-geographic formats. See the Import a Projected Shapefile example for an example of such procedures.

**Broken DGN Files**

DGN may be imported by Manifold in cases where the .dgn is not “broken” (to use Bentley’s terminology). In cases of “broken” .dgn files, importing a .dgn may show elements in the Manifold drawing that were recently deleted in MicroStation before saving the .dgn.

To avoid this situation, try the following:

- In MicroStation, choose **File - Compress Design** to compress the .dgn before it is imported into Manifold.
- If there are still problems, use the **EdG** utility provided with MicroStation to repair the broken .dgn.

**Notes**

DGN is thinly documented and can include format variations that are not openly documented. Although Manifold’s .dgn importer has proven to work very well across a wide range of .dgn files it is always possible that a .dgn may be encountered in an undocumented format variation that cannot be imported into Manifold.

If such files are encountered, the best approach is to track down the person or organization that created them and to convince them to switch to Manifold for all of their GIS needs. This is especially a good thing to do if the organization is a large one and the result is acquisition of thousands of Manifold licenses.

The second-best approach is to ask the issuing person or organization to write out the data in some other GIS format that can be read by Manifold, such as AutoCAD DWG, an ESRI format such as shapefiles or some neutral format such as SDTS.
Import and Export

Import Drawing - DLG

A U.S. Geological Survey (USGS) format, Digital Line Graph (DLG) format is now being replaced by SDTS format. However, many drawings are still available in DLG format. Manifold's DLG importer imports so-called "DLG Optional" format, the DLG format version which replaced the original DLG format used many years ago. Virtually all "DLG" files available use the more modern "optional" format; however, on rare occasion one may encounter very old "dlg" files in the older format. DLG files should have extensions such as .dlg, .do, or .opt.

Select All - Check all fields. All data fields will be imported with this drawing.

Select None - Uncheck all fields. No data fields will be imported. Tech tip: Use this to uncheck all fields before checking those desired.

Select Inverse - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.

Fields pane Check the data attribute fields to be imported.

Compose areas Check to create area objects. Not checking this box will create only lines and points.

Tech Tips

In 1993 USGS published a series of 14 CDs providing 1:100K-scale DLGs covering the entire US. These CDs contain DLGs in zipped format. The DLG files must be first unzipped. The result is files that are named using numbers without a three letter extension, for example SF4RDF04. These must be renamed to add a .opt extension to each file, for example SF4RDF04.opt.

Trouble importing DLGs? Check the obvious:

- Are they in DLG optional format? "Original" format DLG files are extremely rare but may still occur.
- Have you unzipped or otherwise decompressed the files if they were provided in a compressed way?
- Are they really DLG or are they SDTS format? Many files provided by USGS as DLGs are now provided in SDTS format, but the directory structures or other descriptions refer to them as "DLGs" because they were originally provided in DLG format.
- If you have downloaded files via the Internet, try downloading again in case the files were damaged during download.

Manifold will try to import even malformed DLGs. For example, Manifold will automatically handle inconsistent line ends found in malformed DLGs.
Import Drawing - DSN

Manifold can create a drawing directly from data stored in a geocoded table. This capability is directly analogous to the creation of a linked drawing from a geocoded table except that instead of the drawing being linked to the originating table it is created as an independent drawing within the Manifold project.

A Microsoft file DSN is a way of capturing an ODBC connection within a simple connection that may be easily "opened" without the need to deal with complex ODBC dialogs (except once when the DSN is first set up).

Such imports are accomplished by choosing File - Import - Drawing and then choosing Data Sources () in the Files of type box to launch the Data Source dialog. The desired data source can then be configured and used in the Data Source dialog.

Dialogs used are the same as for creating a linked drawing from a geocoded table, except that linked drawings always invoke the Data Source dialog and the result of an import is an imported drawing rather than a linked drawing.

Import and Export

Import Drawing - DWG

AutoCAD .dwg ("drawing") format is a CAD format that is occasionally encountered in GIS, although AutoCAD .dxf ("export") format is more frequently encountered. The format is a first rate choice for CAD work but must be imported with care in GIS work since it saves neither database information nor projection settings. Not surprisingly, .dwg format is used mostly to save CAD work such as diagrams of facilities and other CAD drawings created without any sense of projection or geographic location.

However, one also encounters drawings saved in .dwg where the CAD system was used in an attempt to render cartographic features intended to have meaning within a particular projection or tied to specific geographic locations. The popularity of AutoCAD assures that there will be many drawings saved in .dxf that one may wish to use in Manifold.

Manifold's .dwg importer can import versions 13, 14 and 15 of .dwg (version 15 is produced by AutoCAD 2000).

- **Select All** - Check all the boxes in the layers pane.
- **Select None** - Uncheck all the boxes in the layers pane.
- **Select Inverse** - Check all unchecked boxes and uncheck all checked boxes in the layers pane.

**Layers**

- **Check layers to be imported.**

**Threshold**

Threshold expressed in whatever units are used within the .dwg. Within this threshold straight lines are used to approximate curved elements such as splines or circles. In general, the threshold parameter specifies the maximum error that can be made when approximating curved elements with straight lines in units used within the file.

**Import lines with widths as areas**

Import lines that have non-zero widths as area objects, using the width of the area to represent the width of the line.

**Import Z**

Create an additional drawing with points that provide a Z coordinate.

**Strip format tags**

Remove formatting information from label texts. On by default.

Several formats in common use allow objects such as lines to be defined not just by X,Y coordinates but also by Z coordinates at each coordinate location that defines the line. Checking the **Import Z** box causes an additional drawing to be created filled with points, each of which has a Z coordinate taken from the accessory Z values in the coordinate sequences that define lines or other objects. This drawing can then be used to create a surface. Note: if there are several sets (layers) of objects in the original .dwg, all of the Z points will be created in one Z drawing. Use spatial overlays to select/filter only those Z points desired for a given set of objects.

.dwg drawings will often include many layers. Each layer checked for import will be imported into Manifold as a separate drawing so that they can appear within a map as layers. Manifold will attempt to name the drawing using the layer name within the .dwg file.

To deal with projection issues when importing .dwg, see the Import Drawing - DXF topic, which provides a discussion using import from .dxf files.

Importing a DWG file with external references will cite the names of any reference files in the History pane.
AutoCAD .dxf format is a CAD format that is frequently encountered in GIS. The format is a first rate choice for CAD work but must be imported with care in GIS work since it saves neither database information nor projection settings. Not surprisingly, .dxf format is used mostly to save CAD work such as diagrams of facilities and other CAD drawings created without any sense of projection or geographic location.

However, one also encounters drawings saved in .dxf where the CAD system was used in an attempt to render cartographic features intended to have meaning within a particular projection or tied to specific geographic locations. The popularity of AutoCAD assures that there will be many drawings saved in .dxf that one may wish to use in Manifold.

Manifold’s .dxf importer can import versions 13, 14 and 15 of .dxf (version 15 is produced by AutoCAD 2000).

- **Select All** - Check all the boxes in the layers pane.
- **Select None** - Uncheck all the boxes in the layers pane.
- **Select Inverse** - Check all unchecked boxes and uncheck all checked boxes in the layers pane.

**Layers** Check layers to be imported.

**Threshold** Threshold expressed in whatever units are used within the .dxf. Within this threshold straight lines are used to approximate curved elements such as splines or circles. In general, the threshold parameter specifies the maximum error that can be made when approximating curved elements with straight lines in units used within the file.

**Import lines with widths as areas** Import lines that have non-zero widths as area objects, using the width of the area to represent the width of the line.

**Import Z** Create an additional drawing with points that provide a Z coordinate.

**Strip format tags** Remove formatting information from label texts. On by default.

.dxf drawings will often include layers. Each layer check will be imported into Manifold as a separate drawing so that they can appear within a map as layers. A map component containing all the layers will also be created. Manifold will attempt to name the drawing using a combination of the file name and the layer name within the .dxf file.

Several formats in common use allow objects such as lines to be defined not just by X,Y coordinates but also by Z coordinates at each coordinate location that defines the line. Checking the **Import Z** box causes an additional drawing to be created filled with points, each of which has a Z coordinate taken from the accessory Z values in the coordinate sequences that define lines or other objects. This drawing can then be used to create a surface. Use spatial overlays to select/filter only those Z points desired for a given set of objects.

Importing a DGN, DWG or DXF file with external references will cite the names of any reference files in the History pane.

**Projections and DXF**

All .dxf drawings imported into Manifold will require some manual setting of coordinate properties using the Edit - Assign Projection dialog. Each drawing created from the .dxf (in the case of multiple drawings created when there are multiple layers in the .dxf) will have to have its coordinates properties correctly set. This is tedious.

.dxf drawings will initially be imported using the default Orthographic projection centered at 0 latitude and 0 longitude. To place the drawing into correct geographic context we must provide projection parameters to the
Edit - Assign Projection dialog. To do this we must find out what projection (if any) was used to create the .dxf file.

There are essentially two main classes of .dxf drawings we will import into Manifold:

- CAD drawings created in an Euclidean CAD space using meters or feet or other linear units. These may be various blueprints or other diagrams showing facilities, layout of land parcels and so on. What they have in common is that there is no pretext to show large geographic areas that might involve projections.
- Geographic drawings rendered in .dxf. These may have been imported from some other GIS format. They may or may not show geographic features using a projection.

To be used in a geographic context with other maps and drawings, CAD drawings must be georegistered using features they have in common with an already-georegistered drawing or image. For example, if we have a .dxf drawing of a warehouse facility we will need to find a drawing that shows features that are also found in the drawing of the warehouse facility that may be used as control points. We can then use these common features (such as the corners of the parcel or the location of roads shown both in the CAD drawing and in our georeferenced drawing) as control points.

The process for CAD drawings is to import them using defaults. We can then georegister them. If we don't care about the geographic context of the drawings, we can always use Manifold as a CAD editor by simply leaving the CAD drawings in their default imported state and editing them as we might within AutoCAD.

To use geographic drawings saved in .dxf formats within Manifold, we have basically three situations to deal with:

- Drawings created in Latitude / Longitude unprojected form using degrees as units of measure.
- Drawings created in some projection using feet, meters or some other linear unit of measure.
- Drawings where the projection used is unknown.

For the third case, we have no choice but to attempt to use georegistration to place them in the correct geographic context. For the other two cases, we can proceed as set forth in the following two examples.

Example: Importing an Unprojected DXF

Suppose we know the .dxf being imported was created in the Latitude / Longitude projection using degrees as units of measurements. This is a fairly rare event in the AutoCAD world since most CAD projects, even geographic ones, are created using meters or feet or some other linear unit of measure.

In our example we import a .dxf drawing of the United States. Note that .dxf cannot save areas, so .dxf drawings consist of lines. On import, we can open the drawing and see that it appears like a normal, unprojected view of the United States even though the status bar tells us it is in Orthographic projection.

| Orthographic | 0°00'03"W, 0°00'01"N |

On moving the mouse cursor over the drawing, the status bar will show that the coordinate system in use is wrong.
We can open the Edit - Assign Projection dialog to see what projection settings Manifold is using to interpret the imported drawing. We will use this dialog to change the settings.
All we need do is select Latitude / Longitude from the projections hierarchy and then press OK. The drawing will now be correctly interpreted.

Example: Importing a Projected DXF

The usual situation with .dxf files showing geographic entities is that they are created in some projection, usually a bizarre and painful projection such as UTM. For this example, we assume we have imported a .dxf drawing that we know represents a map in Lambert Conformal Conic projection. Suppose we further know that the projection was centered on latitude 40, longitude -100 using a first standard parallel of 33 and a second standard parallel of 45.

We import the drawing using defaults.
When we click open the drawing we see that it appears to show the United States in typical **Lambert Conformal Conic** projection even though the status bar says the projection in use is **Orthographic**.

![Orthographic Projection](image)

When we pass the mouse cursor over the drawing window we see that the status bar reports nonsensical latitude and longitude values for the central US.

As in the previous example, we can open the **Edit - Assign Projection** dialog to see what projection settings Manifold is using to interpret the imported drawing. They are the same as the previous example since .dxf drawings are always imported by default into **Orthographic** projection.
We choose \textit{Lambert Conformal Conic} as the projection from the hierarchy of projections available. We then double-click into each of the values to change them to the values we know were used in the projection of the drawing. We enter 40 for the \textit{Center Latitude} and -100 for the \textit{Center Longitude}.

"Parallel" is a synonym for "latitude." We therefore enter 33 and 45 as the \textit{1st Standard Latitude} and \textit{2nd Standard Latitude} respectively. The illustration above shows the dialog as we enter 33 for the \textit{1st Standard Latitude}. Press \textit{OK} to apply the values. The drawing will now be correctly interpreted.

\textbf{Comments}

Where did we get the magic values that were entered into the dialog to make sense of the projected .dxf? Because .dxf format does not save projection information we must get these magic values from the creator of the .dxf file. Whenever downloading or otherwise procuring .dxf files that may be projected, it is absolutely critical to stay alert for any accompanying documentation.

Suppose we don't have the accompanying documentation? Suppose we know that the .dxf represents a projected drawing but we have no idea what projection was actually used? In that case, we pause to curse the inconsiderate nature of people who use .dxf formats to save projected drawings without keeping their users informed and then we move on to using georegistration to register the drawing within a geographic context. We do this by matching up features it has in common with a "known good" drawing using control points.

Georegistration is a real hassle. Adding control points is tedious. A more serious problem is that inevitably some slight precision is lost when georegistering as compared to using the original data using precise projection parameters as originally intended, even though any loss of precision is normally far less than the intrinsic accuracy of the drawing. For these reasons it is wise to spare no effort in tracking down a description of the projection used to create a projected .dxf drawing.
Import Drawing - E00

ESRI .e00 is a complex format used with ArcINFO. It is capable of storing different types of data, including images and surfaces ("grids"), but is most often used for drawings. .e00 format occurs in single-precision or double-precision forms and both compressed (binary) and uncompressed (ASCII) types.

The Manifold .e00 importer can automatically determine which form of .e00 is being opened and extract the data it contains. .e00 import will also automatically import any auxiliary attribute tables and label sets.

- **Select All** - Check all fields. All data fields will be imported with this drawing.
- **Select None** - Uncheck all fields. No data fields will be imported. Tech tip: Use this to uncheck all fields before checking those desired.
- **Select Inverse** - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push **Select Inverse**.

**Fields pane** Check the data attribute fields to be imported.

**Compose areas** Create areas (checked by default). Not enabled when the file contains no areas. May be unchecked if areas are not needed. Importing areas is a computationally intensive process so not importing areas will speed up the import process.

**Import Ticks** Create an additional drawing with tick points

**Comments**

.e00 files are sometimes multiple files, where a single data set is contained as a series of files named filename.e00, filename.e01, filename.e02 and so on. When downloading ".e00" files be on the lookout for such additional files and download them all.

.e00 is an undocumented format that apparently has been changed by ESRI over time. Although Manifold's .e00 import and export capabilities will obviously attempt to follow any changes introduced by ESRI, there is no guarantee that what works today with current versions of ESRI products will also work with future ESRI products that did not exist at the time this Manifold release was created. For best compatibility with the widest range of ESRI products that can read or write .e00, make sure to upgrade to the latest Manifold release and service pack available.
Import Drawing - GDF

GDF is a format used for TeleAtlas MultiNet files. These are sometimes casually referred to as TeleAtlas Import Format (TAIF) files, although strictly speaking TAIF is a different format normally used for TeleAtlas StreetNet files.

GDF is also a generic European standard used for GIS data sets. Manifold's GDF importer has been verified with MultiNet drawings and will be extended to import all GDF files using the standard European format.

Select All - Check all modules. All modules will be imported with this drawing.

Select None - Uncheck all modules. No data modules will be imported. Tech tip: Use this to uncheck all modules before checking those desired.

Select Inverse - Uncheck all previously checked modules and check all previously unchecked modules. This is a fast way to check only a few modules out of many: uncheck those desired and then push Select Inverse.

Modules pane

Map fields between tables

Import Z

Several formats in common use allow objects such as lines to be defined not just by X,Y coordinates but also by Z coordinates at each coordinate location that defines the line. Checking the Import Z box causes an additional drawing to be created filled with points, each of which has a Z coordinate taken from the accessory Z values in the coordinate sequences that define lines or other objects. This drawing can then be used to create a surface. Note: if there are several sets (layers) of objects in the original file, all of the Z points will be created in one Z drawing. Use spatial overlays to select/filter only those Z points desired for a given set of objects.

Import and Export

Import Drawing - Geocoding Database

Drawings may be imported from the Manifold Geocoding Database that is provided on the Manifold downloads site. The geocoding database provides information on streets and addresses in the United States that is organized on a county basis, but it also includes supplementary cartographic information. Although the principal use of the geocoding database is to provide address range data for street address geocoding the data may also be used to create drawings that show streets and hydrological features within the United States.

Note that the Manifold Geocoding Database contains data only for the United States; therefore, drawings imported from the geocoding database can only be imported for counties within the United States.

Required Geocoding Tools and Geocoding Database

Like the rest of Manifold’s street address geocoding capability, import from the geocoding database becomes operational only when the optional Manifold Geocoding Tools package is installed. If you do not have the optional Geocoding Tools package, you will not be able to take advantage of the import capability described in this topic.

Note that Manifold Universal Edition automatically installs the Geocoding Tools package. If you are using Universal Edition, you do not need to perform an extra Geocoding Tools installation as it has already been installed.

To install the Manifold Geocoding Database to hard disk, see the instructions in the Geocoding Data Sources topic.

Importing a Drawing

Drawings are normally imported from the geocoding database after it has been installed to hard disk. See the Geocoding Data Sources topic for instructions on installing the Manifold Geocoding Database onto your system’s hard disk.

To import a drawing from the Manifold Geocoding Database:

1. Use File - Import - Drawing. In the Import Drawing dialog choose Geocoding Database Files in the Files of type box.
2. In the Import Drawing dialog browse over to the installation folder for the geocoding database (by default, C:\Program Files\Manifold System\GCDB) and double-click the states.dat file.
3. In the Import Geocoding Database dialog enter a list of one or more counties to be imported in the Counties box.
4. Check fields (columns) to be imported for each object. It is strongly recommended to import at least the CFCC field so that different types of objects can be thematically formatted and separated if need be. Press OK.

A drawing will be imported for each county specified. If the CFCC field has been selected (it is selected by default) a thematic format will be applied that colors hydrology features in blue, railroads in black and other features in neutral brown colors. Railroad line size will be thematically formatted at a larger size than other lines.

If we would like to combine objects from multiple county drawings into a single drawing we can use Copy and Paste to copy objects from one drawing and paste them into another drawing.

If we would like to separate features into different drawings, we can easily do so using the selection toolbar to select different ranges of CFCC codes, cutting the selected features out of the drawing with a CTRL-X and then pasting them as new drawings in the Project pane.

For an example of drawing import from a geocoding database and separation of features into different drawings, see the Import a Drawing from the Geocoding Database example topic.

Controls

Counties One or more counties to import. A county is specified as a county name with a two letter state abbreviation in the format Countname, StateAbbreviation. Place a
semicolon between counties if more than one county is specified. For example, if we wanted to import streets for Alameda county in California as well as streets for Contra Costa county in California we would enter Alameda, CA; Contra Costa, CA

Select All - Check all fields. All fields will be imported with this drawing.

Select None - Uncheck all fields. No data fields will be imported. Tech tip: Use this to uncheck all fields before checking those desired.

Select Inverse - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few fields out of many: uncheck those desired and then push Select Inverse.

Fields pane  Check the fields to be imported.

Import formatting Check (the default) to import default formatting used for geocoding database objects, such as blue color for hydrological features.

Fields

Field names and contents are derived from the original data source, the US Bureau of the Census TIGER/Line database. See the Census Bureau documentation on TIGER/Line attributes for details.

Street  Street name.

CFCC  Census Feature Class Code, a code that classifies objects into different types. CFCC codes that begin with H, for example, refer to hydrological (water) features.

FRADDL  Beginning (From) address number on the left side of the street.

TOADDL  Ending (To) address number on the left side of the street.

FRADDR  Beginning (From) address number on the right side of the street.

TOADDR  Ending (To) address number on the right side of the street.

ZIPL  US Postal Service ZIP code on the left side of the street.

ZIPR  US Postal Service ZIP code on the right side of the street.

CITYL  City name on the left side of the street.

CITYR  City name on the right side of the street.

STATEL  State name on the left side of the street.

STATER  State name on the right side of the street.

COUNTYL  County name on the left side of the street.

COUNTYR  County name on the right side of the street.

Most fields come in Left (L) and Right (R) versions, for example ZIPL and ZIPR. These specify the values for a particular street on the left side of the street or on the right side of the street, left and right being understood given
the orientation of that particular street segment as it is internally defined from the first coordinate that defines the street to the last coordinate.

It may seem odd to think of a street that has different ZIP codes on opposite sides of the same street, or different city, county or state names on opposite sides of the same street but that situation does occur in streets that mark the boundary between different jurisdictions.

**CFCC Codes**

The following codes are used for **CFCC** classification by the US Bureau of the Census:

Geocoding Data Sources
Import a Drawing from the Geocoding Database
Street Address Geocoding
Import Drawing - Geodatabase

Drawings may be imported or linked from ESRI geodatabase files, either SDE geodatabases or Personal geodatabases. Geodatabase files save object metric information within database tables using binary data types.

Personal geodatabases normally use .mdb files. Use Database Console to connect (via the Data Source dialog) to the .mdb file hosting the Personal Geodatabase and then Manifold's spatial DBMS capability will automatically identify the contents of that geodatabase. We can then import or link drawings as desired. See the spatial DBMS topic.

SDE geodatabases can use several different DBMS packages, but are usually found hosted in SQL Server or Oracle. When Database Console connects to such a data source it will recognized SDE geodatabases when it sees them. We can then import or link drawings as desired.

Important Note when Using 64-bit Manifold Editions

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKx format files. This includes no access to the MDB parts of Manifold MFD and MapInfo TAB imports, or an MDB used to store an ESRI geodatabase. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut. Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

Import Drawing - GML

GML is an abbreviation for "Geography Markup Language." A spectacularly inefficient format, GML is based on XML and is being touted as a proposed standard in some circles. Unfortunately, GML is something of a non-standard since every implementation of GML to date for saving GIS data has been incompatible with other implementations. Besides the intrinsic incompatibility designed into GML, the main problem with GML is the extreme inefficiency of the format: GML will frequently require files that are over 100 megabytes in size to store GIS data that other formats can save in only five megabytes.

GML is currently used by the UK's Ordnance Survey (OS) for publishing MasterMap data products, the only concrete form of GML that is currently used to publish a significant amount of data. The Manifold GML importer is therefore an importer for Ordnance Survey GML format, specifically, for OS MasterMap data products. manifold.net expects to work closely with the OS to assure increasing compatibility with OS usage of GML.

GML files may have a .gml extension or, as is the case with some Ordnance Survey (OS) data files with no extension. GML files can occur in both independent and topological polygon forms. Manifold will automatically import either type and will apply any updates specified. Manifold's GML importer supports object versions and will import any metadata as a Manifold comments component.

One interesting aspect of GML format is that a .gml files can contain a complete version of a drawing or it can contain updates to a drawing that represent changes to be made. In fact, a .gml file can contain both an original version as well as subsequent updates.

Importing a GML File

1. Choose File - Import - Drawing
2. In the Import dialog choose GML files in the Files of type box and browse to the folder containing the GML file to be imported. Double click on the file.
3. The Import GML Data Set dialog will pop open to allow specification of any update files to be processed as part of the import. If importing UK Ordnance Survey MasterMap files, make sure the MasterMap data box is checked. It is checked by default since MasterMap is the only known significant collection of files in GML format.
4. If one or more update files are to be processed, click on the New button in the dialog's toolbar and in the resulting Append dialog double click on the desired update file. Using the New button, add as many update files are desired. The update files will be processed in order from top to bottom, so arrange the list in the order desired using the Move buttons in the dialog's toolbar. Press OK.

Example

We will import one of the MasterMap samples provided by the OS on their website at www.ordnancesurvey.co.uk. The example is a map of Birmingham that is provided as an "initial data" file and as a "change-only" update file. The initial data file is called 101-SP0482-2c1.gz (5.6 MB in size) and the update file is called 102-SP0482-2c2.gz (475 KB in size). Given the similarity of names it makes sense for us to avoid confusing the two by keeping the files in different folders, perhaps called "Birmingham initial" and "Birmingham Update."

<table>
<thead>
<tr>
<th>Name</th>
<th>Size (MB)</th>
</tr>
</thead>
<tbody>
<tr>
<td>101-SP0482-2c1.gz</td>
<td>5.649</td>
</tr>
<tr>
<td>102-SP0482-2c2.gz</td>
<td>0.475</td>
</tr>
</tbody>
</table>

The .gz extension indicates the files have been zipped with GnuZIP, which is easily unzipped using WinZip. We routinely use WinZip to unzip .gz files, so our Windows explorer shows the WinZip icon next to the .gz file as seen above.
When WinZip unzips the files it asks us what extension they should have since the OS apparently does not use extensions for MasterMap files.

We used the extension .gml to indicate that it is a GML file so if we encounter these files in the future we won't wonder what they are.

Upon decompression the initial data file, now named 101-SP0482-2c1.gml, has expanded to 105 MB (!), while the update file, named 102-SP0482-2c2.gml, has expanded to 5.9 MB. Note that it would be more efficient to send changes by repeating the entire file in a more efficient GIS format (which would be about the size of the 5.6 MB zipped original file) than it is to use an unzipped GML changes file.

We repeat the procedure above to unzip the update file, which will now be called 102-SP0482-2c2.gml.
To import the .gml file into Manifold we launch Manifold System and then choose File - Import - Drawing using GML Files in the Files of type box. We browse over to our initial data .gml file and choose it.

Manifold opens an Import GML Data Set dialog to allow us to specify any update files desired. We click on the New button to add a new update.

This opens up an Append dialog that allows us to find and add another .gml file as an update file. We browse over to the folder holding our update file and double click on it.
The Import GML Data Set dialog is now loaded with the update file we desire. If we click on the update file to highlight it in the Updates pane the other toolbar buttons will be enabled, so we could delete this update or move it up and down in order relative to other update files we might add to the pane. Press OK and the file will import.

GML format is so inefficient that it can take a very long time to import a GML file, perhaps 20 minutes on an average computer to import a 100 MB GML file. Have patience. Eventually, the result is a drawing and some other components in the project pane.

If we open the drawing and apply some thematic formatting to area background color (using the theme field) we can see the excellent detail in the OS MasterMap product. Effective use of MasterMap requires some familiarity with the Ordnance Survey’s data organization plan. See the OS’s web site for documentation.

Import GML Data Set Dialog Controls
New - Add a new update file.

Move to Top - Move the highlighted update file to the top of the update file stack. The top file will be the first from which updates are applied.

Move Up - Move the highlighted update file up one position in the update file stack.

Move Down - Move the highlighted update file down one position in the update file stack.

Move to Bottom - Move the highlighted update file to the bottom of the update file stack. The bottom file will be the last from which updates are applied.

Delete - Delete highlighted update file.

MasterMap data
Checked by default. When checked, parses the GML stream for projection information used in UK Ordnance Survey Master Map files.

Versions
GML entities include version information that allows distinguishing between multiple versions of the same object (that is, between objects with same unique ID assigned by the data provider). When Manifold encounters an object that has already been imported, perhaps as the result of processing an update, it compares the versions of the existing object and the new object, determines which object is more recent and uses the more recent object.

Notes
The capability to receive updates was presumably motivated by the immense file sizes required by GML. With updates, the original large file would not have to be downloaded or copied when changes need to be made: a smaller GML file containing changes could be provided so that the original file could be used in conjunction with the smaller changes file. However, GML is so inefficient that just about any other GIS format can contain a refreshed version of the entire data set and still be smaller than only the changes expressed in GML. Manifold does not at present support use of incremental change files, but this capability is expected to be added in future releases of Manifold.

One way to get around the large file sizes imposed by GML is to do what the Ordnance Survey, does, which is to provide files already zipped in .gz format. The OS suggests that applications might read directly from the zipped file format, but that is not always a good way of dealing with the inefficiencies of GML.

Because GML files take a very long time to import, if Manifold imported directly from a .gz file in the case of a damaged file users could spend a long time on import finding out that the file was damaged in download or copying. If the .gz file is unzipped first (a rapid process) any errors in the file will be discovered right away before the long process of GML import begins.

Note that the 105 MB Birmingham sample file in GML format takes tens of minutes to import into Manifold. However, it can be saved as a .map project file requiring only 5.8 MB of space in a few tens of seconds and thereafter loaded even faster. Compared to efficient GIS formats, GML format is not only 20 times larger, it is also about 60 times slower. For this reason, we recommend that Manifold users import GML files and then save them in more efficient formats, either as Manifold projects or, for large data, within spatial DBMS storage.

For all the limitations of GML there is much UK data currently available in OS GML form and it is likely that this format will continue in use by the Ordnance Survey. To support UK users of Manifold, manifold.net expects to work closely with the OS to assure increasing compatibility with OS usage of GML.

UK users of Ordnance Survey data in GML format are encouraged to send suggestions to manifold.net for improvements and conveniences they would like to see within enhanced support for GML import by Manifold. See the Contacting manifold.net topic for information on contributing suggestions.
Import Drawing - KML, KMZ

KML is an XML-based format originally used for "annotations" in Google Earth displays. KMZ is exactly the same format compressed using "zip" compression with a three-letter file name extension of .kmz. KML can be used for points, lines or areas with up to two text attributes, a Name field and a Description field, per object. Manifold includes the ability to import a drawing from a Google Earth KML or KMZ file. If a KML file contains more than one folder, each folder will import as a separate drawing.

KML and KMZ provide data in Latitude / Longitude projection using the WGS 84 Auto datum only.

Notes

The initial KML importer in 7x is a simple importer that grabs vector data for points, lines and areas plus the Name and Description values, if present. It does not attempt to translate Google styles or colors into Manifold styles or colors.

Manifold can also export drawings and images to KML and KMZ. See the Export Drawing - KML, KMZ and Export Image - KML, KMZ topics for additional import information.

Import Drawing - LULC

LULC (Land Use and Land Cover) maps are created by USGS for use with their GIRAS information system. The maps are matched to 1:250,000-scale base maps and (in some areas of the US) a limited number of 1:100,000-scale base maps. Land use and land cover data provides information on urban or built up land, agricultural land, rangeland, forest land, water, wetlands, barren land, tundra, and perennial snow or ice. Associated maps display information in five data categories: (1) political units, (2) hydrologic units, (3) census county subdivisions, (4) Federal land ownership, and (5) State land ownership.

The screen shot above shows the San Francisco Bay region. Orange-yellow indicates inland waters (bays, etc) while bright blue indicates ocean. Other color values were chosen using the Temperature preset using Unique Values in the thematic formatting dialog.

The main source for LULC maps are free downloads via Internet from the USGS geodata download page at http://edc.usgs.gov/doc/edchome/ndcdb/ndcdb.html (if this URL changes, start with www.usgs.gov and drill down from their to find the LULC download area).

For each 1:250K or 1:100K region served by USGS, several files showing land use, hydrological regions, political boundaries, census county subdivisions and so forth may be available.

Downloaded files will appear with a .gz extension, since they are compressed with gnu-zip UNIX style compression. Use WinZip or any other .gz-capable decompression utility to unzip them. LULC files do not have a three letter extension by default. We recommend using .luc or similar extension as a mnemonic. Import them using File - Import - Drawing using LULC GIRAS Files (*.*) as the Files of Type choice in the Import dialog.

See the USGS pages for detailed documentation describing all the different data codes used to classify different land use regions in LULC.

Classification Codes

Land use / Land cover classification Codes-first and second level categories:

1 Urban or Built-Up Land
   11 Residential
   12 Commercial Services
   13 Industrial
   14 Transportation, Communications
   15 Industrial and Commercial
16 Mixed Urban or Built-Up Land
17 Other Urban or Built-Up Land

2 Agricultural Land
21 Cropland and Pasture
22 Orchards, Groves, Vineyards, Nurseries
23 Confined Feeding Operations
24 Other Agricultural Land

3 Rangeland
31 Herbaceous Rangeland
32 Shrub and Brush Rangeland
33 Mixed Rangeland

4 Forest Land
41 Deciduous Forest Land
42 Evergreen Forest Land
43 Mixed Forest Land

5 Water
51 Streams and Canals
52 Lakes
53 Reservoirs
54 Bays and Estuaries

6 Wetland
61 Forested Wetlands
62 Non-forested Wetlands

7 Barren Land
71 Dry Salt Flats
72 Beaches
73 Sandy Areas Other than Beaches
74 Bare Exposed Rock
75 Strip Mines, Quarries, and Gravel Pits
76 Transitional Areas
77 Mixed Barren Land

8 Tundra
81 Shrub and Brush Tundra
82 Herbaceous Tundra
83 Bare Ground
84 Wet Tundra
85 Mixed Tundra

9 Perennial Snow and Ice

91 Perennial Snowfields

92 Glaciers

**Notes**

GIRAS stands for Geographic Information Retrieval Analysis System.

Oceans may be coded with a value of 2000000102.
Import Drawing - ETAK MapBase
A proprietary format used to import ETAK GIS data sets. ETAK has been acquired by TeleAtlas and in the future may be known as TeleAtlas only.

Select All - Check all drawings. All drawings will be imported with this drawing.

Select None - Uncheck all drawings. No data drawings will be imported. Tech tip: Use this to uncheck all drawings before checking those desired.

Select Inverse - Uncheck all previously checked drawings and check all previously unchecked drawings. This is a fast way to check only a few drawings out of many: uncheck those desired and then push Select Inverse.

Drawings pane
Check the drawings to be imported. Drawings typically group areas, lines and points as well as other features such as bridges or tunnels, turn restrictions and unmapped address ranges.

Import and Export

**Import Drawing - HTML**

Manifold can create a drawing directly from data stored in a geocoded table. This capability is directly analogous to the creation of a linked drawing from a geocoded table except that instead of the drawing being linked to the originating table it is created as an independent drawing within the Manifold project.

Such imports are accomplished by choosing **File - Import - Drawing** and then choosing **Data Sources** () in the **Files of type** box to launch the Data Source dialog. The desired data source can then be configured and used in the Data Source dialog.

Drawings can be imported from geocoded tables using any of the data access methods, such as from an HTML file, provided by Manifold. Dialogs used are the same as for creating a linked drawing from a geocoded table, except that linked drawings always invoke the Data Source dialog and the result of an import is an imported drawing rather than a linked drawing.

Note that what can visually appear to be a "table" in an HTML file to the eye might not really be organized as a table from the perspective of Microsoft's table-reading, data access software. If Access cannot find a table to read in the HTML file, Manifold will not be able to either.

**Important Note when Using 64-bit Manifold Editions**

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKx format files. This includes no access to the **MDB** parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the **Manifold System (32-bit)** shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the **Manifold System (64-bit)** shortcut. Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

Although Microsoft is slowly moving forward towards 64-bit operation of Office and the JET components used by Access and Excel, at the present writing (2010) this is such a total kludge that while it is possible to get 64-bit access to Access or Excel it is just easier for most to continue using the 32-bit versions. See comments in the 32-bit and 64-bit Manifold Editions topic.

Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

Although Microsoft is slowly moving forward towards 64-bit operation of Office and the JET components used by Access and Excel, at the present writing (2010) this is such a total kludge that while it is possible to get 64-bit access to Access or Excel it is just easier for most to continue using the 32-bit versions. See comments in the 32-bit and 64-bit Manifold Editions topic.

Import Drawing - MFD
Import drawings from Manifold System Release 4.50 .mfd/.mdb format. The importer will work even if the .mfd is not accompanied by any .mdb file, in which case it will import drawing objects only without any data attribute fields in the associated table.

Select All - Check all fields. All data fields will be imported with this drawing.

Select None - Uncheck all fields. No data fields will be imported. Tech tip: Use this to uncheck all fields before checking those desired.

Select Inverse - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.

Fields pane Check the data attribute fields to be imported.

Import by layers Enabled if the .mfd has embedded layers. Check to import each layer as a separate drawing.

Layers in Release 4.50 workspaces are normally saved in the .mws workspace file, which references geometry stored in .mfd files and tables stored in .mdb files. .mfd files can also contain a layering structure. This is not normally used except to prepare .mfd/.mdb files for publication with a pre-built layer structure. If the .mfd file does have embedded layers the Import by layers checkbox will be enabled.

Comments
Technically, there was not an absolute requirement in Release 4.50 to name the .mfd and .mdb with similar names, that is, the same filename before the three letter .mfd or .mdb extension. The MFD importers in 5.00 and later versions of Manifold, however, require that the .mdb file is named the same as the .mfd file.

Important Note when Using 64-bit Manifold Editions
Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKx format files. This includes no access to the MDB parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut. Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

Although Microsoft is slowly moving forward towards 64-bit operation of Office and the JET components used by Access and Excel and the MDB part of Manifold 4.50 MFD/MDB format, at the present writing (2010) this is such a total kludge that while it is possible to get 64-bit access to Access or Excel it is just easier for most to continue using the 32-bit versions. See comments in the 32-bit and 64-bit Manifold Editions topic.

Import Drawing - MWS for information on importing Manifold System 4.50 .mws workstation files.
Import Drawing - MIF

MapInfo .mid/.mif format is widely used for interchange with MapInfo and other GIS applications. The format normally uses two files that have the same base name but with a .mif or .mid extension. The .mif file stores geometry information and the .mid file stores data attributes (fields). If a .mid file is present Manifold will import the table of data attributes it contains.

Select All - Check all fields. All data fields will be imported with this drawing.

Select None - Uncheck all fields. No data fields will be imported. Tech tip: Use this to uncheck all fields before checking those desired.

Select Inverse - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.

Fields pane Check the data attribute fields to be imported.

Import formatting When checked (default) imports colors and styles used for areas, area borders, lines and points. Imported formatting will be implemented using thematic formatting if the drawing includes two or more objects with different formatting values.

Formatting

Mif files can contain color information as well as style parameters for objects. Manifold will read foreground color, background color and style information for objects on import, including formatting for area borders. When exporting to mif format, Manifold will save foreground color, background color and size as well. If no color or size information is present in the file, Manifold will use default format settings.

Because sizes are not the same in MapInfo and Manifold, the .mif importer will attempt match sizes as best as possible.

Data Types

On import of a MapInfo .mif or .tab file, Manifold will translate MapInfo logical data type columns into Boolean data type. Exporting a Manifold drawing to .mif will export Boolean columns into MapInfo logical data type columns.

Datum Naming

Formats such as MapInfo .mif and .tab do not actually store the names of datums within the projection information stored in the file; instead, the numeric parameters for the datum are saved. When Manifold scans such a file the system will examine these numeric parameters to find a named datum that is a match and will use that datum's name to identify the datum in use.

In some cases, more than one datum may use the same numeric parameters. For example, there are many national datums that are mathematically identical to some generically named datums. When several datums match the given numeric parameters, Manifold will choose a neutrally named datum in preference to a name that uses a specific country name.

See Also

Import Drawing - TAB for information on importing MapInfo TAB format files.
Import Drawing - MWS

Manifold System Release 4.50 saves drawings using two files. An .mfd file saves geometry and a similarly-named .mfd file saves data attributes (fields). A third file, an .mws workstation file, saves the 4.50 workspace. The .mws file contains pointers to the various .mfd/.mdb files that make up a given workspace and contains information on how objects should be formatted, labels, layer structure and other information.

When importing .mws files from Release 4.50, one must therefore have not only the .mws file but also all of the .mfd/.mdb files it references. The .mws importer will import each .mfd/.mdb referenced as a separate drawing and will attempt to preserve imports.

Formatting

Because of differences between formats in Release 4.50 and subsequent Manifold editions, not all formatting information stored in an MWS file can be imported automatically into current Manifold editions. A format applied throughout an entire .mfd file will in most cases be imported, but "per object" formats will not. In addition, 4.50 styles for areas, lines and points are different from styles in subsequent Manifold editions. Labels are also different.

The importer will attempt to provide reasonable approximations; however, manual adjustment of formats will usually be required.

Manual Retrieval of Layers

Although the .mws importer will usually be able to get layers out of the .mws, we may be required in rare cases to retrieve layer structures manually. Suppose we wish to transition a counties.mfd file that was shown in four layers in a 4.50 workspace. We import the .mfd to create a countiesDrawing and a countiesTable in the project. We open the countiesDrawing and then while it is open we use File - Create - Drawing to create four new (empty) drawings in the project. Let's call these DrawingA, DrawingB, DrawingC and DrawingD.

We can now select the various items from countiesDrawing that we would like in different layers. We select each layer's worth of objects and use CTRL-X or Edit - Cut to cut them out of countiesDrawing, open the target drawing (A, B or whatever) and Paste the objects into the target drawing. To move objects between drawings we use Cut and Paste.

Once all of the desired objects have been cut out of countiesDrawing and pasted into the target drawings we can assemble all of the drawings into a map. This is easy: use File - Create - Map to create a map and check the boxes for the drawings that are to appear as layers in the map.

Import Drawing - MFD for information on importing Manifold System Release 4.50 .mfd/.mdb files.
Import Drawing - NTAD

NTAD format is used to import drawings from the U.S. Bureau of Transportation Statistics (BTS) National Transportation Atlas Databases (NTAD) and the BTS North American Transportation Atlas Data (NORTAD) CDs. BTS (www.bts.gov) provides fabulous, first rate data on various transportation facilities, road and rail networks and other useful data layers such as counties, states, national park boundaries, etc. At the present writing, BTS will send CDs at no charge when ordered from their web site.

NTAD files are usually organized into files that contain areas (.are), lines (.lnk) or points (.nod or .pnt). Import the desired files by browsing to the desired files.

Select All - Check all fields. All data fields will be imported with this drawing.

Select None - Uncheck all fields. No data fields will be imported. Tech tip: Use this to uncheck all fields before checking those desired.

Select Inverse - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.

Fields pane
Check the data attribute fields to be imported.

Map fields between tables
Create relations within drawing tables to link to common tables.

A Note on .lnk Files

Because Windows uses files with extension .lnk to indicate a link, files using this extension will not be shown in the Import dialog with the extension.

Instead, they will be seen with a small "link" sub-icon in the corner of the file’s icon. The illustration shows a .lnk and a .nod file that make up the National Highway Planning Network (NHPN), a road network of essentially all roads used for intercity transportation in the United States.

Historical Note

Manifold’s first use as a GIS in version 2.00 was to display the NHPN. Developed at Oak Ridge National Laboratory for the U.S. Army, the NHPN was generously provided to manifold.net on a SUN tape cartridge.
Import Drawing - NTF

The Ordnance Survey (OS) is the state cartographic monopoly in the United Kingdom. NTF format is used by the OS to publish both drawings in the Land-Line series as well as surfaces in their DTM grid series. Manifold’s NTF importer will automatically create drawings or surfaces depending on the contents of the NTF.

- **Select All** - Check all fields. All data fields will be imported with this drawing.

- **Select None** - Uncheck all fields. No data fields will be imported. Tech tip: Use this to uncheck all fields before checking those desired.

- **Select Inverse** - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push **Select Inverse**.

**Fields pane** Check the data attribute fields to be imported. (Not applicable when importing a surface).
Import Drawing - SDTS

Spatial Data Transfer Standard (SDTS) format is emerging as the primary GIS data interchange standard for the U.S. federal government. Most USGS drawings (DLGs) and surfaces (DEMs) are now provided using SDTS format. SDTS format is used for both drawings and surfaces. Manifold will automatically create the correct component depending on the contents of the SDTS files.

SDTS format normally includes a large number of files organized within a directory. One of the files is a catalog file that ends in `*.CATD.DDF`. To import an SDTS data set, browse to the directory that contains the files and import the `CATD.DDF` file. Manifold will read the catalog and automatically organize the import of all files involved.

Select All - Check all modules. All data modules will be imported with this drawing.

Select None - Uncheck all modules. No data modules will be imported. Tech tip: Use this to uncheck all modules before checking those desired.

Select Inverse - Uncheck all previously checked modules and check all previously unchecked modules. This is a fast way to check only a few columns out of many; uncheck those desired and then push Select Inverse.

Modules pane
- Check the modules to be imported. Modules will often be organized as containing points, lines or areas.

Map fields between tables
- Create relations within drawing tables to link to common tables. (Not applicable when importing a surface).

Import data definition scheme
- Create an additional table that provides the data definition scheme used for modules in other tables. (Not applicable when importing a surface).

Import Z
- If Z data is available, create an additional drawing with points that provide a Z coordinate.

Use long module names
- Checked by default. Create names for imported component using the TITLE field stored in the identity module. If not checked, creates a shorter name based on the name of the .ddf module.

Use master data dictionary
- Read the specified SDTS master data dictionary. Use the … browse button to navigate to the master data dictionary desired.

SDTS format allows objects such as lines to be defined not just by X,Y coordinates but also by Z coordinates at each coordinate location that defines the line. If Z data exists in the data set, checking the Import Z box causes an additional drawing to be created filled with points, each of which has a Z coordinate taken from the accessory Z values in the coordinate sequences that define lines or other objects. This drawing can then be used to create a surface.

Long names will be prefixed with the module identifier. This allows distinct names like "Hy01 Drawing" (hydrography or hypsography) and "Bd01 Drawing" (boundaries) even when the SDTS identification module contains no titles.

Importing an SDTS file can create many files: drawings, comments and possibly several tables can be created. To keep the project organized, create a folder into which each SDTS data set can be imported.

The Map fields between tables option if checked will automatically create relations between the drawing's table and other tables. Since potentially very many tables can be imported, the relations will not be used within the drawing's table until we choose the columns we want to be used.

To use a relation built during SDTS file import:

1. Open the drawing's table.
2. Launch Table - Relations.
3. Click the desired relation to select it.
4. Check the columns to be included in the drawing's table from that relation. Click OK.

**Tech Tip**

Some SDTS files published by the US government for regions in Puerto Rico contain an error in that the data they contain is projected using the Puerto Rico datum but the SDTS file information says the contents use the NAD27 datum. When such drawings are imported and overlaid on TIGER/Line 2000 drawings they will not align with the TIGER/Line data. This problem has been observed in 1:24K-scale SDTS DLG files as well as 1:24K-scale SDTS DEM files. It may occur in other files for Puerto Rico that are in SDTS format as well.

To fix this problem, open the drawing and use the Edit - Assign Projection dialog to change the datum to the Puerto Rico datum.
Import Drawing - SHP, Shapefiles

ESRI's .shp format, also known as "shape format" or "shapefiles," is used with ArcView, a popular GIS package of the early 1990's. Shape format has been openly published by ESRI and is widely used for data interchange in GIS. Shapefiles usually consist of three similarly named files with differing extensions: a .shp, .shx and a .dbf file. The .dbf file is a dBase database system format file that is used to store data attributes for the drawing. Manifold's importer will import .dbf attributes if present and will import .shp geometry information without data attributes if no .dbf is present.

Shapefiles may also include a .prj file that purports to give coordinate system (projection) information. Manifold can extract all information present in a .prj file; however, users are cautioned that .prj is only a partial standard and should not be relied upon to give the same level of complete projection information that is available in more modern GIS formats.

Select All - Check all the boxes in the fields pane.
Select None - Uncheck all the boxes in the fields pane.
Select Inverse - Check all unchecked boxes and uncheck all checked boxes in the fields pane.

Fields
Check fields to be imported.

Import measure
Creates new drawing containing points, each point of which provides a user-defined measure at that location.

Import Z
Create an additional drawing with points that provide a Z coordinate if Z information is present.

Several formats in common use allow objects such as lines to be defined not just by X,Y coordinates but also by Z coordinates at each coordinate location that defines the line. Checking the Import Z box causes an additional drawing to be created filled with points, each of which has a Z coordinate taken from the accessory Z values in the coordinate sequences that define lines or other objects. This drawing can then be used to create a surface.

Shapefiles and Projections

The experienced GIS operator will use shapefiles only with unprojected data. Unfortunately, many GIS users have been tempted into using shapefiles to save data in projected form.

Shapefiles were not originally designed to save projection information. Recent extensions to ArcView allow the partial saving of projection information in a supplemental .prj file that accompanies the other shapefile files. However, because the notion of a supplemental .prj file has been around only in recent years, most shapefiles that have been published do not use this extension.

A further problem is that some applications use shapefile writing libraries published to Internet that contain errors in how .prj files are written. Although Manifold will read .prj files when they accompany shapefiles and Manifold uses a variety of strategies to deal with invalid .prj data or other flaws, it is still best not to rely upon .prj files.

Shapefile format is therefore best used to interchange data from unprojected drawings. When such shape files are imported into Manifold they will appear in Latitude / Longitude projection without any difficulty. When importing unprojected data from shapefiles, the only variable of concern is which datum was used. Normally, the description of the datum used will be found in whatever descriptive commentary accompanies the drawing.

When importing an unprojected shapefile keep on the lookout for any information that tells you what datum was used for that shapefile. Importing an unprojected shapefile will by default import the shapefile using Latitude / Longitude projection using the WGS 84 centroid. Such imports will be acceptable for many GIS purposes; however, for full accuracy one should find out what centroid (that is, datum) was used for the shapefile being imported and use the Edit - Assign Projection dialog to specify it for the imported drawing.

Be Wary of Projected Shapefiles

Serious difficulties can arise when people project drawings and then save the resulting projected data as a shapefile. In such cases there is no guarantee that the author of the shapefile will warn us that the shapefile
contains projected data and cannot be interpreted as a Latitude / Longitude map. Worse yet, there is no information contained within the shapefiles that specifies the projection and parameters used. If these are not provided within some readme.txt file or (in some cases) an accompanying .prj file or other accompanying documentation, the shapefiles lose their geographic context.

The best first step is to import a shapefile using default settings on the importer. Open the drawing and see what coordinates are reported in the status bar when the mouse passes over the drawing. If they are reasonable latitude and longitude values in the expected range, the shapefile was an unprojected data set using degrees and has been imported correctly.

Since shapefiles cannot save datum information it is always wise to take a moment to find out what datum was used to save the data to the shape file and to select it as the correct datum for this drawing in the Edit - Assign Projection dialog. Quite often the authors of unprojected shapefiles will include documentation with the shapefiles that will inform us what datum was used. Regrettably, not all authors are so considerate.

The case becomes more difficult if projected shapefiles are in play. Projected shapefiles on import may result in a drawing that provides the expected visual appearance when it is opened. However, if the latitude and longitude values in the status bar are nonsensical numbers such as 48593 degrees the shapefile was a projected file. The task now becomes one of finding out what projection and projection parameters were used. These can then be manually specified using the Edit - Assign Projection dialog.

Failing to import a projected drawing from .shp format correctly will lead to unpredictable effects when the drawing is used in a map. If we import a projected drawing from .shp we must tell Manifold the correct projection to use to interpret that data since the format does not save this important information. This is so important that Manifold will nag us to verify the projection of new components to make sure we have reviewed the projection that has been assigned and have confirmed it is the correct projection.

Importing a Projected Shapefile

We import a projected shapefile by first importing it in the usual way and then using the Assign Projection dialog to assign the correct projection.

To import a projected drawing from shapefiles:

1. Import the drawing using File - Import - Drawing. Use default settings.
2. Open the drawing.
3. Use the Edit - Assign Projection dialog to specify the projection information that should be used.

The Edit - Assign Projection dialog allows us to manually provide the correct projection information for the coordinates properties. Manifold will then be able to make sense of the data just imported. If the projected shapefile included a .prj file there may be partial projection information already in the Current Projection dialog. If so and if the information is accurate, that reduces the amount of information we need manually supply.

Do not confuse the use of a chosen projection view in a map window (via Edit - Assign Projection) with the use of Edit - Assign Projection in a drawing window to specify projection information missing from legacy formats. If a projected drawing is imported from shapefiles and we fail to tell Manifold the correct projection to use, that drawing has not yet been correctly imported. Subsequent use of the drawing in maps may cause bizarre effects or lengthy delays as the system attempts to compute a new projection for the map based on fundamentally inaccurate coordinates.

Example
We've imported a shapefile showing the United States into a drawing. When opened, the drawing appears visually as expected.

| Latitude / Longitude | 20834°1.726' E 98451°42.59... |

However, we notice that the status bar reports impossible latitude and longitude values when the mouse passes over the drawing. This tells us that the shapefile contained projected data. We hunt around in the documentation that accompanied the shape file and read the following in a text file:

**The US map is in Lambert Conformal Conic centered on -100, 40 with standard parallels at 33 and 45.**

We are immediately grateful that the author of the map took a moment to tell us this necessary information, albeit in a minimal way. To put this information to work we open the drawing and open the Edit - Assign Projection dialog for the drawing.
This dialog reports the settings Manifold is using to interpret the numbers in the drawing. We can change it to tell Manifold to use a different interpretation. Although this dialog is the same as those used in the Projection system, it does not change the actual data in the drawing. It simply tells Manifold how to interpret what is in the drawing.

In the present instance, the dialog shows that Manifold thinks the data in the shapefile is to be interpreted as Latitude / Longitude data in degrees. We need to change that.
We begin by choosing Lambert Conformal Conic as the projection from the hierarchy of projections available. We then double-click into each of the values to change it to those specified by the author of the map. 

"-100" is obviously a longitude since latitudes range between plus or minus 90. This tells us the author centered the map on longitude -100 and latitude 40. We therefore use 40 for the Center Latitude and -100 for the Center Longitude.

"Parallel" is a synonym for "latitude." We can guess that the 33 and 45 numbers are intended for use as the 1st Standard Latitude and 2nd Standard Latitude respectively. The illustration above shows the dialog as we enter 33 for the 1st Standard Latitude. Press OK to apply the values.
After applying the new coordinate properties there is no change in the appearance of the drawing.

| Lambert Conformal Conic | 98°17.498' W 33°36.207' N |

There is a change in the values reported by the status bar. Now, when the mouse passes over the United States the values reported are the expected latitude and longitude values for this part of the world.

**Comments**

Suppose the author of a projected shapefile did not see fit to provide documentation on what projection settings were used? This is bad news. Without information on projection and parameters the shapefile loses much of its value in a geographic context. We may be able to salvage it by georegistering it if it includes features that can be matched to a known good drawing. Georegistration can be a tedious process, though, so one is forgiven for cursing the author of a shapefile who chose to publish projected data in a shapefile without also publishing the data necessary to use it.

Why isn't Manifold able to know what projection is to be used for a shapefile? That's a limit of shapefile format, not Manifold. Modern formats save projection information. Shape format does not.

**Database Drivers and Shapefiles**

The shapefile standard calls for use of `.dbf` files to save database information within shapefiles. Unfortunately, there is no common standard for `.dbf` in use. `.dbf` originally was the dBase II database format used in early PCs. It lives on as a living fossil database format in modern times. However, since different companies have "extended" `.dbf` in various ways the `.dbf` files accompanying one's shapefiles may be inconsistent from system to system.

Original dBase II `.dbf` format is limited to no more than eight characters for field names beginning with an alphabetic character. `.dbf` file names are also limited to eight ordinary alphabetic characters plus a three character extension. Various recent versions of `.dbf` format (such as, for example, `.dbf` format as used in Microsoft's Visual FoxPro DBMS) may extend the number of characters possible both for field names and for file names.

Note that some ESRI products will create and read shapefiles with unusual `.dbf` file names, even those with spaces in them, depending on the operating system or ESRI product involved. However, in Windows it is a massive violation of `.dbf` spec to use `.dbf` file names with spaces in them for `.dbf` files. Manifold normally uses only the Microsoft standard drivers that are installed in your Windows system; however, shapefile import is an exception because ESRI products are willing to violate the standards set by Microsoft `.dbf` drivers. To deal with such ESRI departures from Microsoft standards Manifold is equipped with a special Manifold `.dbf` driver that is used only when importing shapefiles.

When used to import shapefiles, the Manifold `.dbf` driver is willing to accept nearly any naming of fields and files that are used in the `.dbf` portion of the shapefile. When importing tables from `.dbf` files in all cases other than the import of shapefiles, Manifold always uses the host `.dbf` drivers resident on your Windows system.

**Regional Settings**

When importing data from text file formats like `.csv` or from `.dbf` or shapefiles the Regional Options in the system have to match settings within the file that is being imported. This is because such simple formats are too stupid to understand that in different countries people use different symbols to denote decimal points (that is, either a dot character or a comma). To change Regional Options, do the following:

- Go to the Control Panel and open the Regional Options applet.
- Go to the Numbers page,
- Ensure that the Decimal Symbol is set to ‘.’ (dot),
- Ensure that the List Separator Symbol is set to ‘,’ (comma),
- Press Apply to apply changes if there were any,
- Import the `.csv` file or shapefile desired.
- After import, restore the original settings of Decimal Symbol and List Separator Symbol if you like.
Another option is to invoke the Data Sources applet (hidden within Administrative Tools folder of the Control Panel if you're running Win2K) and create a file DSN for the .csv file you want to import. After creating the DSN configure it to use the comma character as a data separator.

**Shapefiles and PRJ Files**

The use of .prj files together with shapefiles to specify projections is a recent development that, unfortunately, has come into play without any definitive standards being published to precisely specify how the .prj should code its contents. Although the use of .prj files works most of the time, it is something of a haphazard system. If a shapefile is accompanied by a .prj file Manifold will analyze the .prj to try to determine what projection and projection parameters are intended for the shapefile.

Manifold recognizes over 490 projection types used in .prj files and so will be able to extract the projection information in almost all cases, reading more different types of .prj than almost all other software packages that can read shapefiles. However, because .prj files do not use standardized nomenclature for projections it is possible that in some cases it will not be possible to read the desired projection even if the shapefile is accompanied by a .prj file.

Another problem is that some third party applications write flawed .prj files. Manifold contains special code to identify and work around the most common .prj flaws. Manifold will also take reasonable steps to deal with partial or unusual .prj situations. For example, when encountering a .prj file that includes datum information (GEOGCS) but no projection information (PROJCS) Manifold will extract the datum but use the latitude / longitude coordinate system.

Despite these special Manifold features to deal with the idiocy occasionally found in .prj files, it is always possible you may encounter a .prj file that Manifold cannot import in a way that captures the coordinate system supposedly in use. manifold.net is always on the lookout for .prj files containing previously-unknown standards to add to our "zoo" of strange examples. If you encounter a shapefile using a .prj that does not import into Manifold correctly, please contact tech support for instructions on how to FTP it to manifold.net for examination.

**See Also**

Projections and Legacy Formats for a rant on the hassles involved in using some legacy formats.

Import a Shapefile for a step by step example of importing a projected shapefile and setting the correct datum.
Import and Export

Import Drawing - TAB
MapInfo TAB format may be imported by Manifold in cases where the .tab file uses projections also available within Manifold (almost all).

**Select All** - Check all the boxes in the fields pane.

**Select None** - Uncheck all the boxes in the fields pane.

**Select Inverse** - Check all unchecked boxes and uncheck all checked boxes in the fields pane.

**Fields** Check fields to be imported.

**Import formatting** Import formatting for colors and styles used for areas, area borders, lines and points when checked. On by default. Imported formatting will be implemented using thematic formatting if the drawing includes two or more objects with different formatting values.

**Register image** Read image control points embedded by MapInfo. When turned on, this option embeds control points in the image and also creates a drawing with both point objects and control points at the designated locations.

**Formatting**

Tab files can contain color information as well as style parameters for objects. Manifold will read foreground color, background color and style information for objects on import, including formatting for area borders. If no color or size information is present in the file, Manifold will use default format settings.

Because sizes are not the same in MapInfo and Manifold, the .tab importer will attempt match sizes as best as possible.

**Data Types**

On import of a MapInfo .mif or .tab file, Manifold will translate MapInfo logical data type columns into **Boolean** data type. Exporting a Manifold drawing to .mif will export **Boolean** columns into MapInfo logical data type columns.

**Datum Naming**

Formats such as MapInfo .mif and .tab do not actually store the names of datums within the projection information stored in the file; instead, the numeric parameters for the datum are saved. When Manifold scans such a file the system will examine these numeric parameters to find a named datum that is a match and will use that datum's name to identify the datum in use.

In some cases, more than one datum may use the same numeric parameters. For example, there are many national datums that are mathematically identical to some generically named datums. When several datums match the given numeric parameters, Manifold will choose a neutrally named datum in preference to a name that uses a specific country name.

**Important Note when Using 64-bit Manifold Editions**

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKx format files. This includes no access to the **MDB** parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut.

Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.
Tech Tips

Depending on MapInfo operation, .tab files containing recently deleted objects may not be imported properly. In such cases, the .tab file may be imported with some or nearly all fields missing. To avoid this situation, before saving the file from MapInfo choose Table - Maintenance - Pack Table to physically delete all elements previously marked as deleted.

Manifold is able to import cases of .tab files that reference shapefiles (.shp), in which case Manifold will automatically import the reference .shp file.

When importing from .tab format Manifold will automatically compare field names given in .tab and .dat files and will choose the longest field name in each case if there is a difference between the .tab and .dat files.
**Import Drawing - TAIF**

TeleAtlas Import Format (TAIF) is normally used for TeleAtlas StreetNet files. Files are normally kept together in a separate directory. Choose any of the files in the directory to start the import process.

**Subtype**  
Choose the **TAIF** subtype: **level 1**, **level 2** or **StreetNet**.

- **Select All** - Check all the boxes in the modules pane.
- **Select None** - Uncheck all the boxes in the modules pane.
- **Select Inverse** - Check all unchecked boxes and uncheck all checked boxes in the modules pane.

**Modules**  
Check modules to be imported. Each module will import as a separate drawing. A map will be created using all the drawings.

**See Also**

Import Drawing - GDF for imports of TeleAtlas MultiNet data sets using **GDF** format.
Import Drawing - MapBase for imports of TeleAtlas (formerly ETAK) MapBase format.
Import Drawing - TIGER/Line

TIGER/Line is a very comprehensive data set created by the U.S. Bureau of the Census. It is issued every year or two to support the Census Bureau's operations. Recent editions have appeared every year or so. TIGER/Line 2000 has appeared in two forms, a "redistricting" version and (in 2001) a full 2000 version that includes Zip Code Tabulation Areas (ZCTAs). ZCTAs provide standardized area representations that approximate the locations of zip code linear features.

Manifold's TIGER/Line importer will read all TIGER/Line versions as of the date of publication of this Manifold release, up to and including TIGER/Line 2006 SE (Second Edition).

Select All - Check all fields. All data fields will be imported with this drawing.

Select None - Uncheck all fields. No data fields will be imported. Tech tip: Use this to uncheck all fields before checking those desired.

Select Inverse - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.

Fields pane Check the data attribute fields to be imported.

Compose areas Check to create area objects. Not checking this box will create only lines and points.

TIGER/Line files can import with hundreds of data fields. It is a good idea to become familiar with the TIGER/Line documentation and to import only those fields that are necessary.

How to import a TIGER/Line file:

1. Decompress the file using WinZip or other utility. This creates numerous files ending in various .RTx extensions.
2. In Manifold, use File - Import - Drawing using Files of type "TIGER/Line Files (*.bw, *.rt*)" to open the file ending in the .RT1 extension.
3. Import the fields of interest. Important fields for most users are the CFCC field that specifies what type of line most lines are and the FENAME (Feature Name) and FETYPE (Feature Type) fields that give the names of roads and other features. Uncheck the Compose areas box unless you are an experienced TIGER/Line user.
4. The result is usually three drawings: a "Chains" drawing that contains lines, a "Polygon Points" drawing that contains points for the centroids for what would be all closed areas if the Compose areas box would have been checked and a "Landmark Features" drawing that contains points showing the locations of landmarks of interest to the Census Bureau.

For base maps, most users will use only the Chains drawing and will delete the other two drawings. The Chains drawing contains roads, water features and other lines in a single drawing. The different objects may be separated into different drawings of roads, water features, etc., by selecting using the CFCC field as follows:

<table>
<thead>
<tr>
<th>CFCC Starts with</th>
<th>Objects</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>Roads</td>
</tr>
<tr>
<td>B</td>
<td>Railroads</td>
</tr>
<tr>
<td>C</td>
<td>Other Transportation</td>
</tr>
<tr>
<td>H</td>
<td>Water Features</td>
</tr>
</tbody>
</table>

To select all roads, use the Query Toolbar to select all records for the CFCC field Starting with A. Edit - Cut the records out of the "Chains" drawing and Paste them into a new drawing called Roads. Likewise, after selecting all records for the CFCC field Starting with H you can Edit - Cut the water lines out of the original "Chains" drawing and Paste them into a new drawing called Water.
TIGER/Line Files

The TIGER/Line files are extracts of selected geographic and cartographic information from the Census Bureau's TIGER (Topologically Integrated Geographic Encoding and Referencing) database. There is one archived (zipped) TIGER/Line file for each county or county equivalent. The file names consist of "TGR" + the 2-digit state FIPS (Federal Information Processing Standards) code + the 3-digit county FIPS code. For example, "TGR01031.ZIP" is the TIGER/Line file set for Coffee County, Alabama.

Unzipping a TIGER/Line .zip file creates a set of 17 files, one per TIGER/Line "record type" that collectively contain the drawings and tables for that TIGER/Line county. For example, the Redistricting Census 2000 TIGER/Line files consist of 17 record types that collectively contain geographic information (attributes) such as address ranges and ZIP Codes and their Add-On codes for streets, names, feature classification codes, codes for legal and statistical entities, latitude/longitude coordinates of linear and point features, landmark features, area landmarks, key geographic locations, and area and polygon boundaries.

Some counties or statistically equivalent entities do not require all of the 17 record types and therefore have less than 17 files. If the types of data contained in Record Types 4, 6, 7, 8, 9, and Z are not appropriate for a given county or statistically equivalent entity, then the U.S. Census Bureau does not include files for those record types.

The file for each county (or statistically equivalent entity) is identified by the state and county FIPS code after the "tgr" in the file name (for example, tgr42107.rt1). The suffixes used for the record type files have been changed to make it easier to identify each record type file (when working with uncompressed versions of the county files). The suffix consistently is .rtn where n is the record type.

For detailed information on TIGER/Line (including which record types correspond to which features and fields), visit the Census Bureau's site at www.census.gov and drill down into their TIGER pages. Download the TIGER/Line documentation in .pdf form, currently running over 300 pages. The TIGER/Line data dictionary in Chapter 6 of the documentation contains a complete list of all the fields in the 17 record types. Other chapters cross-list the fields by feature attribute and geographic entity type.

ZIP Code Fields

ZIPL, ZIPR and similar fields (providing ZIP codes in TIGER/Line) are imported as fixed-length ANSI text fields. ZIP codes cannot be imported as integers because leading zeros, as in "02138", are significant in ZIP codes.

Notes

The manifold.net team would like to thank Bob Heitzman for his excellent tutorial on TIGER/Line usage within Manifold as well as for his continued advice and his generous contribution of TIGER/Line expertise. The tutorial is available from the manifold.net web site's Resources page.
Import Drawing - UDL

Manifold can create a drawing directly from data stored in a geocoded table. This capability is directly analogous to the creation of a linked drawing from a geocoded table except that instead of the drawing being linked to the originating table it is created as an independent drawing within the Manifold project.

A Microsoft Universal Data Link (UDL) file is a way of capturing an OLE DB connection within a file that may be easily "opened" without the need to deal with complex OLE DB dialogs (except once when the UDL is first set up).

Such imports are accomplished by choosing File - Import - Drawing and then choosing Data Sources () in the Files of type box to launch the Data Source dialog. The desired data source can then be configured and used in the Data Source dialog.

Drawings can be imported from geocoded tables using any of the data access methods, such as connection to an OLE DB data source specified by a UDL file, provided by Manifold. Dialogs used are the same as for creating a linked drawing from a geocoded table, except that linked drawings always invoke the Data Source dialog and the result of an import is an imported drawing rather than a linked drawing.

Importing and Linking Tables
Linked Drawings
Create a Linked Drawing from a Geocoded Table
Import Drawing - VCT

Idrisi32, a GIS application, uses .vct format to store drawings. Manifold's .vct importer works automatically to import the drawing with no options.

VCT format is used by Idrisi32 to store vector data. The format consists of two files, a .vct file and a .vdc file that are similarly named, for example, isolines.vct and isolines.vdc. Both files are required to get objects as well as data attributes. If either of the required files is missing the data has been damaged and Manifold will not be able to import the file.
Import Drawing - VMAP

VMap data set products use the "vector product format" (vpf) utilized first by the US Defense Mapping Agency and later by its successor, the National Imagery and Mapping Agency (NIMA). They feature a vast number of files organized into libraries. "VMap" is derived from "Vector Smart Map". The Manifold VMAP importer can also handle World Vector Shoreline Plus (WVS+) data as published in "vpf" form.

VMap data set products are produced in several levels of resolution:

- **VMap Level 0** - Details similar to 1:1 million-scale or 1:2 million-scale paper charts.
- **VMap Level 1** - Details similar to 1:250,000-scale paper charts.
- **VMap Level 2** - Details similar to 1:50,000-scale and 1:100,000-scale paper charts.

VMap Level 0 is equivalent to the famous Digital Chart of the World with slightly different attribute coding. Some, but not all, VMap Level 1 data sets are available to the public in the US. VMap Level 2 may or may not be available to the public. Manifold's VMap importers read all three VMap variations.

VMAP data sets are organized as "libraries" that are kept in DHT files. There is no extension to the DHT file, as see above. In the illustration above we open a DHT file on CD number 155 of the VMap Level 1 collection that cover the entire Earth.
Most VMAP1 files have both a "lib" library and a "rference" library. The lib library contains most of the points, lines and areas while the rference library contains place names and other text labels that will be imported into Manifold as labels.

Library
Choose the library within this DHT to be imported.

Select All - Check all the boxes in the coverages pane.

Select None - Uncheck all the boxes in the coverages pane.

Select Inverse - Check all unchecked boxes and uncheck all checked boxes in the coverages pane.

Coverages
A list of layer categories within the library. Most layer categories will import as several drawings.

Import each coverage to separate folder
A good idea to leave checked: will create a new folder in the project into which all of the components from this coverage will be imported. Helps keep the project organized.

Import Fields
Check to import data attributes along with object geometry.

Import Z
Import elevation if provided for an object. Import Z causes an additional drawing to be created filled with points, each of which has a Z coordinate.

Tip: The fastest way to check just one box is to first Select None and then check the box desired. The fastest way to check all boxes except one is to first Select All, uncheck that box, and then choose Select Inverse.

Typical VMap Contents

Data in most VMap data sets are separated into twelve categories that NIMA calls coverages. Although the word "coverage" in legacy GIS usage normally means "layer", in this case the word is used to mean "category of
layers." In VMap each coverage contains data related to a particular subject category, for example "Transportation."

VMap data sets group coverages within "libraries." A reference library containing four reference coverages is also provided with general information to orient the user. The usual arrangement is that a VMap data set is provided on a CD together with a main DHT file that lists all the libraries on that CD. The reference library contains overview cartographic information showing the very broad area (at low resolution) within which the more detailed libraries on the CD are provided.

VMap Level 0 organizes data sets for the entire world onto four CDs. VMap Level 1 organizes worldwide coverage on over 200 CDs. VMap Level 2, of course, uses many hundreds of CDs. The following VMap 1 coverages are typical of all three VMap versions.

**Data Library**

**VMap Import Results**

Importing most VMap "coverages" results in the automatic import of numerous drawings. For convenience, these are organized into maps that correspond to the "coverage." In the example above, we have imported the bnd "coverage" and so have created a bnd map that includes the various drawings listed.
The illustration above shows part of the map in a greatly reduced map window (using camouflage green color for the background, of course!).

**VMap Data Fields**

For specific information on the numerous data fields and other data characteristics of VMap data sets, visit NIMA's page at [http://www.nima.mil](http://www.nima.mil) and download the various online publications that describe VMap.

**See Also**

See the Example Import a VMAP Level 1 File
Import Drawing - WKx

Manifold can create a drawing directly from data stored in a geocoded table. This capability is directly analogous to the creation of a linked drawing from a geocoded table except that instead of the drawing being linked to the originating table it is created as an independent drawing within the Manifold project.

Such imports are accomplished by choosing File - Import - Drawing and then choosing Data Sources () in the Files of type box to launch the Data Source dialog. The desired data source can then be configured and used in the Data Source dialog.

Drawings can be imported from geocoded tables using any of the data access methods, such as from a Lotus WKx file, provided by Manifold. Dialogs used are the same as for creating a linked drawing from a geocoded table, except that linked drawings always invoke the Data Source dialog and the result of an import is an imported drawing rather than a linked drawing.

Note that what can visually appear to be a "table" in a spreadsheet file to the eye might not really be organized as a table from the perspective of Microsoft's table-reading, data access software. If Access cannot find a table to read in the Lotus file, Manifold will not be able to either.

Important Note when Using 64-bit Manifold Editions

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKx format files. This includes no access to the MDB parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut.

Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

Although Microsoft is slowly moving forward towards 64-bit operation of Office and the JET components used by Access and Excel, at the present writing (2010) this is such a total kludge that while it is possible to get 64-bit access to Access or Excel it is just easier for most to continue using the 32-bit versions. See comments in the 32-bit and 64-bit Manifold Editions topic.

Create a Linked Drawing from a Geocoded Table
**Import and Export**

**Import Drawing - XLS**

Manifold can create a drawing directly from data stored in a geocoded table. This capability is directly analogous to the creation of a linked drawing from a geocoded table except that instead of the data table being linked to the original spreadsheet inside the XLS file it is created as an independent table within the Manifold project. The drawing (or drawings, since the import can create more than one drawing depending on the import options) is still linked to the data table via a query, so updating the coordinate values in the data table and refreshing the drawing by using the View - Refresh Data command will move the drawing objects. If desired, the drawing can be unlinked from the query and the data table with the Drawing - Unlink command.

Such imports are accomplished by choosing File - Import - Drawing and then choosing Data Sources () in the Files of type box to launch the Data Source dialog. The desired data source can then be configured and used in the Data Source dialog.

Drawings can be imported from geocoded tables using any of the data access methods, such as from an Excel XLS file, provided by Manifold. Dialogs used are the same as for creating a linked drawing from a geocoded table, except that linked drawings always invoke the Data Source dialog and the result of an import is an imported drawing rather than a linked drawing.

Note that what can visually appear to be a "table" in a spreadsheet file to the eye might not really be organized as a table from the perspective of Microsoft's table-reading, data access software. If Access cannot find a table to read in the Excel file, Manifold will not be able to either.

**Important Note when Using 64-bit Manifold Editions**

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKx format files. This includes no access to the MDB parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut.

Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

Although Microsoft is slowly moving forward towards 64-bit operation of Office and the JET components used by Access and Excel, at the present writing (2010) this is such a total kludge that while it is possible to get 64-bit access to Access or Excel it is just easier for most to continue using the 32-bit versions. See comments in the 32-bit and 64-bit Manifold Editions topic.

**Import Image**

**Importing Images**

Import images into Manifold using the File - Import - Image dialog. In addition, images stored within databases using spatial DBMS technology can be imported by connecting to the database using Database Console, clicking on the image to highlight it and then clicking the Import button in the Database Console toolbar.

When using the File - Import - Image dialog the Files of type choice acts as a filter for what is displayed in the browse pane in the Import dialog. Simple file types are imported directly from the Import dialog by choosing the desired type in the Files of type box. More complex imports from data sources such as databases are imported by choosing Data Sources () in the Files of type box and then using the Data Source dialog.

Formats used to save drawings vary widely in their capabilities. Some formats save projection information and some, such as .dxf or many types of .shp files, do not. When a drawing format contains projection information, Manifold will automatically use that projection information.
Formats that do not preserve projection information (the majority) will require manual intervention to place and scale the image correctly within a geographic context. Most often the image will be placed in a geographic context through georegistration.

**Note:** USGS DOQ files as provided on CDs are normally not georegistered. Most often these are .jpg format files created from the original DOQ format files and provided on CD without the .jpg extension.

See the Projections and Images topic for an introduction to projection issues involving images.

**Importing Satellite Image Formats**

Many formats used for satellite images are located under File - Import - Surface because such formats are often used to present non-visual data as raster data sets. See the Importing Surfaces topic.

For example, HDF, HDF EOS and HDF SeaWiFS formats are found in the File - Import - Surface dialogs. If you don't see a desired format listed in the image importers, check under surfaces.

When importing HDF files, use HDF SeaWiFS for SeaWiFS data in .hdf format and use HDF EOS for Earth Observation Satellite data in .hdf format. While the ordinary HDF converter will also import some data from HDF SeaWiFS files it will ignore multidimensional data chunks (called Scientific Data Sets or SDSs) that are used to contain pixels. Note also there is a CEOS SeaWiFS importer for data in that form.

Some file types, such as ENVI, ERDAS and ERS (ECW) files, can contain either surface or image data, depending on how the data is intended to be interpreted. The ENVI, ERDAS and ERS (ECW) importers occur both in the File - Import - Surface and File - Import - Image menus and have a subtype option to allow specification of image or surface upon import.

**Importing Georegistered Images**

The preferred format for importing georegistered images is GeoTIFF format. This standard is supported by over 150 companies and provides for reliable import of images with correct georegistration. Some other formats, such as ECW can also save projection information.

**Use of World Files**

An obsolete way of providing partial projection information for images is the use of "world" files. World files do not contain the name of the projection used. They simply provide certain local projection values and leave it up to the user to manually specify the actual projection in use. A world file is a small text file that accompanies the image file. For example, an image called Europe.jpg that is an ordinary graphics file in JPG format might be accompanied by a small file called Europe.jpegw, which is the world file. The Europe.jpegw file is an ordinary ASCII text file containing a few lines of text. The extension ".jpgw" is used to let GIS software know that it is a world file.

If we opened up the Europe.jpegw world files in Notepad we would see something like the following:

```
4.000000
0.000000
0.000000
-4.000000
574400.000000
4145600.000000
```

The numbers provide information on local offset and local scale for whatever projection is in use. However, the world file does not actually say what projection has been used. When publishing images accompanied by world files the assumption is that the user knows what projection is supposed to be used and is capable of manually specifying it in the GIS software being used.

This is a really stupid system, of course, since the moment images are distributed away from their author and other people who know the secret of what projection was used there is nothing in the world file to tell the rest of normal humanity what the author intended. If you are using images accompanied by world files, it is critically
important to search carefully through the website from which you downloaded the images to find any information that describes what projection was used. If you cannot find a file or web page that specifies the actual projection that was used the world file alone will not help you georegister the image.

Once you know the projection you can georegister images accompanied by world files by adding the local projection parameters they specify to the projection in use. Manifold makes this easier by automatically reading the local projection information from a world file that accompanies an image file. When loading images from TIF, BMP, GIF, JPG, PCX, PNG and TGA formats, Manifold scans the directory to see if there is a similarly named file having one of the two common world file extensions. If so, Manifold opens the world file and loads the local projection information from the world file.

For TIF, BMP, GIF, JPG, PCX, PNG and TGA formats the world file extensions are usually in the form .tifw, .bmpw, .gifw, .jpw, .pcxw, .pngw and .tgaw respectively; however, some world files may have extensions in the form .tfw, .bpw, .gfw, .jgw, .pxw, .pgw and .taw respectively. Manifold will automatically read world files having either the ".tifw" or ".tfw" style of filename extension.

Once the image has been imported, it must be opened and the Edit - Assign Projection dialog must be used to specify the correct projection. See the Download and Mosaic Terraserver Images topic for an example of this process using world files and images.

**Typical Image Formats**

Manifold can import from many different image formats. Some are highly specialized formats that provide much data organized in a complex way. Precise description of certain specialty formats is beyond the scope of this document. In such cases, please refer to the originating agency or company for detailed documentation on their format.

Interested in support for a new format not listed below? See the Contacting manifold.net topic for information on suggesting a new format.

Searching Internet with a good search engine will find numerous references to format documentation as well. For example, searching for "PNG" and "Portable Network Graphics format" on Google turns up the PNG home page as the first hit.

- **ADRG** NIMA Arc Digitized Raster Graphics.
- **BMP** Microsoft .bmp graphics format. Imported as a partially georegistered image if accompanied with a .bpw or .bmpw "world" file. Manifold can import .bmp images that are RLE compressed.
- **CADRG / CIB** NIMA Compressed Arc Digitized Raster Graphics (CADRG) and Controlled Image Base (CIB) images. Get free downloads of Operational Navigation Charts (ONC), Tactical Pilotage Charts (TPC) and Joint Operations Graphic - Air (JOG-A). The importer can import individual tiles as well as a composite image defined by an .toc file. Since composite images can be huge, importing individual tiles is a great space and time saver when the entire image is not required.
- **DNG** An Adobe variation of TIFF used in digital photography.
- **DOQ** USGS Digital Ortho Quad images. True "DOQ" files occur with a .doq or .coq extension. "DOQ" files are often provided in the form of .jpg compressed jpeg format images. Use the .jpg image importer for those
- **ECW / JPEG2000** Compressed images in either ECW or JPEG2000 compressed format. Any size ECW or JPEG2000 image may be imported.
- **EMF** Microsoft Windows Extended Meta File (.emf) and Windows Meta File (.wmf) format. Images imported from will have their dimensions adjusted to not exceed 4096 pixels in X or Y dimension. This limitation avoids possible problems in the Microsoft GDI driver. Images imported
will use white background color.

**ENVI IMG**  Image/surface format from ENVI, "The Environment for Visualizing Images". Import uncompressed ENVI .img files. (Manifold does not support compressed ENVI image import.) In addition to the usual image types, the importer will import 12 bit images from .img files.

**ERDAS GIS**  ERDAS files in .gis or .lan formats. Imported using the File - Import - Surface dialog.

**ERDAS IMG**  ERDAS files in .img format. Works for IMAGINE format .img files.

**ERS**  Earth Resources Mapping (ERMapper) images or surfaces in .ers files. .ers files saved with projection information will be correctly georegistered on import if the projection used is one supported by Manifold. Since this format can be used for either images or surfaces, when importing choose the subtype (either surface or image) desired once the importer launches.

**GIF**  Common .gif graphics files. Imported as a partially georegistered image if accompanied with a .gfw or .gifw "world" file.

**HDF**  A graphics format often used in remote sensing.

**JPEG**  Standard .jpg and .jpeg format, all types. Imported as a partially georegistered image if accompanied with a .jgw or .jpgw "world" file. Imports EXIF tags as well.

**NITF**  National Imagery Transmission Format - a format used mostly by military users in the US and UK for images. Also used for some satellite images generated by high-resolution commercial satellites. Often has .ntf extension. Any extended data (such as text) in an NITF file will be imported into a comments component.

**PCX**  PC Paintbrush format by ZSoft. Imported as a partially georegistered image if accompanied with a .pxw or .pcxw "world" file.

**PNG**  Portable Network Graphics (PNG) format, pronounced "ping." Imported as a partially georegistered image if accompanied with a .pgw or .pngw "world" file. Billed on the current PNG home page as "A Turbo-Study Image Format with Lossless Compression." The original acronym is said to mean "PNG's Not GIF." This is a superb format that can be used to replace GIF everywhere (even on web pages) with better compression and higher quality images.

**PPM**  Portable PixMap (PPM) format. Intended as a "lowest common denominator" color image file format. Used in UNIX systems.

**SGI**  Silicon Graphics workstation graphics format.

**SID**  "MrSID" images using LizardTech proprietary format. Requires prior installation of the free LizardTech MrSidDecode.exe utility. See the Import Image - SID, MrSID help topic for details.

**SPOT**  SPOT satellite images, often provided in 10-meter resolution.

**SRTM**  NASA Shuttle Radar Topography Mission data using files in one or more of the following file formats:

- .hgt - Height. Files import as Int16 surfaces.
- .err - Error data. Files import as Int16 surfaces named "…Error".
Import and Export

.import - Incidence angle data. Files import as Int16 surfaces named "...Incidence".

.imag - Image. Files import as grayscale images named "...Image".

.pol - Polarization angle. Files import as palette images named "...Polarization".

SUN Sun workstation graphics format.

TGA AT&T Truevision Targa format. Imported as a partially georegistered image if accompanied with a .taw or .tgaw "world" file.

TIFF Tagged image file format, using .tif and .tiff extensions. Manifold's .tif importer reads all types of .tif files including GeoTIFF georegistered images and .tif images partially georegistered using a .tfw or .tifw "world" file.

(Various DBMS formats) Manifold can import images from information stored in tables or created by queries. Imported using the Data Source dialog. See the discussion below.

DB2 Data Sources Connect to IBM DB2 equipped with the DB2 Spatial Extender using IBM's native spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

Oracle Data Sources Connect to an Oracle data sources using the Oracle Call Interface (OCI), the native Oracle interface for exchanging data. Exchanging images with Oracle data sources via OCI automatically maps images into Oracle GeoRaster form (if GeoRasters are supported by the Oracle product in use). A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

PostgreSQL Data Sources Connect to PostgreSQL equipped with the PostGIS spatial extender using native PostgreSQL connection technology. Connections made using this data source will have any password required masked so that later usage will not inadvertently expose the password. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

SQL Server Data Sources Connect to Microsoft SQL Server 2008 spatial DBMS facilities using native SQL Server 2008 spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

Important: Using a vendor's native spatial DBMS connection technology (like those above) provides better performance and allows using features, such as built-in spatial DBMS facilities, not exposed through generic database interfaces such as ODBC, OLE DB and ADO .NET. At the present writing, only Oracle Spatial provides a built-in GeoRaster type. Other spatial DBMS products are supported using Manifold-managed image and surface storage.

Note: because the Database Console provides a more convenient user interface for browsing databases, we will almost always use the Database Console to import or link components from a database instead of using the File - Import or File - Link menu commands.

XML Files Created upon Export and Used on Import
Not all formats to which Manifold can export have the ability to correctly save projection information. As a safety measure to ensure that projection information is never lost, Manifold always writes an accompanying .xml file when exporting drawings, images, labels, maps or surface components to a file. The accompanying .xml file contains coordinate system information and some other metadata. The XML file is created for all formats, even those that correctly save coordinate system information.

When Manifold imports drawings, images, labels or surfaces, the system will check for an accompanying .xml file that might have been written by Manifold. If such an .xml file exists, Manifold will read it and use the information it contains to load a correct coordinate system.

See the XML Accessory File Format topic for details on the internal organization of this file.

Imported or Linked Images from Tables or Queries

Manifold can import images or link images from information stored in tables or provided by queries by using the Data Source dialog. The tables and queries used to create linked images may be inside the Manifold project or they may be in external databases.

Linked images may also be created in a two step process, where the virtual table for an existing image is used in a query to manipulate that image or to fetch part of the image based upon desired criteria. A linked image can then be created from that query. This technique is often used within Manifold projects that will be used in an IMS website.

Linked images may also be created from tables or queries stored in external databases. For example, we could use a query to select all columns for all pixels in an image's virtual table and then export that query as a table into an .mdb file or to some other database storage.

When an image is linked from a table or query, each record in the table or query produces a pixel. The coordinates of the pixel are taken from the X and Y columns (cast to integer) specified in the Link dialog. The color of the pixel is taken from either the Color column or the channel columns.

If you have Manifold System Enterprise Edition or greater you can also import images or link images from Oracle data sources that use Oracle's Spatial or Locator technologies. Importing images from Oracle data sources is virtually identical to linking them from Oracle data sources. See the Linked Images from Oracle Servers topic.

Importing or linking images from databases is normally accomplished using the Database Console to connect to the DBMS, and then the Import or Link Database Console toolbar button is used to import or link the desired image from the database.

Importing Images from Image Servers

In addition to the straight File - Import - Image importers within Manifold we can also import images by first creating a linked image that is dynamically fetched from an image server and then unlinking or downloading that linked image to create a local image. This allows us to import images covering a desired area from image servers. See the Linked Images topic to learn more about linked images and image servers.

Important Note when Using 64-bit Manifold Editions

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKx format files. This includes no access to the MDB parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut. Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

Historical Notes

Some graphics formats popular with the graphics communities arise from formerly elite machines used before PCs redefined the meaning of "elite." In case the companies involved are gone or forgotten by the time this is read, a few notes for younger readers:

SGI was an elite graphics company in Mountain View that ended up as a sort-of UNIX workstation vendor famous for three things: 1) Inventing OpenGL, 2) Having a very cool building across the street from the Century 16 cineplex in Mountain View that now, appropriately enough, serves as a museum of computer technology, and 3) Last, but not least, failing to keep up with the price/performance competition of Wintel clones running cool new graphics engines from companies like NVIDIA.

SUN once was an elite UNIX workstation company in Palo Alto before clones banished it to a netherworld existence as a server appliance company. Sun was yet another company that started with a plug-in graphics card, a Multibus card for the "Stanford University Network" (SUN) machines then in use at Stanford. They went on to bigger and better things, including a respectable workstation and server business. Unfortunately, they were run over by the steamroller of high power / low cost clones running ever more applications-rich Windows operating systems, and "workstation" became just another synonym for "PC."

AT&T at one point was the fearsome owner of all telecommunications mojo in the US. They also (we're not making this up) built a "high performance" graphics card called the Targa that plugged into PCs. The AT&T brand lives on as a new identity for one of the "baby Bells" that ended up consuming the parent and is now busy gobbling up cell phone companies.
Import Image - JPG, JPEG

JPEG is a standard for image formatting saved in files that end in a .jpg or .jpeg extension. Manifold recognizes both. For brevity this topic uses only the .jpg extension and should be understood to apply to both .jpg and .jpeg files.

The "JPG" importers in Manifold can import various forms of .jpg or .jpeg files:

- Ordinary .jpg images.
- .jpg images that are accompanied by a jfw "world" file to (hopefully) provide georegistration information.
- .jpg images that contain EXIF tags.

The JPG importer will scan the contents of the .jpg file and automatically select the correct import mechanism.

Ordinary .jpg files are simple graphics files that have no georegistration information. They import as ordinary images and must be georegistered using Manifold’s georegistration tools.

JFW World Files

Sometimes .jpg files intended for geographic usage in a GIS may be accompanied by "world" files in .jfw format. This combination uses two files, a .jpg file and a similarly-named .jfw "world" file to provide some georeferencing information. The .jfw file provided in such cases is not part of the JPEG standard but rather is an auxiliary file invented by GIS types who for whatever reason did not have the ability to use a truly geographically-aware image file format. The use of world files is an incomplete hack that causes much trouble for novices.

When a .jpg is imported Manifold checks for a .jfw file and does its best to import using whatever information may be found in that file. If a .jfw file is not found Manifold will import the .jpg as an ordinary graphics file without any georegistration.

Limitations of JFW files

JFW’s often will not have all of the information required to georegister an image. For example, some JFW files will only hold offsets and scales (which are correctly read by the importer) but these are not enough to register an image to a location and projection on Earth. For this reason, GeoTIFF or other geographically-aware graphics standards are better standards to use for interchange than JFW.

On occasion it is possible to rescue a JPG/JFW that does not contain complete georegistration information. Many JFW files are saved using Latitude / Longitude values for the pixels in the accompanying .jpg image. The actual .jfw file is a plain text file that can be opened with Notepad or some other text editor and inspected to see what it contains. We can sometimes guess by looking at the scales, offsets and dimensions numbers in the JFW that the intended projection system is simple Latitude / Longitude.

If the data is in Latitude / Longitude projection it is fairly easy to import the files and add the necessary projection information by changing the values in the Edit - Assign Projection dialog.

To import a .jpg / .jfw in Latitude / Longitude projection:

1. Import the file using the JPG importer.
2. Open the Edit - Assign Projection dialog. The coordinate system will be reported as the default Orthographic projection with offsets and scales from the JFW correctly read into Local Offsets and Local Scales.
3. Write down the values for Local Offsets and Local Scales.
4. Change the projection to Latitude / Longitude.
5. Modify Local Offsets and Local Scales to the values written down in step 3 above.
6. Check to make sure the coordinate system units combo is set to Degree.
7. Press OK.
Note that if one cannot determine the intended projection of the .jfw by inspecting the file there may be some accompanying documentation that describes the intended use of these files.

**EXIF Tags**

Exchangeable Image File Format (EXIF) is a standard used mostly by digital cameras for adding information to JPEG images produced by those cameras. EXIF tags can contain a very wide variety of information that is inserted into images by camera programmers. Manifold recognizes both EXIF tags as well as EXIF tag directories written by major camera vendors.

If a .jpg image contains EXIF tags, Manifold will write the information from those tags into the Notes pane properties for that image. To see the EXIF information, open the image: with the focus on the opened image the Notes pane will show the EXIF information for that image.

.jpg images containing orientation EXIF tags will be rotated and flipped as necessary to use the orientation specified.

**XMP Tags**

Extensible Metadata Platform (XMP) is an XML based metadata format used to embed a seemingly endless variety of information into images. If a .jpg image contains XMP tags Manifold will read the information into the component notes as is done with EXIF tags.

**Comments**

In addition to use with JPG files, Manifold supports the use of "world" files to import georegistered images from other formats, specifically from BMP, GIF, JPG, PCX, PNG, TIF and TGA files using JFW-like "world" files (with BPW, GFW, JGW, PXW, PGW, TFW and TAW extensions respectively).
Import Image - SID, MrSID

Multiresolution Seamless Image Database (MrSID) is a closed, proprietary format for storing images originally developed at the US Government's Los Alamos National Laboratory in the early and mid 1990's and then exclusively licensed in a somewhat aberrant transaction to a small private company. Despite the general replacement of MrSID by more modern formats such as ECW and JPEG2000 (both of which are true open formats), there are still legacy collections of images that utilize MrSID format.

There are three ways of getting MrSID files into Manifold:

- In Windows, open a command prompt window and use the LizardTech mrsiddecode.exe utility to convert MrSID files into GeoTIFF and then import the GeoTIFF. This utility can be used in a background command prompt batch file so that the long time required can be invested during off hours.
- In Manifold, use the Import - Image dialog for MrSID files. This Manifold capability depends upon having the mrsiddecode.exe utility or equivalent installed on the computer and is equivalent to the above. This is a good idea only for smaller MrSID files since the process of conversion and import takes so long.
- Use a third party utility or script that converts MrSID into ECW or some other modern format. The ECW files can then be instantly opened in Manifold.

Using the Manifold Import - Image dialog, the MrSID files can take nearly forever to import into Manifold because they are first converted by a LizardTech or other vendor's utility into GeoTIFF and then the GeoTIFF file is imported into Manifold. Depending on the speed of the hardware used, the version of windows, the amount of RAM available and other system configuration issues, the conversion and import process takes tens of minutes for small files, hours for medium or large images, many hours for larger images and days for very large images.

Even using the mrsiddecode.exe converter as a standalone program in a command prompt window the conversion process is very slow because the conversion process can go no further than the speed of the converter provided by LizardTech, which is not known for speedy performance. Users should be forewarned that a MrSID image occupying 100MB on hard disk as a .sid format file can expand into tens of gigabytes as a GeoTIFF file and take days to convert. Recent editions of the LizardTech decoder are said to be faster, but users should nonetheless brace themselves for a trial by endurance.

Comments published on various web sites have expressed the opinion that the LizardTech converter has artificially been made slow to discourage users from abandoning MrSID format in favor of more modern alternatives. Whether that is true or not, it is certainly true that there are converters available that have been written by third parties which are said to operate much faster than the LizardTech converter and which use the same command line interface. Manifold can work with any such compatible converter as well.

Whatever the speed of the decoder used, the wisest strategy for dealing with MrSID images is usually to acquire or to create a small Windows command prompt batch file to use the LizardTech or other decoder to convert all MrSID images in background to a more modern format like ECW, running the decoder at night or during the weekend. If this process is accomplished before the images need to be used there will be no inconveniences from delays in importing when using the images in Manifold. See the comments at the end of this topic on how to accomplish this strategy.

Until that strategy is accomplished, the Manifold Import - Image dialog used for MrSID import as discussed in this topic should be used only for relatively small MrSID files when sufficient time is available, such as when taking a break or going to lunch, for the process to be completed.

Requirements for Importing MrSID Files

Manifold can import images from MrSID format if a compatible MrSID decoder has been installed on the same computer. Manifold can work with any MrSID decoder that is compatible with the mrsiddecode.exe decoder distributed by the LizardTech company, the current licensees of MrSID. At this writing, the mrsiddecode.exe decoder may be downloaded at no charge from the www.lizardtech.com website. Drill down through the site to find the download page for this utility.

A possibly better idea than using the LizardTech tools (which run unnecessarily slow) is to use MrSidDecodeFast or MrSidExtract or similar third party tools that run much faster.

Since websites change frequently, if you cannot find the decoder on the LizardTech website, use Google or some other search engine to find the current location for downloads of that utility. For example use MSN search or Google to search for "MrSidDecodeFast.zip" or "MrSidDecodeFast" to locate these utilities.
Since company policies frequently change, if the necessary decoder is not available for free at some time in the future from the LizardTech site, you may use any other compatible MrSID decoder by changing the name of the .exe file to use in the Tools - Options - File Locations dialog to the name of the decoder.exe you use. For example, you could change it to MrSidDecodeFast.exe if you have downloaded that free third party utility.

To prepare your system for MrSID use:

1. Login as Administrator if running Windows 2000, XP or 2003.
2. Visit the www.lizardtech.com site and find and download the mrsiddecode.exe and mrsidinfo.exe utilities. These may be packaged in zip files that may be downloaded and then unzipped to get the .exe files they contain.
3. Place both .exe files somewhere in the PATH defined for executable programs on your Windows system, such as in the C:\WINDOWS or C:\WINNT folder.
4. Verify the programs have been installed and are functional by opening a command prompt window in Windows and doing a mrsiddecode.exe -help command. If it runs OK you know your .exe has been installed correctly.
5. Launch Manifold and in the Tools - Options - File Locations dialog verify that the correct names for the mrsiddecode.exe and mrsidinfo.exe files are entered.

Once the mrsiddecode.exe and mrsidinfo.exe utilities have been installed on your system and their names have been correctly entered into the Tools - Options - File Locations dialog, you may use File - Import - Image to import MrSID format images into Manifold.

To import a MrSID image:

1. Choose File - Import - Image
2. In the Import Image dialog's Files of type box choose SID Files (*.sid)
3. Browse to the file desired and double-click on the file to be imported.

**Import Image Dialog Options**

- **Scale**: Scale reduction factor ranging from x1 (native) (full resolution) to x64 (one sixty-fourth the resolution). Use this when importing large MrSID images to automatically create a smaller, albeit lower resolution, image.
- **Use password**: Check this box to supply a password if the MrSID file requires a password.

MrSID images are very large images and even small MrSID files can take a substantial amount of time (tens of minutes or even longer) to import into Manifold. The process is lengthy because first the decoder utility program is used to decode the MrSID image and then the decoded image must be imported into Manifold. The entire process of using an external utility is hidden from the user with Manifold showing only the standard import and progress bar dialogs.

By default, Manifold will automatically set the Scale factor so the resulting image will contain less than 4 million pixels. For large MrSID images, this will result in an image with substantially less resolution than is possible. To import a full resolution image, use the x1 (native) setting for Scale. **Caution**: large MrSID images can be very slow to import due to the incredibly slow functioning of the LizardTech MrSidDecode utility. As a safety measure, Manifold will raise a confirmation dialog when commanded to import a MrSID image with more than 16 million pixels.

Since MrSID has largely been replaced in modern usage by open formats such as ECW and JPEG2000, Manifold will import MrSID images but it will not export images to MrSID nor utilize MrSID as a native format for linking images as compressed images as is possible with ECW and JPEG2000.

The assumption is that if you are working with Manifold and must deal with an image in MrSID format, your first objective will be to immediately convert the image into a compressed image and to save it out as an ECW or JPEG2000 format image. Once the image has been converted into and saved as a compressed image, loading it and viewing it will be instantaneous and it no longer will be imprisoned in MrSID format.
Because many images are trapped in MrSID format and most GIS users would prefer to use a more open format, some software developers who have licenses to work with ECW or JPEG2000 have created scripts or utilities such as MrSidExtract.exe that can automatically traverse a hard disk and find and convert all MrSID files into ECW files. That is the most efficient way of freeing images trapped in MrSID format since the lengthy process of converting a MrSID image to a more modern format can be accomplished at night or over the weekend.

Although at the present writing the mrsiddecode.exe and mrsidinfo.exe utilities may be freely downloaded from the www.lizardtech.com website, it is not clear exactly what their licensing agreement says about who may or may not use those utilities. If these utilities disappear or if you disagree with their licensing terms, you may be able to find alternative decoders on the web that perform the same function.

Manifold.net has not tested any alternative decoders, but just as there was once only a single MP3 encoder/decoder and now there are many including MrSidDecodeFast. Manifold includes the ability to work with alternative decoders should such emerge in the future so long as they are compatible with the mrsiddecode.exe and mrsidinfo.exe utilities.

Projections and MrSID Files

MrSID format can optionally store projection information for the contents; however, many MrSID files do not contain such information. Such files may or may not be accompanied by .sdw "world" files. Unfortunately, the LizardTech code for decoding MrSID files cannot be relied upon to capture either any projection information within the MrSID file or from the accompanying "world" file, if any. Manifold has facilities to deal with these issues should the need arise.

Although in theory the mrsiddecode.exe decoder created by LizardTech should capture any coordinate system (projection) information available for the MrSID file when converting to GeoTIFF, as a practical matter there is no guarantee that it will do this correctly in all cases, since it might not know the GeoTIFF equivalents for certain coordinate systems that can occur in a MrSID file. It would be unwise to expect the LizardTech code to accurately capture projection information in all cases: instead, the experienced user is always ready to manually assign the desired projection to the imported image.

When relying upon third party decoders, such as MrSidDecodeFast or MrSidExtract there is no guarantee there will be any projection information inside the MrSID or that the third party decoder will be able to do anything with it. In such cases it is wise always to assume the worst and to manually assign the desired projection to the resultant ECW or image.

When manually assigning projections, we can consult any metadata or readme files that accompany the imagery, as well as manually opening and reading any "world" files that might accompany the images. See the discussion on importing shapefiles and in the Importing Images topic for a forewarning of the hassles that may be encountered using "world" files and strategies for dealing with those hassles. Users of MrSID files should be ready to assign a correct projection manually after importing such images using the Manifold facilities provided for assigning projections.

Users of MrSID files should also be forewarned that MrSID compilations that are published by various government bodies historically have had a much higher percentage of erroneous metadata descriptions than any other format known to Manifold Technical Support. Users routinely report problems of misaligned MrSID images that were obtained from some government web site, imported into Manifold, the projection described by the metadata carefully assigned and then when the image was found to be inaccurately registered the problem was ultimately traced to inaccurate metadata published on that web site.

The Strange History of MrSID

According to the Los Alamos National Laboratory website, MrSID technology is based upon two Los Alamos inventions: MCICR and MrSID.

Monte Carlo Image Conversion and Representation (MCICR) technology was developed at Los Alamos by Vance Faber, James White, and Jeffrey Saltzman. MCICR consists of two patented techniques for compressing 24-bit digital images into smaller 8-bit images without loss of resolution.

Multiresolution Seamless Image Database (MrSID) was developed by Jonathan Bradley through the Los Alamos laboratory's Sunrise Project funding. The combination of MCICR with MrSID produced image technology that became known as MrSID.

As described on the Laboratory's web site, "Before licensing Los Alamos' technologies, Paradigm Concepts, Inc. was a small service-based New Mexico company consisting of 4 employees. Since licensing MCICR and MrSID, the company has grown to 55 employees, including Bradley, Faber, and White - three of the original developers."

Also quoted on the Laboratory's web site was the then-President of LizardTech, John R. "Grizz" Deal, stating, "The creation of the MrSID technology could have only happened at the world's premier applied research institution, Los Alamos National Laboratory. Without MrSID, LizardTech would not be in business today."

According to news reports, LizardTech grew considerably after the above was written, and at its peak employed approximately 150 people. However, the company apparently never achieved a solid financial footing and spent considerable effort in an obnoxious legal action against Earth Resource Mapping, the company that created ECW, a competing image compression technology.

LizardTech was apparently trying to win in court what it could not accomplish in a competitive marketplace. The lawsuits failed, in some cases so miserably that courts ruled against LizardTech in summary judgments. Nonetheless, the legal actions consumed large sums in legal fees. A further negative outcome was that LizardTech clouded the status of open standards like ECW and JPEG2000 with potential patent claims, however unfounded, and so caused unnecessary expense within the open source community as LizardTech's claims in court were examined, refuted and ultimately rejected.

Although LizardTech was reported to have raised over $44 million in venture capital money, by 2001 the company was already making massive layoffs, firing about half of its employees, with more layoffs in 2002 as well. It appeared to be well on its way to wasting a staggering amount of venture capital.

By 2003 LizardTech had managed to bum through tens of millions of dollars of venture capital and was forced to fire almost all of its employees and sell the remaining assets to a Japanese company, Celartem Technology Inc. As of this writing, it remains to be seen if Celartem can revive MrSID despite the market preference for open technologies such as ECW and JPEG2000.

Why is MrSID Conversion and Import so Slow?

The incredibly slow functioning of the LizardTech mrsiddecode.exe program when converting MrSID images to an open standard like GeoTIFF appears to be yet another negative result of having to work with a seriously "closed" format like MrSID. Because the read/write technology inside the decoder is also closed, users are kept hostage by whatever inclination LizardTech may or may not have to improve the functioning of the decoder. Some critics have expressed the opinion that LizardTech has provided a deliberately slowed-down conversion utility to make it difficult to convert images from MrSID format to modern, open formats like ECW or JPEG2000.

Considering that LizardTech's historical strategy has been to maintain MrSID as a deeply closed format, it is obvious that LizardTech has every incentive not to try to speed up a decoder that allows people to free themselves from MrSID captivity. If anything, a cynic would point out that LizardTech would want to offer a decoder that works well enough for the company to say that MrSID can be converted to open formats but which works so poorly that as a practical matter few people will be able to use the decoder to free themselves from MrSID.

Contrast that situation to the much more open world of ECW or JPEG2000, where source code is easily available and as a result anyone who wants to contribute to improved performance can do so. As a result, both ECW and JPEG2000 provide at least four times faster performance in “native” compressed format applications and allow conversion to other formats using dramatically faster processes than made available by LizardTech.

The recommended Manifold strategy for dealing with MrSID is to convert MrSID format images into ECW format. Although LizardTech may not provide any tools for that purpose, there are third party tools such as MrSidExtract.exe that can do an automatic conversion of all MrSID files in a given folder or folders into ECW.

Many people have written scripts or programs like MrSidExtract.exe that can search through a folder or even a hard disk full of MrSID files and in background accomplish the above two-step process to convert those images into ECW. If accomplished in background, such as at night or during weekends, the tremendously slow process of getting images out of MrSID and into fast, modern formats like ECW can be done without the interactive pain of sitting and watching a conversion process taking forever. The resulting ECW images can be loaded into Manifold and viewed in seconds.
Such scripts or programs are not a part of Manifold and so are not covered by this documentation. Use a search engine like MSN search or Google or search Manifold forums such as the Georeference forum on the manifold.net home page and the archives of the Manifold-L discussion list to find links to pages that provide such scripts.

**Tech Support**

Although Manifold works with the LizardTech tools and other third party tools, such tools are not a part of Manifold System and are not supported by Manifold Technical Support. As noted above, tools vary greatly in performance, memory requirements, ability to extract projection information and other characteristics. These characteristics are not under the control of manifold.net, nor does manifold.net have any inside ability to either analyze or repair shortcomings in non-Manifold products. If you experience any unexpected results when using a third party tool, contact the source of that tool for assistance.

Compressed Images
Import and Export

Import Image - TIF [Various types]

The "TIF" importers in Manifold can import different types of .tif or .tiff files (*.tiff files are treated the same as *.tif files and vice versa):

- Ordinary tif images that do not have embedded georegistration information.
- DRG's and other tif images that are accompanied by a tfw "world" file to (hopefully) provide georegistration information.
- .tif images written in GeoTIFF standard. This standard embed projection information using "tags" within a single tif file.
- .tif images encoded using 11-bit data.
- .tif images encoded using 16-bit data.
- .tif files containing 16-bit integer LAB data.
- .tif files containing 16-bit integer and 32-bit / 64-bit floating point CMYK data.
- .tif files containing complex (that is, real + imaginary) number values.
- .tif images that contain EXIF tags.

The TIF importer will scan the contents of the .tif file and automatically select the correct import mechanism. Surfaces imported from .tif files with floating-point values will automatically set pixels with invalid or infinite floating-point values invisible.

Ordinary .tif or .tiff files are simple graphics files that have no georegistration information. They import as ordinary images and must be georegistered using Manifold's georegistration tools.

TIF or TIFF format files can occur in a specialized form called GeoTIFF files that save projection information along with the image. GeoTIFF files embed information about the projection within tags in the .tif or .tiff format file. Images saved using GeoTIFF require only one file with a .tiff or .tif file extension. True GeoTIFF files will import automatically with correct georegistration.

Do not confuse the GeoTIFF format with a different format using .tif files called the "TFW" format. This format uses two files, a .tif file and a=tfw "world" file to provide some georeferencing information. TFW is not the same as GeoTIFF. Adding to the confusion is that some packages will create both a GeoTIFF file as well as a .tfw "world" file. The .tfw file provided in such cases is not part of the GeoTIFF standard.

Manifold looks first for GeoTIFF tags within the image. If these are found the image is imported using GeoTIFF standards. If GeoTIFF tags are not found Manifold checks for a .tfw file and does its best to import using whatever information may be found in that file. If neither GeoTIFF tags nor a .tfw file are found Manifold will import the .tif as an ordinary graphics file without any georegistration.

Limitations of .tfw files

TFW's often will not have all of the information required to georegister an image. For example, some TFW files will only hold offsets and scales (which are correctly read by the importer) but these are not enough to register an image to a location and projection on Earth. For this reason, GeoTIFF is a better standard to use for interchange than TFW.

On occasion it is possible to rescue a TIF/TFW that does not contain complete georegistration information. Many TFW files are saved using Latitude / Longitude values for the pixels in the accompanying .tif image. The actual .tfw file is a plain text file that can be opened with Notepad or some other text editor and inspected to see what it contains. We can sometimes guess by looking at the scales, offsets and dimensions numbers in the TFW that the intended projection system is simple Latitude / Longitude.

If the data is in Latitude / Longitude projection it is fairly easy to import the files and add the necessary projection information by changing the values in the Edit - Assign Projection dialog.

To import a .tif / .tfw in Latitude / Longitude projection:

1. Import the file using the TIF importer.
2. Open the Edit - Assign Projection dialog. The coordinate system will be reported as the default Orthographic projection with offsets and scales from the TFW correctly read into Local Offsets and Local Scales.

3. Write down the values for Local Offsets and Local Scales.

4. Change the projection to Latitude / Longitude.

5. Modify Local Offsets and Local Scales to the values written down in step 3 above.

6. Check to make sure the coordinate system units combo is set to Degree.

7. Press OK.

Note that if one cannot determine the intended projection of the .tfw by inspecting the file there may be some accompanying documentation that describes the intended use of these files.

TIF Files with 16-bit Channels

Image channels are normally 8 bit so that RGB images can be created in the usual way but some TIF files, such as those published by DigitalGlobe that contain satellite images, contain 16 bit image channels.

If a TIF file contains multiple 16-bit channels each channel will be imported into a separate surface component. If the TIF file contains three 16-bit channels the system will create an RGB image component as well. If the TIF file contains four 16-bit channels the system will create an RGBA image component as well.

The composite RGB or RGBA image is synthesized by shrinking each 16-bit channel into an 8-bit range and guessing which channels should be assigned to R, G, B and possibly A. This is bound to result in an unnatural appearance in some cases. If we would like to synthesize an RGB or RGBA image using some other technique or arrangement of channels, we can do this using the full 16-bit surfaces that are also imported.

Although surfaces are normally created with the Display Options shading choice turned on, surfaces created from TIF files will have shading turned off to provide a more "image like" appearance.

EXIF Tags

Exchangeable Image File Format (EXIF) is a standard used mostly by digital cameras for adding information to JPEG images produced by those cameras. EXIF tags can contain a very wide variety of information that is inserted into images by camera programmers. Manifold recognizes both EXIF tags as well as EXIF tag directories written by major camera vendors.

If a GeoTIFF image contains EXIF tags, Manifold will write the information from those tags into the Notes pane properties for that image. To see the EXIF information, open the image: with the focus on the opened image the Notes pane will show the EXIF information for that image.

GeoTIFF images containing orientation EXIF tags will be rotated and flipped as necessary to use the orientation specified.

XMP Tags

Extensible Metadata Platform (XMP) is an XML based metadata format used to embed a seemingly endless variety of information into images. If a GeoTIFF image contains XMP tags Manifold will read the information into the component notes as is done with EXIF tags.

Killing GeoTIFFs with PhotoShop

A GeoTIFF is just a plain, ordinary TIF image with extra tags tossed into the image that specify projection information. That works great if the image editing software you use understands such extra tags. Manifold and certain other image processing packages in the GIS world understand those extra tags. PhotoShop (versions in common usage as of this writing) and virtually all other non-GIS image editing packages don't understand the extra tags. Opening a GeoTIFF with such non-GIS software will almost certainly kill the projection information it contains.

When PhotoShop loads a GeoTIFF it ignores the extra projection system tags and proceeds to display the TIF image just as if it was a plain, ordinary, dumb-format, non-GIS image. When PhotoShop saves that GeoTIFF or
updates it in any way those projection tags have already been lost and the result is that the image is now just a plain, ordinary, dumb-format, non-GIS TIF image. Adios, GeoTIFF!

It is therefore critically important to keep inexpert users away from your GeoTIFF files because they can't seem to resist opening them with some sort of brainless consumer image editing program that will kill the GeoTIFF. Worse yet, it is almost a law of nature that the same sort of inexpert user who does such things will deny to the end of time that they ever touched any files.

The result is that you'll end up with a collection of .tif files that you thought were GeoTIFFs but which you will discover, unpredictably and at random, have been converted into ordinary TIF files and which no longer contain projection information. That's the really annoying part of GeoTIFFs versus TIFs in that since they both end in the same .tif extension there is really nothing to distinguish the two except the presence of invisible projection tags inside the format that only GIS software like Manifold understands.

If you have had the bad luck of inadvertently killing a GeoTIFF by opening it in PhotoShop the bad news is that those projection tags are gone forever. There's nothing about what remains in the .tif that will allow you to get them back. You are now stuck with either getting fresh copies of the GeoTIFFs from the original source, or painfully trying to find out from that original source exactly what the projections were and manually specifying them for each such image using the Edit - Assign Projection dialog.

The solution to the above problems is either to a) keep inexpert users away from your GeoTIFF files, or b) immediately upon acquisition convert the GeoTIFF files to some format, such as ECW, that is less vulnerable to being destroyed by inexpert users. Using ECW is not a bad idea since the files will load a zillion times faster anyway.

World Files and other Formats

In addition to use with TIF files, Manifold supports the use of "world" files to import georegistered images from other formats, specifically from BMP, GIF, JPG, PCX, PNG and TGA files using TFW-like "world" files (with BPW, GFW, GJW, PXW, PGW and TAW extensions respectively).

 Discovery of New TIF Types

TIF and GeoTIFF files can exist in many possible variations, some with very peculiar internal structure known only to their authors. Manifold’s TIF importer handles a very wide range of TIF and GeoTIFF file types, including all commonly occurring types, but it is always possible you may encounter a previously unknown exotic variation. In such cases, the imported image may appear to be blank or all black. If you do encounter a new TIF type and are sure the image does in fact contain data (and is not really blank!), please report the new type to tech@manifold.net so it may be added to the importer.

While all reports of new TIF types are welcome, don't confuse the donation of a new type of TIF with a request for technical support. If you ask any questions or otherwise indicate you would like a response, that's a request for technical support.

If a particular TIF you are working with is not working, the way to get technical support is to use a technical support incident as set forth in the Technical Support topic. If you can’t get a TIF image to appear in a map it is almost certainly a projection error of some kind caused by inaccurate use of the Assign Projection dialog and is almost certainly not a bug in Manifold. Even if it turns out to be a bug in Manifold or the discovery of a new TIF variation (both of which are possible, albeit very rare events), getting an answer back from Technical Support to confirm such a bug or new discovery requires a tech support incident. See the Technical Support topic for details.

Note: A side effect of Manifold’s hunt for new bizarre TIF variations is that users have contributed many examples of TIF files with corrupted headers and other defects. Manifold has therefore evolved the ability to recover from several common cases of corrupted headers and is able in such cases to successfully import the damaged TIF file.

XML Files Created upon Export and Used on Import

Not all formats to which Manifold can export have the ability to correctly save projection information. As a safety measure to ensure that projection information is never lost, Manifold always writes an accompanying .xml file when exporting drawings, images, labels, maps or surface components to a file. The accompanying .xml file contains coordinate system information and some other metadata. The XML file is created for all formats, even those that correctly save coordinate system information.
When Manifold imports drawings, images, labels or surfaces, the system will check for an accompanying .xml file that might have been written by Manifold. If such an .xml file exists, Manifold will read it and use the information it contains to load a correct coordinate system.

See the XML Accessory File Format topic for details on the internal organization of this file.

**Tech Tip**

If you do have a GeoTIFF killed by an inexpert user and that GeoTIFF was created by Manifold, if you still have the auxiliary XML file created by Manifold the situation can be saved. Place the GeoTIFF and its accompanying XML file in the same folder so that when you open the former GeoTIFF the projection information will be restored. Save the GeoTIFF again and the projection information will be re-embedded into what will be once again a GeoTIFF when it is saved. The inclination of inexpert users to kill GeoTIFFs was one of the main reasons Manifold introduced an auxiliary XML file to save projection information, just in case.

**Import Surface**

**Importing Surfaces**

Import surfaces into Manifold using the File - Import - Surface dialog. In addition, surfaces stored within databases as "images" using spatial DBMS technology can be imported by connecting to the database using Database Console, expanding the image to show the Height channel and then importing that Height channel to form an image.

When using the File - Import - Surface dialog the Files of type choice acts as a filter for what is displayed in the browse pane in the Import dialog. Simple file types are imported directly from the Import dialog by choosing the desired type in the Files of type box. More complex imports from data sources such as databases are imported by choosing Data Sources () in the Files of type box and then using the Data Source dialog.

Most surfaces will be imported from file formats, such as USGS DEM, that are dedicated for use as terrain elevation data formats. At times we will also import surfaces from different formats, such as SDTS, which are capable of storing data for surfaces as well as drawings. Some formats, such as .e00, can be used to store drawings, images or surfaces.

Note also that some formats, such as DEM, may occur in different variations that may require use of different formats. For example, 1:250K-scale DEM files use .dem file formats while 1:24K-scale DEM files are really SDTS format files that encode digital elevation data. The former are imported using File - Import - Surface using the DEM importer while the latter are imported using File - Import - Drawing using the SDTS choice.

Some file types, such as ENVI, ERDAS and ERS (ECW) files, can contain either surface or image data, depending on how the data is intended to be interpreted. The ENVI, ERDAS and ERS (ECW) importers occur both in the File - Import - Surface and File - Import - Image menus and have a subtype option to allow specification of image or surface upon import.

Formats used to save surfaces vary widely in their capabilities. Some formats save projection information and some, such as .dxf or many types of .shp files, do not. When a surface format contains projection information, Manifold will automatically use that projection information.

When a surface format does not save projection information, for GIS formats such as ESRI .shp files the surface will be imported into Latitude / Longitude projection as if the units contained were degrees. Most people are sensible enough not to use .shp and similar formats to publish projected maps so this will usually work.

For surfaces imported from non-GIS formats such as AutoCAD .dxf, the surface will be imported using the same default Orthographic projection used for non-geographic images. Such surfaces will always require manual adjustment of parameters in the Edit - Assign Projection dialog.

If a surface format does not save projection information, that information must be added after import via the Edit - Assign Projection dialog.

**Importing Satellite Image Formats**
Many formats used for satellite images are located under File - Import - Surface because such formats are often used to present non-visual data as raster data sets.

For example, HDF, HDF EOS and HDF SeaWiFS formats are found in the File - Import - Surface dialogs. If you don't see a desired format listed in the image importers, check under surfaces.

When importing HDF files, use HDF SeaWiFS for SeaWiFS data in .hdf format and use HDF EOS for Earth Observation Satellite data in .hdf format. While the ordinary HDF converter will also import some data from HDF SeaWiFS files it will ignore multidimensional data chunks (called Scientific Data Sets or SDSs) that are used to contain pixels. Note also there is a CEOS SeaWiFS importer for data in that form.

Importing ESRI exported raster grid files

.e00 is the preferred format for importing grid files from ESRI products. However, ArcInfo can export raster data using "gridsasc" format either as integer or floating point data. There appear to be no standard extensions for such files in universal use within the ESRI community. We suggest saving (or renaming) such files to use either a .grd extension for integer data or an .flt extension for floating point data. Use the File - Import - Surface importer set to GRD files for integer data and FLT files for floating point data.

Typical Surface Formats

Many formats listed as "surfaces" within Manifold could also be considered to be "image" formats. For current information on the following formats, use a good Internet search engine. For example, search "SeaWiFS" for pages describing the SeaWiFS project and data sets.

Interested in support for a new format not listed below? See the Contacting manifold.net topic for information on suggesting a new format.

ADF ESRI .adf format, also sometimes called ArcGrid format. Note that .adf files can contain either raster or vector data. When attempting to import an .adf file as a surface it must contain raster data since surfaces are raster data types. If the .adf file contains vector data it must be imported as a drawing and cannot be imported as a surface.

AVHRR Advanced Very High Resolution Radiometer (AVHRR) data. The AVHRR is a broadband, four or five channel (depending on the model) scanner, sensing in the visible, near-infrared, and thermal infrared bands. Flown on earth observation satellites from TIROS-N to NOAA-15 (orbited 05/13/98). Data available from USGS on CD with resolution of approximately 1.1 km. Get free CDs with intense imagery and EOS sensing that's great for regional observations of vegetation, crop changes.

BIL ESRI .bil files. The ESRI version of what most people call "DEM" files.

CEOS SeaWiFS Sea-viewing Wild Field-of-view Sensor (SeaWiFS). Very cool ocean observation satellite. An eight-band sensor carried on board the SeaStar spacecraft that launched into low Earth orbit on 1 August 1997. 1.1 km resolution. SeaWiFS provides a view of subtle changes in ocean color that signify various types and quantities of marine phytoplankton.

DEM USGS Digital Elevation Module (DEM) files. Note that "real" DEM files are different than DEM data published within SDTS format. To import DEM files published in SDTS format, use the SDTS "drawing" importer.

DEM GLOBE Global Land One-km Base Elevation (GLOBE) project. A 1 km resolution database of terrain elevations for the entire Earth. Perfect for regional terrain elevations such as shaded relief displays for countries or regions. Yet another cool project of the Committee on Earth Observation Satellites (CEOS). Free download via
DEM GTOPO30
GTOPO30 is a global Digital Elevation Model (DEM) with a horizontal grid spacing of 30 arc seconds, approximately 1 kilometer. An older (1996) alternative to GLOBE derived from several raster and vector sources.

DTED
Digital Terrain Elevation Data (DTED) - NIMA military format for terrain elevation. Available in DTED Level 0 resolution for free public download. Higher resolution DTED Level 1 and Level 2 are available to NIMA’s special friends. Manifold reads them all.

EOO
ESRI ArcInfo Export (.e00) format can contain surfaces. If so, Manifold will extract them.

ENVI IMG
Image/surface format from ENVI ("The Environment for Visualizing Images").

ERDAS GIS
ERDAS files in .gis or .lan formats.

ERDAS IMG
ERDAS files in .img format. Works for IMAGINE format .img files.

ERS
ERMapper format used for surfaces. Importing a surface from an ERS file named abc.ERS tries to obtain data from a file named abc.DAT file if the abc file can not be found.

ESRI ASCII GRD
ESRI ASCII format for grids.

ESRI Float Grid FLT
ESRI floating point .flt format (or .hdr format associated with .flt files) for terrain elevation data.

GeoSPOT
A georegistered format for SPOTview data from the SPOT satellite.

GRASS
Surfaces and image in the freeware "GRASS" raster GIS program created by the US Army Corps of Engineers. "70's people find it amusing the Army would call anything it created "grass."

GXF
Geosoft .gxf, an ASCII grid format used for terrain elevation data. Found on the NURE National Uranium Resources USGS CD and in other sources.

HDF

HDF EOS
EOS satellite data in HDF format.

HDF SeaWiFS
SeaWiFS satellite data in HDF format.

IDRISI IMG
IDRISI raster format.

IMDISP
Image Display Program for IDL format.

LAS
Log ASCII Standard (LAS) format used for well logging data. An ASCII format originally developed by the Canadian Well Logging society in the late 1980’s and now used by USGS and others. Choose the .ddr file in the LAS file set.

LULC CTG
Land Use and Land Cover (LULC) data in Composite Theme Grid (CTG) format. Consist of fixed length records with one grid cell for each record. Grid cells are regular point samples of the quad where the center point of each cell is 200 meters from other center points in adjacent cells.

NetCDF
Network Common Data Form data, a format used to describe a very wide variety of data in the scientific
community, using a number of different conventions, or
cantations, as to how that data should be structured
and what it should mean. Manifold's NetCDF importer
makes no effort to interpret data and instead attempts
to import as much of it as possible, in the form of
surfaces or tables. Scalars and 1-dimensional data
modules are imported as tables. 2-dimensional data
modules are imported as surfaces. 3-dimensional data
modules and modules of higher dimensions are
imported as sets of surfaces. The coordinates in the $\text{lat}$
and $\text{lon}$ tables within a NetCDF file are assumed to
refer to the centers of respective pixels for registration
purposes. Components will be registered to the values
in $\text{lat}$ and $\text{lon}$ tables, provided they are uniformly
spaced. Pixels with infinite or invalid floating-point
values will be set invisible on import. Manifold
recognizes and will apply the value of the
$\text{missing_value}$ variable, if present.

**Northwood GRC/GRD**

Northwood / Vertical Mapper grid files containing either
continuous (.grd) or classified (.grc) grids. .grc files
import as palette images since one value is assigned to
all pixels in that class. .grd files import as surfaces since
they provide smoothly-varying gradation.

**NTF**

UK Ordnance Survey NTF files.

**PIX**

Silicon Graphics Alias / Wavefront .pix format

**Raw Text**

Import data from a variety of ASCII files using
configurable user settings.

**Raw Binary**

Import data from a variety of binary files using
configurable user settings.

**SDTS**

SDTS files that contain DEM (Digital Elevation Model)
terrain elevation data. USGS publishes many 1:24K-
scale data sets as SDTS DEM.

**SRTM**

NASA Shuttle Radar Topography Mission data using files
in one or more of the following file formats:

- .hgt - Height. Files import as Int16 surfaces.
- .err - Error data. Files import as Int16 surfaces named
  "...Error".
- .inc - Incidence angle data. Files import as Int16 surfaces
  named "...Incidence".
- .mag - Image. Files import as grayscale images named
  "...Image".
- .pol - Polarization angle. Files import as palette images
  named "...Polarization".

**Surfer GRD**

Surfer 6, 7 or ASCII GRD files, automatically
recognizing the correct Surfer format. Importing a
surface from a Surfer GRD file will derive the local
offset and local scale parameters used for the surface
coordinate system from the file header.

**TAB**

MapInfo .tab files containing surface raster data.

**TIFF**

TIFF rasters containing raster/surface data. Surfaces
imported from .tif files with floating-point values will
automatically set pixels with invalid or infinite floating-
point values invisible.

**XYZ**

Comma-delimited ASCII files containing X, Y and Z
coordinates.

**DB2 Data Sources**

Connect to IBM DB2 equipped with the DB2 Spatial
Extender using IBM’s native spatial connection
technology. A spatial DBMS connection accessed
through the Data Source dialog. This option requires
Enterprise Edition or above.
Oracle Data Sources  Connect to an Oracle data sources using the Oracle Call Interface (OCI), the native Oracle interface for exchanging data. Exchanging images with Oracle data sources via OCI automatically maps images into Oracle GeoRaster form (if GeoRasters are supported by the Oracle product in use). A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

PostgreSQL Data Sources  Connect to PostgreSQL equipped with the PostGIS spatial extender using native PostgreSQL connection technology. Connections made using this data source will have any password required masked so that later usage will not inadvertently expose the password. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

SQL Server Data Sources  Connect to Microsoft SQL Server 2008 spatial DBMS facilities using native SQL Server 2008 spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

Important: Using a vendor's native spatial DBMS connection technology (like those above) provides better performance and allows using features, such as built-in spatial DBMS facilities, not exposed through generic database interfaces such as ODBC, OLE DB and ADO .NET. At the present writing, only Oracle Spatial provides a built-in GeoRaster type. Other spatial DBMS products are supported using Manifold-managed image and surface storage.

Note: because the Database Console provides a more convenient user interface for browsing databases, we will almost always use the Database Console to import or link components from a database instead of using the File - Import or File - Link menu commands.

XML Files Created upon Export and Used on Import

Not all formats to which Manifold can export have the ability to correctly save projection information. As a safety measure to ensure that projection information is never lost, Manifold always writes an accompanying .xml file when exporting drawings, images, labels, maps or surface components to a file. The accompanying .xml file contains coordinate system information and some other metadata. The XML file is created for all formats, even those that correctly save coordinate system information.

When Manifold imports drawings, images, labels or surfaces, the system will check for an accompanying .xml file that might have been written by Manifold. If such an .xml file exists, Manifold will read it and use the information it contains to load a correct coordinate system.

See the XML Accessory File Format topic for details on the internal organization of this file.
Import and Export

Import Surface - ADF
Import ESRI .adf format files. ESRI .adf is sometimes called ArcGrid format.

.adf files can contain raster data, ESRI TIN data or vector (drawing) data. The Manifold .adf importer will automatically configure itself to import either drawings or surfaces as applicable regardless of whether the importer was launched via File - Import - Drawing or via File - Import - Surface. For information on importing .adf files that contain vector data, see the Import Drawing - ADF topic. This topic discusses import of TINs.

Importing a TIN

Importing an .adf file that contains an ESRI TIN pops opens a dialog with the following options:

- **Import points** Import the TIN as a drawing of points, including the height of each point as an attribute in the drawing's table.
- **Import triangles** Import the TIN as a drawing of triangles.
- **Import surface** Create a surface from the TIN of the given Size in pixels (the default).

See Also

Import Drawing - ADF
Import Surface - DEM

DEM files are the most important source of surfaces in the United States. The USGS (www.usgs.gov) publishes vast amounts of data as DEM files for free download from its web site. In addition to the DEM files published by USGS, DEM-style files are used with ESRI's ArcINFO package, with GLOBE worldwide digital elevation data and with GTOPO30 worldwide digital elevation data. All forms of DEM are slightly different and require a different importer.

All DEMS listed below will be imported as georegistered surfaces. Cool!

USGS DEMs

USGS publishes digital elevation data in two resolution levels:

1:250K DEM - 1:250,000-scale Digital Elevation Modules (terrain elevation) suitable for use as surfaces at the county level. These files have a .dem extension. Import them using the DEM Files (*.dem, *.*) setting.

1:24K DEM - 1:24,000-scale Digital Elevation Modules published in SDTS format suitable for use as surfaces at the local level. These correspond to USGS "Quad" maps and are extraordinarily detailed. These files follow SDTS file naming conventions. Use the SDTS drawing importer to import these files (a surface will automatically be created even though a drawing importer was used). Note that unzipping STDS files for a particular USGS Quad will often result in three compressed files. The largest of these files is usually the full accuracy DEM. The others are interpolated to smaller sizes and less detail.

GLOBE

The Global Land One-km Base Elevation (GLOBE) project provides the latest, most modern, public domain terrain elevation database for the entire world. Currently at http://www.ngdc.noaa.gov/seg/topo/globeget.shtml, the data set may be downloaded in 16 "tiles," most of which are very large files (over 100MB each) when unzipped. When unzipped, the GLOBE files have no extensions but will have names like g10g. Import using the DEM GLOBE Files (*.*) setting in File - Import - Surface. GLOBE tiles are so large that most users will crop them to the area of interest using the Crop transform toolbar operator.

GTOPO30

GTOPO30 is a global digital elevation data set with a horizontal grid spacing of 30 arc seconds (approximately 1 kilometer). GTOPO30 was derived from several raster and vector sources of topographic information. GTOPO30 was completed in late 1996. It was developed over a three-year period through a collaborative effort led by staff at USGS’s EROS Data Center. Downloads are currently at http://edcdaac.usgs.gov/gtopo30/gtopo30.html and (after unzipping) may be imported using the DEM GTOPO30 Files (*.dem) setting in File - Import - Surface. Note that although GTOPO30 files use the .dem extension (as well as other file extensions in the GTOPO30 file set) they must be imported using a different importer than the USGS 1:250K-scale DEMs.

GTOPO30 files import into Manifold with invisible pixels at sea level. This makes them handy for use as components in maps showing large areas, since seas may be colored.

ArcINFO DEM

DEM files from ArcINFO are often saved using either a .grd extension or a .bil extension. Import DEM files from ArcINFO using either GRD Files (*.grd) or BIL Files (*.bil, *.hdr) in File - Import - Surface.

Examples
The Alps from GLOBE tile g10, seen as a layer in a map projected into Orthographic projection.

Norwegian fiords from GTOPO30 W020N90 tile seen in a map in Orthographic projection. The surface at left has no background while the one at right has a blue background.
Import Surface - DTED

Using File - Import - Surface with the Files of type filter set to DTED files allows us to import NIMA Digital Terrain Elevation Data (DTED) data. This is a NIMA military format for terrain elevation. DTED data occurs in three resolutions: DTED Level 0 data is published in 30 arc second resolution for free public download. Higher resolution DTED Level 1 and Level 2 are available to NIMA's special friends. Manifold reads them all.

DTED files are georegistered upon import.

Example

Download some DTED data in Military Specification format from the NIMA geospatial engine data server at:

http://geoengine.nima.mil

The data is packaged as a zip file, which will unzip into a dmed file, and dted and text folders. Within the dted folder will be located other folders containing the individual DTED data tiles, usually in files ending in a .dt* extension such as .dt0. Import the .dt* files to create surfaces.

To tile the various surfaces into one big surface, use Copy and Paste to paste them all into one surface.

For example, if in NIMA's server we zoom into the San Francisco Bay area and download the DTED data, after many long minutes of waiting the NIMA server will give us a link to a zip file. We download the zip file, unzip it and find that within the dted folder there are two folders, w122 and w123. Within the w122 folder are four files, n37.avg, n37.dt0, n37.max and n37.min. Within the w123 folder are also four files, also called n37.avg, n37.dt0, n37.max and n37.min. If we import both of the n37.dt0 files (one from the w122 folder and one from the w123 folder), we will end up with two surfaces, one called n37 and the other one called n37 2 (Manifold's default naming scheme appends a "2" to distinguish it from the identically named component already in the project).

The two surfaces show adjacent regions of the San Francisco Bay region. We can copy the n37 2 surface and paste it into the n37 surface to create a single, seamless surface showing the topography of the San Francisco Bay region.
Import and Export

Import Surface - HDF EOS

Although HDF EOS format is found in the importing surfaces menus for Manifold, this format can also be used to store images.

Select All - Check all modules. All data modules will be imported.

Select None - Uncheck all modules. No data modules will be imported. Tech tip: Use this to uncheck all modules before checking those desired.

Select Inverse - Uncheck all previously checked modules and check all previously unchecked modules. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.

Modules pane

Check the modules to be imported.

Subtype

Choose between image or surface. Note that one cannot import EOS data that is a surface as an image and vice versa. If one subtype setting does not work, try the other and re-import.

Create Folders

Create folders in the project to host components created from modules.

Tech Tip: Data that arrives in "hdf" files may be any one of the various HDF formats. Try them all if one doesn't work.
Import Surface - Northwood GRC / GRD

The **Import Northwood GRC / GRD File** dialog allows us to import Northwood / Vertical Mapper grid files containing either continuous (.grd) or classified (.grc) grids. *.grc* files import as palette images since one value is assigned to all pixels in that class. *.grd* files import as surfaces since they provide smoothly-varying gradation.

The **Transform Z values with scale and offset parameters** option when checked will transform imported heights using scale and offset parameters stored within the file. By default the option is turned off.
The **Import Raw Text File** dialog allows us to import surfaces from a variety of ASCII files (`.csv`, `.asc`, `.txt`) that provide terrain elevation data with one data point per line and individual fields within the line separated by some delimiting character. The most common form of such files uses a comma character to separate the fields and is thus known as a *comma separated value* file. Such files are often saved with a `.csv` extension but may also be found with other extensions such as `.asc` and `.txt`. This importer is very similar to the XYZ surface importer.

**Type**
Choose the data type represented by the numbers in the file. Complex data types (that is, a pair of floating point values) will be automatically converted to a single floating point value of equivalent precision.

**Channels**
Number of channels.

**Width**
Horizontal (East / West) dimension of resulting surface.

**Height**
Vertical (North / South) dimension of resulting surface.

**Skip**
Number of lines to skip at the beginning of the file before data begins. Used to ignore titles, comment blocks and other prefatory remarks.

**Interleaving**
Interleaving mode for multi-channel surfaces. Not enabled unless the number of channels is greater than 1.

**Delimiter**
Enter characters that should be considered as delimiters. White space characters (space, tab, end-of-line) are always considered delimiters.

**Null value**
Text string used to represent "no data" in the file. For example, `-9999` is often used to indicate no data for a field.
Import Surface - Raw Binary

The Import Raw Binary File dialog provides a generic importer that can import binary surface data from a very wide variety of different binary data files. Such files may appear with a variety of extensions, such as .bin, .dat or other extensions. ADRG files may be imported using this importer.

**Import Raw Binary File**

![Image of the Import Raw Binary File dialog]

- **Type**: Choose the data type represented by the binary data in the file. Complex data types (that is, a pair of floating point values) will be automatically converted to a single floating point value of equivalent precision.

  The type format box next to the **Type** box contains choices for encoding formats for each of the possible types. For example, integer types can have two possible encodings: Little-Endian (Intel) or Big-Endian (Motorola), and floating point types can be one of ten possible encodings: Cray, Data General, Gould, Hewlett Packard, IBM AIX, IBM MVS, IEEE, IEEE Intel, PRIME, Silicon Graphics, Sun, VAX Ultrix, VAX VMS.

- **Channels**: The number of channels in the file.

- **Width**: Horizontal (East / West) dimension of resulting terrain.

- **Height**: Vertical (North / South) dimension of resulting terrain.

- **Skip**: Number of bytes to skip at the beginning of the file before data begins. Used to ignore unnecessary headers and other prefatory items.

  **Interleaving**: Enabled when the number of channels is greater than 1. Determines channel order within the file:

  - **by band**: File contains all samples for channel 1 followed by all for channel 2 and so on.
  - **by line**: File contains all samples for line 1 of channel 1 followed by all samples for line 1 of channel 2 and so on.
  - **by pixel**: File contains samples from all channels for pixel 1 of line 1 followed by samples from all channels for pixel 2 of line 1 and so on.

- **Line Padding**: Number of bytes to skip after each line.

- **Null value**: Text string used to represent "no data" in the file. For example, -9999 is often used to indicate no data for a field.

For an example using the Raw Binary importer, see the Import a Raw Binary File - NLCD topic.
When importing surfaces using Raw Binary, if there is a similarly-named .xml file in the same folder (for example, importing a Montara.bin raw binary surface file plus a Montara.xml accompanying .xml file in the same folder) Manifold will read the .xml file as well. Manifold can then automatically guess the coordinate system, dimensions and type of the imported surface using metadata found in the .xml file to pre-load choices in the Import Raw Binary File dialog.

.xml files accompanying raw binary surface files are expected to be in the same XML format used when exporting surfaces to raw binary. See the Exporting Surfaces topic.
Import Surface - SRTM

SRTM data is derived from NASA’s Shuttle Radar Topography Mission data, collected on the Space Shuttle STS-99 mission. A shuttle-based radar was used to map virtually the entire land area of Earth between latitudes + and - 60 degrees at resolution of one arc second, with a single elevation pixel covering approximately 30 meters. In addition, a 3 arc second (approximately 90-meter resolution) version of the SRTM data has been prepared.

SRTM data is delivered in up to five files for each region covered. The five files deliver height, error, incidence angle, interferometer image and polarization angle. Most commonly distributed SRTM data is simply the height file. In addition, some US government web sites may distribute portions of the SRTM data (such as SRTM data within the US) converted to various other formats such as ESRI .adf or .bil file formats. The Manifold SRTM importer imports all SRTM files. Because Manifold uses standardized SRTM file names to derive coordinate system information, do not rename SRTM files.

The illustration above shows Mount St. Helens in a terrain view from the N46W123.hgt SRTM 30-meter height data file. Z height has been set to 2.5.

The view in the terrain is from the location marked by a reticle in the surface window seen above. Note that the surface contains some scattered portions of invisible pixels from regions where the SRTM data is missing.

SRTM File Types

|hgt| Height data file. Imports as an Int16 surface using the name of the originating file. |
|err| Error data file. Imports as an Int16 surface named "...Error". |
.inc  Incidence angle data file. Imports as an Int16 surface named "...Incidence". Since incidence angles represent natural shading of the surface as seen from the direction opposite to the satellite, Shading for incidence surfaces is turned off by default.

.mag  Image file. Imports as a grayscale image named "...Image".

.pol  Polarization angle file. Imports as a palette image named "...Polarization*. Gray areas indicate HH polarization and green areas indicate VV polarization.

Coordinate system information for SRTM files is taken from the SRTM filenames, which will be in the form N46W123.hgt (the SRTM 1 arcsecond file showing Mount St. Helens). Therefore, do not rename SRTM files before importing them.

The Manifold SRTM importer will automatically switch between 30-meter and 90-meter resolution mode based on the size of the SRTM file being imported.

**Getting Access to SRTM Data**

Access to SRTM elevation data for the US is fast and easy: download it from USGS web sites. However, the US SRTM data is not as useful as SRTM coverages outside the US.

USGS has long provided terrain elevation data for the United States in much greater resolution than the 30-meter maximum resolution of the SRTM data set, but the availability of 30-meter terrain elevation data for almost the entire world is a real breakthrough for public benefit. 30-meter resolution may not as good as data sets that are available for sale to the public by various private entities and state cartographic monopolies like the UK’s Ordnance Survey, but nonetheless it is a significant improvement over previous public domain data sets. The main interest in SRTM data, therefore, is access to those parts of the SRTM data located outside the US.

Unfortunately, access to the SRTM data set is controlled by NASA and NIMA, who have decided to deny the public full access to this important public data set. NASA and NIMA have made public only those parts of the SRTM data set that are within the borders of the US. Worse still, NASA and NIMA have announced an intention of denying the public access to the 30-meter SRTM data if such data is for a region outside the US. They have announced that the public will be allowed access to only the degraded, 90-meter SRTM data.

As of this writing, NASA and NIMA will allow access to international SRTM data only to selected scientists and other persons who agree with NASA’s and NIMA’s data release politics and who are willing to conform to the repressive, and apparently illegal, constraints imposed on this public data by NASA and NIMA. For example, even if a person is "approved" by NASA and NIMA for access to this public data set, that person must agree to give up his or her First Amendment rights to communicate this public data together with their findings to others.

At manifold.net we believe this is yet another example of how NASA and NIMA go about misusing their funding to illegally deny public access to public data. We believe that the anti-public program for international SRTM data is a classic case of how NASA and NIMA are willing to violate the law to prevent the general public from benefiting from public data.

The SRTM data is not classified and is entirely US in origin. There are no copyrights on the data held by any foreign entity or commercial firm. The data was collected in an unclassified program using public funds and does not appear to qualify in any way for the very limited number of provisions that would allow any agency to deny public access to this public data set. SRTM is considerably lower in resolution than terrain elevation data that is freely sold to the public by agencies such as the UK’s Ordnance Survey or published in innumerable paper maps. We believe that by law, NASA and NIMA must provide access to the full 30-meter SRTM data set to all members of the public.

If you agree, please support the effort to pry SRTM data out of NASA. You can do this by filing a Freedom of Information Act request for 30-meter SRTM data for the international region of your choice. If enough users file FOIA requests for this public data set, it makes it tactically more difficult for NASA and NIMA to deny the FOIA requests or to tell lies about why the data has not been made available to the public as required by law.

**Web Sites**
As always, web sites are subject to change at the whim of the webmaster. The following sites were active as of the date of publication of this Help file:

**http://seamless.usgs.gov/** - Entry page for USGS seamless terrain elevation data. Use it to fetch NED (National Elevation Data) files and SRTM files in various formats.

**http://www.jpl.nasa.gov/srtm/cbanddataproducts.html** - Information page on getting access to international data. Use this as a starter page to find contacts at NASA to who you could discuss filing a Freedom of Information Act request to get access to the 1 arc second international data that NASA and NIMA do not want you to have.

**See Also**

Public Access to Public Data - Manifold's call to action to help pry public data out of repressive agencies. Includes a few tips on making FOIA requests.
Import and Export

Import Surface - XYZ

The Import XYZ File dialog allows us to import surfaces from a variety of ASCII files with the extension .xyz or no extension that provide terrain elevation data with one data point per line and individual fields within the line separated by some delimiting character. The most common form of such files uses a comma character to separate the fields and is thus known as a comma separated value file. The importer is very similar to the Raw Text importer.

This importer will scan the file to be imported to automatically detect the correct values for Type, Width, Height, Delimiter and number of header lines (the Skip parameter). The detected values will be pre-loaded into the dialog.

Type Choose the data type represented by the numbers in the file. Complex data types (that is, a pair of floating point values) will be automatically converted to a single floating point value of equivalent precision.

Width Horizontal (East / West) dimension of resulting surface.

Height Vertical (North / South) dimension of resulting surface.

Skip Number of lines to skip at the beginning of the file before data begins. Used to ignore titles, comment blocks and other prefatory remarks that may occur in header lines.

Delimiter Enter characters that should be considered as delimiters. White space characters (space, tab, end-of-line) are always considered delimiters.

Null value Text string used to represent "no data" in the file. For example, -9999 is often used to indicate no data for a field.

Import Table

Importing Tables

Import tables into Manifold using the File - Import - Table dialog. In addition, tables stored within databases using spatial DBMS technology can be imported by connecting to the database using Database Console, clicking on the table to highlight it and then clicking the Import button in the Database Console toolbar.

When using the File - Import - Table dialog the Files of type choice acts as a filter for what is displayed in the browse pane in the Import dialog. Simple file types are imported directly from the Import dialog by choosing the desired type in the Files of type box. More complex imports from data sources such as databases are imported by choosing Data Sources () in the Files of type box and then using the Data Source dialog.

Tables may be imported into a Manifold project or linked into a project. Importing the table brings the data into Manifold so that it may be stored in the Manifold .map file and managed by Manifold System. Linking the table leaves the data stored in an external file. See the Linking Tables topic for information on linking tables into a Manifold project.
Use **File - Import - Table** to import tables from the following data sources:

**ACCDB**  Microsoft Office 2007 and later.

**CSV**  Comma separated values ASCII files, including files using .txt or .csv or other extensions.

**DB**  Borland Paradox.

**DBF**  dBase and FoxPro.

**DSN**  ODBC file data source that describes an ODBC driver to use. Imported using the Data Source dialog.

**HTML**  Tables in web pages.

**MDB**  Access 97 and later versions of Access .mdb files.

**UDL**  Microsoft Universal Data Link file that describes an OLE DB connection. Imported using the Data Source dialog.

**WKx**  Lotus tables.

**XLS**  Excel tables.

**XLSX**  Microsoft Office 2007 and later.

**ADO.NET Data Sources**  A generic ADO.NET connection allowing use of a .NET .DLL assembly, provider class and connection string (parameters). Imported using the Data Source dialog.

**ADO.NET ODBC Data Sources**  Connect using the standard Microsoft .NET ADO.NET provider for ODBC. Imported using the Data Source dialog.

**ADO.NET OLE DB Data Sources**  Connect using the standard Microsoft .NET ADO.NET provider for OLE DB. Imported using the Data Source dialog.

**ADO.NET Oracle Data Sources**  Connect using the standard Microsoft .NET ADO.NET provider for Oracle. Imported using the Data Source dialog.

**ADO.NET SQL Server Data Sources**  Connect using the standard Microsoft .NET ADO.NET provider for SQL Server. Imported using the Data Source dialog.

**ODBC Data Sources**  Connect to a data source using ODBC drivers installed on this system. Imported using the Data Source dialog.

**OLE DB Data Sources**  Connect to an OLE DB data source using an OLE DB provider installed on this system. Imported using the Data Source dialog.

**DB2 Data Sources**  Connect to IBM DB2 equipped with the DB2 Spatial Extender using IBM’s native spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**Oracle Data Sources**  Connect to an Oracle data sources using the Oracle Call Interface (OCI), the native Oracle interface for exchanging data. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**PostgreSQL Data Sources**  Connect to PostgreSQL equipped with the PostGIS spatial extender using native PostgreSQL connection technology. Connections made using this data source will have any password required masked so that later usage will not inadvertently expose the password. A
Import and Export

spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**SQL Server Data Sources**

Connect to Microsoft SQL Server 2008 spatial DBMS facilities using native SQL Server 2008 spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**Important:** Using a vendor's native spatial DBMS connection technology (like those above) provides better performance and allows using features, such as built-in spatial DBMS facilities, not exposed through generic database interfaces such as ODBC, OLE DB and ADO .NET. For example, exchanging data with Oracle data sources via OCI automatically maps geometry columns into Oracle SDO_GEOMETRY data and will likewise map geometry columns into the native geometry types used by DB2, PostgreSQL and SQL Server 2008.

**Note:** because the Database Console provides a more convenient user interface for browsing databases, we will almost always use the Database Console to import or link components from a database instead of using the File - Import or File - Link menu commands.

In general, except when connecting to Oracle data sources, ADO.NET is a much faster connection technology than OLE.DB or ODBC.

**Importing Tables from Text Formats**

The CSV importer is used to import tables from most text formats, even those that do not use commas to separate the fields. The CSV importer may be set to use different characters as a delimiter. See the Import Table - CSV topic.

**Windows Locale Settings and Table Import**

Manifold's table import routines will recognize Windows locale settings for .mdb, .xls, some .dbf files (depending on drivers used) and some other formats and will automatically convert text fields to Unicode when the database file locale is incompatible with current regional options. For example, an .mdb database created with Spanish locale settings will have text fields automatically converted to Unicode if it is imported on a Windows machine employing French settings.

**Importing .dbf**

The .dbf or DBF format in MS-DOS and Windows arises from the dBase database management system. Due to the popularity of dBase in the 1980's this format has been adopted by many applications, including those in UNIX and other operating systems. Unfortunately, implementers of programs that read and write ".dbf" have at times "extended" the .dbf standard in ways that are not used by any version of dBase and which cannot be read and written by programs that are strictly compatible with the .dbf format as supported by Microsoft.

Some products will create and read .dbf with unusual names, even those with spaces in them, depending on the operating system or product involved. However, in Windows it is a violation of .dbf spec to use file names with spaces in them for .dbf files.

Manifold includes a special .dbf importer that attempts to auto-adapt to different varieties of .dbf files that may be encountered. This is especially important because ESRI "shapefiles," one of the most popular legacy GIS formats, use .dbf files to store data attributes. Because ESRI shapefiles created in UNIX will frequently violate Microsoft standards for .dbf, the Manifold .dbf driver will accept a wide range of bizarre violations of Microsoft spec that occur in shapefiles created with ESRI products.

For example, .dbf records that begin with an invalid leading character but which are otherwise readable are treated as valid, and Manifold's .dbf driver will read .dbf files with non-standard file and field names, even those with spaces in them.
One problem that does arise is that on occasion MEMO fields written by Microsoft's FoxPro application will not load correctly. A workaround is to use ODBC or OLE DB to connect to such files instead of the built-in .dbf importer. That is, instead of specifying a .dbf file in the Files of type box when importing a .dbf file or linking to it, we would specify an ODBC or OLE DB connection in the Files of type box and then use the ODBC or OLE DB dialogs to connect to that .dbf file.

To connect to a FoxPro .dbf file we must first install an ODBC driver for FoxPro which is part of MDAC 2.5, available at:

To read the file via OLE DB we must install an OLE DB provider for FoxPro, available from Microsoft by searching their downloads page at:

http://www.microsoft.com/downloads

**Importing from Excel**

In general, the most efficient way of saving and working with database information, such as tables, is to use a database, namely Microsoft's Access DBMS or similar product. However, many people use Excel as a "quick and dirty" program in which tables are stored. This is rarely as good a strategy as keeping DBMS information in a real DBMS, but it is usually acceptable so long as we keep in mind the limitations of Excel as compared to a real DBMS.

Tables may be imported from Excel spreadsheets provided that the spreadsheet does, in fact, contain something that can be identified as a table. When importing from Excel, Manifold uses Microsoft's own "Jet" database and file access engine using Microsoft's Jet XLS driver to read Excel .xls file format. If the spreadsheet contains something Microsoft recognizes as a table, Manifold will be able to read that table as well.

A "table" in an Excel spreadsheet is a group of columns with the name of the column at the top and values within each column.

For example, the Excel spreadsheet shown above contains a table. Three columns are labeled at the top with values proceeding down the columns.
In contrast, the spreadsheet above does not contain a “table” as far as Microsoft software or drivers are concerned. There are many ways of intermixing data in what to the human eye is a tabular format that nonetheless as far as Microsoft software is concerned is not a table.

The rule of thumb for success is to keep it simple: save tables in Excel with only one table per .xls file, with each table organized as shown in the first Excel illustration above. Do not add anything else, such as explanatory comments, extra titles or text, subtotal calculations and so on. If you are having difficulty importing an Excel table into Manifold, try opening Access and importing the Excel table into Access. If Access can't find a table in the spreadsheet then Manifold also will not be able to find a table in that spreadsheet.

One limitation of Excel when used instead of a DBMS is that Excel does not maintain strong data types as would a DBMS. When the Microsoft Jet XLS driver reads in a table from Excel, it must infer the desired data types by examining the first few values it encounters.

For example, if an Excel column contains both text and numeric entries but the first dozen entries in the column are all numeric, the Jet XLS driver may decide that the column should be treated as a numeric column and might therefore import all values as if they were representations, say, of Floating Point Double numbers instead of a mixture of text and numbers.

The classic situation in which trouble occurs is the case of Excel tables with columns that contain ZIP codes. ZIP codes are postal codes in the United States that, despite appearing as numbers, must be treated as text since leading zeros are significant. For example, there are ZIP codes in the US such as "02138" (in Cambridge, Massachusetts) in which the leading zero is significant. Much software that utilizes ZIP codes will reject the numeric equivalent of "2138" as a malformed ZIP code because it does not contain five characters.

If we store ZIP codes in a column in an Excel table, upon import into Microsoft Access or any other program (such as Manifold) that uses Microsoft's Jet XLS driver to read the .xls file the column containing ZIP codes will be imported as a numeric column and thus leading zeros will be truncated.

This situation may be remedied by either storing such DBMS information in a true DBMS, like Access, or if we must use Excel tables by manipulating it after import into Manifold. For example, such a ZIP code column that was imported as a numeric column could be changed into a text column, all values with only four digits identified and then a leading "0" added to them under the assumption that the reason they are four digits is because a leading "0" was truncated.

Another method is to add ten or so “dummy” values at the beginning of the table where each of the ZIP code values is alphabetic text, thus forcing the Jet XLS driver to recognize that column as text and so preserve any leading zero characters. After the table is imported into Manifold, we can delete the dummy values at the beginning of the table.

**Regional Settings**

When importing data from text file formats like .csv or from .dbf or shapefiles the Regional Options in the system have to match settings within the file that is being imported. This is because such simple formats are too stupid to
understand that in different countries people use different symbols to denote decimal points (that is, either a dot character or a comma). To change Regional Options, do the following:

- Go to the Control Panel and open the Regional Options applet.
- Go to the Numbers page,
- Ensure that the Decimal Symbol is set to ‘.’ (dot),
- Ensure that the List Separator Symbol is set to ‘,’ (comma),
- Press Apply to apply changes if there were any,
- Import the .csv file or shapefile desired.
- After import, restore the original settings of Decimal Symbol and List Separator Symbol if you like.

Another option is to invoke the Data Sources applet (hidden within Administrative Tools folder of the Control Panel if you’re running Win2K) and create a file DSN for the .csv file you want to import. After creating the DSN configure it to use the comma character as a data separator.

Important Note when Using 64-bit Manifold Editions

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKx format files. This includes no access to the MDB parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut. Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

Importing and Linking Tables
Import Table - CSV
Import Table - CSV

CSV refers to a family of ASCII (plain text) formats that save tabular data in the form of one line per record with the values for each field in that record separated by a delimiting character. The comma is most frequently used as a delimiter, hence the name Comma Separated Value (CSV) format. Files that use characters other than commas, such as tab characters or some other character, are not "CSV" files as a matter of strict nomenclature and often use a different three letter extension such as .txt or .tab. Manifold's CSV importer can handle most such cases.

There is considerable variation in how different programs work with "CSV" format. Some programs like to see a comma at the end of each line and others do not. Most programs expect to see only string field values enclosed in quotes, but some like to see all values enclosed in quotation marks whether they are strings or not. Manifold's CSV exporter provides options to deal with both situations.

To import a table from .csv format:

1. Make sure the file to be imported is located on read/write media such as your hard disk, and that you have write permissions in the folder in which the file is located.
2. Choose File - Import - Table from the main menu.
3. In the Import dialog choose CSV Files in the Files of type box and navigate to the file desired. Double-click on the file or click on it and press Open.
4. In the Import CSV File dialog, choose the List Delimiter character and other options. Check the First line contains field names box if the first line in the file contains field names.
5. Press OK.

Controls

- **List delimiter** Enter that character that is used as the delimiter between fields, or choose from a pull down list of frequently used characters. Manifold will suggest a default character, such as a comma, based on an examination of the first few lines of the file.

- **Decimal delimiter** Enter that character that is used as the decimal point delimiter, or choose from a pull down list of frequently used characters. Manifold will suggest a default character, such as a period (in the US) or a comma (in Europe), based on an examination of the first few lines of the file.

- **Text qualifier** Enter that character that is used to denote text fields, or choose from a pull down list of frequently used characters. Manifold will suggest a default character, such as a quotation mark, based on an examination of the first few lines of the file.

- **First line contains field names** Some CSV files contain the names of the fields in the first line. Check this box if that is the case for the file being imported.

- **Force ANSI character set** If unchecked (the default) text data is interpreted using the locale of the current user. If checked, text data is interpreted as using the ANSI code page.

- **Import all fields as text** Import all fields, including numeric fields, as text fields.

- **Scan first … lines to determine field type** Manifold can scan the given number of lines to guess what should be used as a field type for most fields. If the first few lines are likely to be blank or to contain non-representative data, use more lines. For example, suppose a given field might contain values like "123", "333" or "Suite B". If in the first few lines only obvious numeric types are encountered Manifold will guess the field should be a numeric field. If a larger number of lines are scanned Manifold might encounter a "Suite B" type value and thus realize that the field should be a text field. This helps resolve confusion in cases where quotes are
not used within the CSV file to distinguish text fields.

(preview pane) Previews the effect of the specified import options. If what is seen in this pane doesn't make sense, adjust the import options such as the List delimiter or other options.

CSV and similar text formats lose fine control over how numeric fields are represented. Values end up being either text fields or numbers. A better choice for data interchange in the Microsoft world is to use Microsoft's .mdb format whenever possible.

If desired, we can manually specify the types of fields after the table is imported. For example, we could import all fields as text and then manually specify different fields to be integers, floating point numbers and so on as desired.

Export Table - CSV

Link Table

Linking Tables

Link tables into Manifold using the File - Link - Table dialog. In addition, tables stored within databases using spatial DBMS technology can be linked by connecting to the database using Database Console, clicking on the table to highlight it and then clicking the Link button in the Database Console toolbar.

When using the File - Link - Table dialog the Files of type choice acts as a filter for what is displayed in the browse pane in the Link dialog. Simple file types are linked directly from the Link dialog by choosing the desired type in the Files of type box. More complex links from data sources such as databases are linked by choosing Data Sources () in the Files of type box and then using the Data Source dialog.

Tables may be imported into a Manifold project or linked into a project. Importing the table brings the data into Manifold so that it may be stored in the Manifold .map file and managed by Manifold System. Linking the table leaves the data stored in an external file. See the Importing Tables topic for information on importing tables into a Manifold project.

Linking a table into a project leaves the table's data stored in an external database file that is managed by a database provider other than Manifold. Linked tables may be created from external data sources using the following formats and data sources:

- **ACCDB** Microsoft Office 2007 and later. Can be linked read/write.
- **CSV** Comma separated values ASCII files, including files using .txt or .csv or other extensions.
- **DB** Borland Paradox.
- **DBF** dBase and FoxPro.
- **DSN** ODBC file data source that describes an ODBC driver to use. Linked using the Data Source dialog.
- **HTML** Tables in web pages.
- **MDB** Access 97 and later versions of Access .mdb files.
- **UDL** Microsoft Universal Data Link file that describes an OLE DB connection. Linked using the Data Source dialog.
- **WKx** Lotus tables.
- **XLS** Excel tables.
XLSX  Microsoft Office 2007 and later. Can be linked read-only.

**ADO.NET Data Sources**
A generic ADO.NET connection allowing use of a .NET .DLL assembly, provider class and connection string (parameters). Linked using the Data Source dialog.

**ADO.NET ODBC Data Sources**
Connect using the standard Microsoft .NET ADO.NET provider for ODBC. Linked using the Data Source dialog.

**ADO.NET OLE DB Data Sources**
Connect using the standard Microsoft .NET ADO.NET provider for OLE DB. Linked using the Data Source dialog.

**ADO.NET Oracle Data Sources**
Connect using the standard Microsoft .NET ADO.NET provider for Oracle. Linked using the Data Source dialog.

**ADO.NET SQL Server Data Sources**
Connect using the standard Microsoft .NET ADO.NET provider for SQL Server. Linked using the Data Source dialog.

**ODBC Data Sources**
Connect to a data source using ODBC drivers installed on this system. Linked using the Data Source dialog.

**OLE DB Data Sources**
Connect to an OLE DB data source using an OLE DB provider installed on this system. Linked using the Data Source dialog.

**DB2 Data Sources**
Connect to IBM DB2 equipped with the DB2 Spatial Extender using IBM's native spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**Oracle Data Sources**
Connect to an Oracle data sources using the Oracle Call Interface (OCI), the native Oracle interface for exchanging data. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**PostgreSQL Data Sources**
Connect to PostgreSQL equipped with the PostGIS spatial extender using native PostgreSQL connection technology. Connections made using this data source will have any password required masked so that later usage will not inadvertently expose the password. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**SQL Server Data Sources**
Connect to Microsoft SQL Server 2008 spatial DBMS facilities using native SQL Server 2008 spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**Important:** Using a vendor's native spatial DBMS connection technology (like those above) provides better performance and allows using features, such as built-in spatial DBMS facilities, not exposed through generic database interfaces such as ODBC, OLE DB and ADO .NET. For example, exchanging data with Oracle data sources via OCI automatically maps geometry columns into Oracle SDO_GEOMETRY data and will likewise map geometry columns into the native geometry types used by DB2, PostgreSQL and SQL Server 2008.

**Note:** because the Database Console provides a more convenient user interface for browsing databases, we will almost always use the Database Console to import or link components from a database instead of using the File - Import or File - Link menu commands.

In general, **ADO.NET** is a much faster connection technology than **OLE.DB** or **ODBC**.
Linking to a Table within the Project Not Allowed

Although Manifold can link a drawing, image or surface to a table within the same project, linking a table to a different table in the same project is not allowed. This prevents circular references (tables that link to each other in a circular loop) from happening.

Important Note when Using 64-bit Manifold Editions

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKX format files. This includes no access to the MDB parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut.

Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

Importing and Linking Tables for more detailed discussion.

Link Drawing

Link Drawings

Link drawings into Manifold using the File - Link - Drawing dialog. In addition, drawings stored within databases using spatial DBMS technology can be linked by connecting to the database using Database Console, clicking on the drawing to highlight it and then clicking the Link button in the Database Console toolbar.

The File - Link - Drawing dialog always launches the Data Source dialog to enable choice of a data source from which the drawing will be linked. The Data Source dialog is used even in the case of linking drawings from databases stored in simple file types, such as .mdb. See the Data Source dialog topic for an example of creating a data source for a simple file type.

Manifold can create a linked drawing from data stored in tables or queries, using either geometry information stored in the table or latitude / longitude data in columns (geocoded tables). Manifold can also link drawings from spatial DBMS storage.

Linked drawings using geometry in tables are fully editable, are read/write and can include areas, lines or points. When using simple geocoded tables, linked drawings are read-only and by default consist of points, one point for each record, but may optionally be configured to create lines as well.

Linked drawings can be created from tables using any of the data access methods provided by Manifold for use in the Data Source dialog, such as connection to an ADO.NET, ODBC or OLE DB data source. When connecting to vendor-provided spatial DBMS, such as DB2 with IBM Spatial Extender, Oracle, PostgreSQL or SQL Server 2008, Manifold can connect using the vendor's native spatial DBMS connection technology for enhanced performance. Enterprise Edition is required to connect to a native spatial DBMS using the vendor's native connection technology, for example, to connect to Oracle using Oracle's OCI.

Linking to a Table within the Project

Manifold can also link a drawing to a table within the same project. Choose File - Link - Drawing and then use This Project in the Data Source dialog. See the example in the Linked Drawings from Geocoded Tables topic.

Important Note when Using 64-bit Manifold Editions

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKX format files. This includes no access to the MDB parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a
.map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut.

Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

Link Image

Linking Images

Link images into Manifold using the File - Link - Image dialog. In addition, images stored within databases using spatial DBMS technology can be linked by connecting to the database using Database Console, clicking on the image to highlight it and then clicking the Link button in the Database Console toolbar.

When using the File - Link - Image dialog the Files of type choice acts as a filter for what is displayed in the browse pane in the Link dialog. Simple file types and dedicated server options are linked directly from the Link dialog by choosing the desired type in the Files of type box. More complex links from data sources such as databases are linked by choosing Data Sources () in the Files of type box and then using the Data Source dialog.

Images may be imported into a Manifold project or linked into a project. Importing the image brings the data into Manifold so that it may be stored in the Manifold .map file and managed by Manifold System. Linking the image leaves the data stored in an external file or acquired dynamically from an external provider. See the Linked Images topic for important information on using linked images.

Manifold can link images from the following sources:

- **CSV**  Comma separated values ASCII files, including files using .txt or .csv or other extensions. Linked using the Data Source dialog.
- **DB**   Borland Paradox. Linked using the Data Source dialog.
- **DBF**  dBase and FoxPro. Linked using the Data Source dialog.
- **DSN**  ODBC file data source that describes an ODBC driver to use. Linked using the Data Source dialog.
- **ECW / JPEG2000**  Compressed image in either ECW or JPEG2000 compressed format. Any size ECW or JPEG2000 image may be imported.
- **HTML**  Tables in web pages. Linked using the Data Source dialog.
- **MDB**  Access 97 and later versions of Access .mdb files. Linked using the Data Source dialog.
- **UDL**  Microsoft Universal Data Link file that describes an OLE DB connection. Linked using the Data Source dialog.
- **WKx**  Lotus tables. Linked using the Data Source dialog.
- **XLS**  Excel tables. Linked using the Data Source dialog.
- **Image Library Files**  An image library is a folder that contains one or more individual image files, called image tiles, that together
from the desired image.

**ADO.NET Data Sources**
A generic ADO.NET connection allowing use of a .NET .DLL assembly, provider class and connection string (parameters). Linked using the Data Source dialog.

**ADO.NET ODBC Data Sources**
Connect using the standard Microsoft .NET ADO.NET provider for ODBC. Linked using the Data Source dialog.

**ADO.NET OLE DB Data Sources**
Connect using the standard Microsoft .NET ADO.NET provider for OLE DB. Linked using the Data Source dialog.

**ADO.NET Oracle Data Sources**
Connect using the standard Microsoft .NET ADO.NET provider for Oracle. Linked using the Data Source dialog.

**ADO.NET SQL Server Data Sources**
Connect using the standard Microsoft .NET ADO.NET provider for SQL Server. Linked using the Data Source dialog.

**ECWP Image Servers**
Streaming image server providing compressed images in ECW format.

**Manifold Image Servers**
Link images from image servers connected by ISI drivers to Manifold, such as Manifold Image Servers or third party servers such as Google, Yahoo! or Microsoft Virtual Earth. Use of third party servers requires installation of open source ISI drivers for Google servers. See the Linked Images from Manifold Image Servers topic for details.

**ODBC Data Sources**
Connect to a data source using ODBC drivers installed on this system. Linked using the Data Source dialog.

**OLE DB Data Sources**
Connect to an OLE DB data source using an OLE DB provider installed on this system. Linked using the Data Source dialog.

**OGC WMS Servers**
Streaming image server using well-known OGC WMS protocols.

**TerraServer Server**
Link an image from Microsoft's TerraServer image server.

**DB2 Data Sources**
Connect to IBM DB2 equipped with the DB2 Spatial Extender using IBM's native spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**Oracle Data Sources**
Connect to an Oracle data sources using the Oracle Call Interface (OCI), the native Oracle interface for exchanging data. Exchanging images with Oracle data sources via OCI automatically maps images into Oracle GeoRaster form (if GeoRasters are supported by the Oracle product in use). A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**PostgreSQL Data Sources**
Connect to PostgreSQL equipped with the PostGIS spatial extender using native PostgreSQL connection technology. Connections made using this data source will have any password required masked so that later usage will not inadvertently expose the password. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**SQL Server Data Sources**
Connect to Microsoft SQL Server 2008 spatial DBMS facilities using native SQL Server 2008 spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**Important:** Using a vendor's native spatial DBMS connection
technology (like those above) provides better performance and allows using features, such as built-in spatial DBMS facilities, not exposed through generic database interfaces such as ODBC, OLE DB and ADO.NET. At the present writing, only Oracle Spatial provides a built-in GeoRaster type. Other spatial DBMS products are supported using Manifold-managed image and surface storage.

**Note:** because the Database Console provides a more convenient user interface for browsing databases, we will almost always use the Database Console to import or link components from a database instead of using the File - Import or File - Link menu commands.

In general, **ADO.NET** is a much faster connection technology than **OLE.DB** or **ODBC**.

**Imported or Linked Images from Tables or Queries**

Manifold can import images or link images from information stored in tables or provided by queries. The tables and queries used to create linked images may be inside the Manifold project or they may be in external databases.

Linked images may also be created in a two step process, where the virtual table for an existing image is used in a query to manipulate that image or to fetch part of the image based upon desired criteria. A linked image can then be created from that query. This technique is often used within Manifold projects that will be used in an IMS website.

Linked images may also be created from tables or queries stored in external databases. For example, we could use a query to select all columns for all pixels in an image's virtual table and then export that query as a table into an .mdb file or to some other database storage.

When an image is linked from a table or query, each record in the table or query produces a pixel. The coordinates of the pixel are taken from the X and Y columns (cast to integer) specified in the Link dialog. The color of the pixel is taken from either the Color column or the channel columns.

If you have Manifold System Enterprise Edition or greater you can also import images or link images from Oracle data sources that use Oracle's Spatial or Locator technologies. Importing images from Oracle data sources is virtually identical to linking them from Oracle data sources. See the **Linked Images from Oracle Servers** topic.

**Linking to a Table within the Project**

Manifold can also link an image to a table within the same project. In the Link dialog choose Data Sources () and then use This Project in the Data Source box.

**Converting a Linked Image to a Local Image**

An image linked from a remote server can be converted to a native (local) image within the project using the Image - Convert To or Image - Unlink commands. Images can also be fetched with different levels available using the Image - Download command.

**Important Note when Using 64-bit Manifold Editions**

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to **DB**, **HTML**, **MDB**, **XLS** or **WKx** format files. This includes no access to the **MDB** parts of Manifold **MFD** and MapInfo **TAB** imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut. Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

Queries and Images or Surfaces

Link Surface

Linking Surfaces

Link surfaces into Manifold using the File - Link - Surface dialog. The File - Link - Surface dialog always launches the Data Source dialog to enable choice of a data source from which the surface will be linked. The Data Source dialog is used even in the case of linking surfaces from databases stored in simple file types, such as .mdb. See the Data Source dialog topic for an example of creating a data source for a simple file type.

Manifold can create a linked surface from data stored in an external table or query, the records of which contain position and height values for the surface's pixels. If the data in the table or query changes, such as when records are added, deleted, or their height values are changed, the corresponding pixels in the surface will automatically be added, deleted or changed in height. Linked surfaces are read-only because their content is controlled entirely by the external table or query. To make a change in a linked surface, change the data in the external table or returned by the query.

Linked surfaces are therefore perfect for a wide class of Manifold IMS applications where surfaces must be dynamically updated based on changing information stored in database management systems. For example, a pollution emissions tracking application might show the current shape and density contouring of a surface representing a pollutant cloud based upon data that is stored in a SQL Server database. To take another example, a layer in an IMS application may be created that shows that part of a surface that is above a particular height, so that users viewing a map can see what parts of the map lie above or below a particular height.

Linked surfaces may be created from tables or queries using the following formats and data sources, connecting through the Data Source dialog:

- CSV Comma separated values ASCII files, including files using .txt or .csv or other extensions.
- DB Borland Paradox.
- DBF dBase and FoxPro.
- DSN ODBC file data source that describes an ODBC driver to use.
- HTML Tables in web pages.
- MDB Access 97 and later versions of Access .mdb files.
- UDL Microsoft Universal Data Link file that describes an OLE DB connection.
- WKx Lotus tables.
- XLS Excel tables.
- ADO.NET Data Sources A generic ADO.NET connection allowing use of a .NET .DLL assembly, provider class and connection string (parameters).
- ADO.NET ODBC Data Connect using the standard Microsoft .NET ADO.NET
Import and Export

Sources provider for ODBC.

**ADO.NET OLE DB Data Sources**
Connect using the standard Microsoft .NET ADO.NET provider for OLE DB.

**ADO.NET Oracle Data Sources**
Connect using the standard Microsoft .NET ADO.NET provider for Oracle.

**ADO.NET SQL Server Data Sources**
Connect using the standard Microsoft .NET ADO.NET provider for SQL Server.

**ODBC Data Sources**
Connect to a data source using ODBC drivers installed on this system.

**OLE DB Data Sources**
Connect to an OLE DB data source using an OLE DB provider installed on this system.

**Oracle Data Sources**
Connect to an Oracle data sources using the Oracle Call Interface (OCI), the native Oracle interface for exchanging data. Manifold can **import** surfaces from Oracle when surfaces are stored as GeoRasters in Oracle, but can **link** surfaces only from a table or query in Oracle using a combination of coordinate and height columns.

**Note:** because the Database Console provides a more convenient user interface for browsing Oracle databases, we will almost always use the Database Console to import or link components from an Oracle database instead of using the File - Import or File - Link menu commands. This option requires Enterprise Edition or above. See the Oracle Spatial Facilities topic for additional information.

**This Project**
Link a surface to a table within this project.

In general, **ADO.NET** is a much faster connection technology than **OLE.DB** or **ODBC**.

**Linking to a Table within the Project**

Manifold can also link a surface to a table within the same project. In the Link dialog choose **Data Sources ()** and then use **This Project** in the **Data Source** box.

**Important Note when Using 64-bit Manifold Editions**

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to **DB**, **HTML**, **MDB**, **XLS** or **WKx** format files. This includes no access to the **MDB** parts of Manifold **MFD** and MapInfo **TAB** imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the **Manifold System (32-bit)** shortcut, perform the export from or import into a **.map** project file and then re-launch Manifold in 64-bit mode using the **Manifold System (64-bit)** shortcut. Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold **.map** project file and linked using the Manifold ODBC driver.

Export Drawing

Exporting Drawings

Export drawings from Manifold by right-clicking on the drawing in the project pane and choosing export, or by opening the drawing and then using the **File - Export - Drawing** dialog. In addition, drawings can be exported into databases using spatial DBMS technology can be exported by using the Data Source dialog. See the Export Drawing - Oracle topic for a typical example of exporting to a spatial DBMS as can also be done for DB 2 with Spatial Extender, PostgreSQL/PostGIS, SQL Server 2008, SQL Server 2005 with Manifold Spatial Extender, and just about any DBMS using Manifold's ability to create and use generic spatial indices.

When using the **File - Export - Drawing** dialog the **Files of type** choice acts as a filter for what is displayed in the browse pane in the Export dialog. Simple file types are exported directly from the Export dialog by choosing the desired type in the Files of type box. More complex exports into data sources such as databases are exported by choosing Data Sources in the Files of type box and then using the Data Source dialog.

Manifold System exports drawings directly into a selected set of the most common GIS interchange formats. Enterprise Edition exports to all Professional Edition formats as well as adding .e00 and export to spatial DBMS formats such as Oracle spatial database formats.

**Professional Edition**

- **DXF** AutoCAD 14 and greater .dxf format.
- **MIF** MapInfo .mid / .mif format.
- **KML, KMZ** XML-based KML or KMZ format used by Google Earth and others.
- **MFD/MDB** Manifold Release 4.50 .mfd / .mdb format.
- **SDTS** US Federal SDTS (Spatial Data Transfer Standard) format.
- **SHP** ESRI ArcView .shp ("shapefile") format.

**Enterprise Edition**

- **E00** ESRI ArcInfo .e00 format.

**DB2 Data Sources** Connect to IBM DB2 equipped with the DB2 Spatial Extender using IBM's native spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**Oracle Data Sources** Connect to an Oracle data sources using the Oracle Call Interface (OCI), the native Oracle interface for exchanging data. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**PostgreSQL Data Sources** Connect to PostgreSQL equipped with the PostGIS spatial extender using native PostgreSQL connection technology. Connections made using this data source will have any password required masked so that later usage will not inadvertently expose the password. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**SQL Server Data Sources** Connect to Microsoft SQL Server 2008 spatial DBMS facilities using native SQL Server 2008 spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**Important:** Using a vendor's native spatial DBMS connection technology (like those above) provides better performance and allows using features, such as built-in spatial DBMS facilities, not exposed through generic database interfaces such as ODBC, OLE DB and ADO.
.NET. For example, exchanging data with Oracle data sources via OCI automatically maps geometry columns into Oracle SDO_GEOMETRY data and will likewise map geometry columns into the native geometry types used by DB2, PostgreSQL and SQL Server 2008.

See the links above for topics on each exporter.

To export a drawing:

1. Open the drawing.
2. Choose File - Export - Drawing.
3. In the Export dialog choose the desired format in the Save as type box.
4. Browse to the desired folder and specify a name (without extension) in the File name box.
5. Press OK.

Limitations of Target Formats

Drawing formats in common use in GIS and CAD do not usually have the ability to host the full set of information content available within Manifold drawings. Most exports therefore will simplify data in some way. Field names may need to be truncated to eight characters, or projection information may need to be abandoned. Data attributes may not be able to store the full range of data types allowed within Manifold. Formats will not be preserved except with colors in .mif export.

If a drawing is to be exported to a legacy GIS format, such as .shp format, it should be maintained with the limitations of the target format in mind. A least common denominator set of guidelines:

- Use simple field names, no more than eight characters.
- Avoid spaces or other special characters in drawing or field names.
- Use only simple data types: integer, floating point, or text.
- Assume any opacity settings will be lost.
- Assume only default formats will apply.

The above limitations are profound, of course, and negate some of the benefits of using Manifold.

XML Files Created upon Export and Used on Import

Not all formats to which Manifold can export have the ability to correctly save projection information. As a safety measure to ensure that projection information is never lost, Manifold always writes an accompanying .xml file when exporting drawings, images, labels, maps or surface components to a file. The accompanying .xml file contains coordinate system information and some other metadata. The XML file is created for all formats, even those that correctly save coordinate system information.

When Manifold imports drawings, images, labels or surfaces, the system will check for an accompanying .xml file that might have been written by Manifold. If such an .xml file exists, Manifold will read it and use the information it contains to load a correct coordinate system.

See the XML Accessory File Format topic for details on the internal organization of this file.

Important Note when Using 64-bit Manifold Editions

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKx format files. This includes no access to the MDB parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut. Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

Example: Storing a Drawing in Manifold Spatial DBMS
Export Drawing - DXF

DXF or .dxf is a format used by AutoCAD. Manifold exports to DXF format files suitable for use with AutoCAD 14 and higher versions. Drawings and labels components may be exported to DXF.

To export a drawing to DXF format:

1. Open the drawing in a drawing window.
2. Choose File - Export - Drawing from the main menu.
3. In the Export dialog choose DXF Files in the Save as type box and specify a filename to use. Press Save.
4. Check the Synthesize Z data box and choose a field to be used for Z data if Z data is to be exported into the drawing.
5. Press OK.

Controls

**Synthesize Z data**  
When checked, the field selected in the combo box will be used to generate Z data that will be exported into the drawing. Not checked by default.

Exporting a DXF with elevation data will embed elevation tags into the resulting polyline entities.

Exporting Labels to DXF

Label components may be exported to DXF as follows:

- Labels bound to lines are exported as though they are bound to the centroids of each line.
- Line breaks within multi-line labels are removed.
- Label rotation angles are preserved.
- Exported labels will follow their display order (from lowest to highest).

Exporting Maps to DXF

Map components may also be exported to DXF. Any image and surface layers in the map will be omitted during export to DXF.

Tech Tip

When exporting a drawing or map to a DXF file Manifold will adjust component names by replacing characters that are not supported by AutoCAD with spaces.
Export Drawing - E00

E00 or .e00 format is an ESRI format used for spatial interchange with ArcInfo and similar products. Export to .e00 format is available only with Manifold Enterprise Edition licenses. If you have not purchased Enterprise Edition, you will not be able to export to .e00 format.

To export a drawing to E00 format:

1. Open the drawing in a drawing window.
2. Choose File - Export - Drawing from the main menu.
3. In the Export dialog choose E00 Files in the Save as type box and specify a filename to use. Press Save.
4. Check the fields that are to be exported. Buttons are provided for Select All, Select None and Select Inverse to rapidly change which fields are to be exported for drawings containing many fields.
5. Press OK.

Controls

Select All - Check all fields. All data fields in the drawing will be exported.

Select None - Uncheck all fields. No data fields will be exported. Tech tip: Use this to uncheck all fields before checking those desired.

Select Inverse - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.

Technical Note

All Manifold editions can import .e00 files containing both vector and raster data, along with coordinate system (projection) information.

Manifold Enterprise Edition can export vector and raster data in .e00 format as well. Exporting vector data generates the following data sections: ARC (double-precision), CNT, PAL, PRJ, IFO (with .AAT, .BND, .PAT and other subsections as necessary). Exporting vector data to .e00 creates .e00 files analogous to .e00 files of "coverages" exported by ESRI products.

.e00 is an undocumented format that apparently has been changed by ESRI over time. Although Manifold's .e00 import and export capabilities will obviously attempt to follow any changes introduced by ESRI, there is no guarantee that what works today with current versions of ESRI products will also work with future ESRI products that did not exist at the time this Manifold release was created. For best compatibility with the widest range of ESRI products that can read or write .e00, make sure to upgrade to the latest Manifold release and service pack available.

Enterprise Edition
Export Drawing - KML, KMZ

KML is an XML-based format originally used for “annotations” in Google Earth displays. KMZ is exactly the same format compressed using “zip” compression with a three-letter file name extension of .kmz. KML can be used for showing points or other vector objects from a GIS format drawing as well as for images. Manifold includes the ability to export a drawing or image as a Google Earth KML or KMZ file. It's a quick and convenient way of publishing your GIS data for use with Google Earth or other applications that can use KML, such as NASA World Wind, Microsoft Virtual Earth applications and others.

Manifold can also import KML and KMZ. See the Import Drawing - KML, KMZ topic for additional import information.

KML and KMZ support Latitude / Longitude projection using the WGS 84 Auto datum only. Drawings to be exported to KML or KMZ can be in any projection and will be re-projected on the fly into Latitude / Longitude during export; however, to avoid a potentially slow re-projection process it is wise to explicitly re-project drawings into Latitude / Longitude using the WGS 84 Auto datum before export. This not only avoids a slow export, it also provides an opportunity to catch errors before export if the re-projection results in a strange display as might happen if the initial projection was not correctly assigned, say, after importing projected data from some format that does not store projection information.

Unlike drawings, images must be already in Latitude / Longitude projection using the WGS 84 Auto datum to be exported to KML or KMZ.

KML format as produced for Google Earth is a simplified format that records only the geographic locations and shapes of objects and up to two fields per object, a Name field and a Description field. It does not allow storage of more sophisticated database information. If Manifold fields other than text fields are used for the Name and Description, Manifold will capture the data as text for storage into the KML file. Missing or blank field values will be ignored when a drawing or map is exported to KML.

Drawings exported to KML or KMZ can contain points, lines and areas. Areas will be rendered using partial opacity while points and lines will be rendered at full opacity. To use transparency with points and lines, export a map which has the drawing as a layer with layer opacity set to the desired value; however, areas are always rendered using partial opacity with that partial opacity being modified by whatever layer opacity setting has been used in a map. That is, areas can be made even more transparent but can not be made fully opaque.

To export a drawing to KML format:

1. Open the drawing in a drawing window.
2. Choose File - Export - Drawing from the main menu.
3. In the Export dialog choose KML Files in the Save as type box and specify a filename to use. Press Save.
4. In the Export KML File dialog if desired specify the columns in the drawing's table that will be used for Name and Description fields in the KML file.
5. If you would like to extrude points, lines or areas into 3D shapes, specify a column in the drawing's table that will be used for the Height to give the height in meters. By default this is meters above sea level. Check the Relative heights box to extrude the object to that height in meters above the terrain elevation.
6. Press OK.

Exporting Maps

To export all drawings in a map to KML or KMZ, follow the above procedure with the map. Individual map layers are exported as separate folders in the KML. Note that all drawings in the map should have columns with the same names if such column names are specified for Name, Description or Height.

KML or KMZ exported from maps will respect layer transparency (opacity). That is, if a layer has had partial transparency set using the Opacity setting for a layer, upon export to KML the objects displayed in Google Earth will also be partially transparent. This can be used to create outstanding effects.

When a map is exported, folders in the resultant KML for drawings that have more than ten objects will be closed by default. This prevents the folder display in Google Earth from growing overly large by default.

Creating KMZ Files
The Manifold KML exporter will create .kmz files if the extension for the filename given is .kmz. KMZ format is simply a "zipped" KML file.

**About the WGS 84 Auto Datum**

This is a special datum based on the standard WGS84 datum that has automatic fine adjustment to account for different image servers or applications that use WGS84. When projecting a component for ultimate export to KML or KMZ, use the WGS 84 Auto datum.

**Extruding 3D Shapes**

Specifying a Height column that contains a value for each object in the drawing to use as an altitude will **extrude** the object into a 3D shape of that height in meters above sea level. Checking the Relative heights box (unchecked by default) will convert that height to a relative height above ground level in that location. It is usually a good idea to check the Relative heights box.

The above illustration shows gerrymandered congressional districts as areas that were exported to Google Earth using a Height column that gave values of tens of thousands of meters. The districts are very large, so to have them be obviously higher than the surrounding terrain requires large heights. The areas were colored using the same colors for both area background and also area border line. Google Earth shows the border line in opaque rendering even as the main area is partially opaque. This is a pleasant effect in that it results in nice highlights for the "walls" of the extruded shape.
For the above illustration black color was used for area border color. Choosing a good color combination for area color and area border line color is an important part of the art of making appealing Google Earth displays.

**Coordinate Accuracy**

Exporting a drawing to a KML file preserves at least 8 decimal digits in coordinate values and trims trailing zeros. This typically results in a file that is smaller yet retaining full precision for coordinates.

**Caution**

Export to Google KML and KMZ is an experimental capability due to the constantly evolving and poorly documented nature of Google Earth itself. Google Earth appears to have been designed mainly for visual overview by consumers and not as a rigorous GIS application for use by professionals requiring full precision. Of special importance is that essential documentation on the use of projections and the data composition methods used to prepare raster data for display by Google's mapping services is absolutely lacking.

Therefore, while Manifold export to KML and KMZ makes it easy to create striking visual displays with very little effort, users should not expect that at very detailed zoom levels the objects exported by Manifold will line up perfectly with images generated by Google Earth. The Manifold objects will be placed to absolute precision given the limits of whatever data source has provided those objects, but Google may not always be in agreement with data sources such as USGS, the Census Bureau or US military data sources.

Because Google provides little information on how it cobbles up a particular visual display, it is not possible to diagnose why a particular Google image sometimes does not match commonly accepted, authoritative sources of GIS data that are written to KML or KMZ using the information provided by Google.

Given the relative newness of Google Earth and the focus on consumer viewing, it is possible that it is simply not a matter of concern for the application that some imagery might have shifts of a few meters or even a few dozen meters as compared to GIS data from other sources. After all, since the announced goal of the application is consumer "mash ups" showing things like the locations of one's favorite beer halls it is more important that points of interest may be declared in a simple and easy-to-apply format than that such points appear with accuracy better than a few meters. One suspects that tight integration with the many sources of professional GIS data might be such a low priority matter that Google itself may not at the present time have investigated all details necessary to resolve data compatibility issues as can be done within dedicated GIS applications.

Given Google's often-stated commitment to supporting "open" development by the Google user community we expect Google Earth to evolve and be improved in many ways, including support for closer matches between user-supplied data and Google Earth displays when using KML and KMZ. Should Google Earth or KML and
KMZ format change before the next edition of Manifold becomes available, it is possible that new versions of export to KML and KMZ format might become available as add-ins to Manifold System.

Exporting KML to Google Earth
Fun with Google Earth
Linked Images from Google Servers
Export Image - KML, KMZ
Import Drawing - KML, KMZ
Export Drawing - MIF

MapInfo .mid/.mif format is widely used for interchange with MapInfo and other GIS applications. The format normally uses two files that have the same base name but with a .mif or .mid extension. The exporter asks for a mif file name and will create a similarly named mid file as well. When we use the term "mif" file in this topic we mean both the .mif file and its .mid companion as well.

Formatting

Mif files can contain color information as well as size parameters for objects. Manifold will read foreground color, background color and size information for objects on import. When exporting to mif format, Manifold will save foreground color, background color and size as well.

Exporting a drawing as a mif sets the outline color of each exported area to the area border foreground color.

Data Types

On import of a MapInfo .mif or .tab file, Manifold will translate MapInfo logical data type columns into Boolean data type. Exporting a Manifold drawing to .mif will export Boolean columns into MapInfo logical data type columns.
Export Drawing - Oracle

Requires Manifold Enterprise Edition or above. This topic provides a typical example of exporting a drawing to a spatial DBMS using Oracle. The same procedure can also be used to export drawings to any spatial DBMS, including DB 2 with Spatial Extender, PostgreSQL/PostGIS, SQL Server 2008, SQL Server 2005 with Manifold Spatial Extender, and just about any DBMS using Manifold's ability to create and use generic spatial indices.

Manifold Enterprise Edition or higher editions can export drawings to Oracle data sources, saving the drawing attributes within the database and drawing geometry as SDO_GEOMETRY as used by Oracle Spatial databases as well as the Locator facility within standard Oracle databases. Export of drawings to Oracle databases is not supported by Manifold editions below Enterprise.

To export a drawing to an Oracle database:

1. Open the drawing in a drawing window.
2. Choose File - Export - Drawing from the main menu.
3. In the Export dialog choose Data Sources () in the Save as type box.
4. Connect to the desired Oracle data source, creating a data source for the Oracle server desired if one has not already been created in the Data Source dialog.
5. Provide the information required in the Export Drawing dialog. Choose Oracle in the Type box to export using Oracle SDO_GEOMETRY and Oracle spatial facilities. Choose Manifold in the Type box to use Manifold-managed spatial facilities. Check the fields that are to be exported and other options as desired.
5. Press OK.

Export Drawing Dialog Controls

<table>
<thead>
<tr>
<th>Data Source</th>
<th>The name of the data source selected in the Data Source dialog.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Type</td>
<td>Either Oracle or Manifold. Choose Oracle in the Type box to export using Oracle SDO_GEOMETRY and Oracle spatial facilities. Choose Manifold in the Type box to use Manifold-managed spatial facilities.</td>
</tr>
<tr>
<td>Name</td>
<td>Name of the new table to create in the server in which this drawing will be stored. By default, Manifold will try to construct a valid Oracle name from the name of the drawing.</td>
</tr>
<tr>
<td>Select All</td>
<td>Check all fields. All data fields in the drawing will be exported.</td>
</tr>
<tr>
<td>Select None</td>
<td>Uncheck all fields. No data fields will be exported. Tech tip: Use this to uncheck all fields before checking those desired.</td>
</tr>
<tr>
<td>Select Inverse</td>
<td>Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.</td>
</tr>
<tr>
<td>Columns</td>
<td>Check the box for each column (field) that is to be exported with the drawing. By default, Manifold will export all columns except intrinsic columns. Note: The ID column and the Geom(I) column will not appear in the Columns pane because they are always exported.</td>
</tr>
<tr>
<td>Identity</td>
<td>Allows customizing the name of the identity column. OID by default.</td>
</tr>
<tr>
<td>Geometry</td>
<td>Allows customizing the name of the geometry column. Geometry by default.</td>
</tr>
<tr>
<td>Geometry type</td>
<td>Disabled when used with Oracle type, since SDO_GEOMETRY will be used as the geometry type.</td>
</tr>
</tbody>
</table>
### Import and Export

Enabled when Manifold type is used to allow specification of the desired geometry type from a choice of Geometry, Geometry (SHP) or Geometry (WKB). Use Geometry for maximum performance and robustness.

<table>
<thead>
<tr>
<th>Feature</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Version column</strong></td>
<td>Allows customizing the name of the version column. Version by default.</td>
</tr>
<tr>
<td><strong>Precision</strong></td>
<td>Allows customizing the value of the location precision parameter. Expressed in whatever native drawing units are used by that drawing.</td>
</tr>
<tr>
<td><strong>Projection</strong></td>
<td>The projection to use when storing the drawing, which is chosen by default from the projections supported by the server. Manifold will use the same projection used by the drawing if it is supported by the server (nearly always possible) or whichever is the most similar projection available on the server. Press the [...] to manually alter the projection chosen by Manifold. Using a projection on the server different than that used by the drawing will require re-projecting the drawing, which can take a significant amount of time for large drawings. Disabled when Manifold type is used since Manifold always stores an exact match when Manifold manages the spatial storage.</td>
</tr>
<tr>
<td><strong>Do not reproject data</strong></td>
<td>Off by default. Check to prevent re-projection of data on export, as might be required to match the projection in use by Manifold to an available Oracle projection. Disabled when Manifold type is used since Manifold always stores an exact match when Manifold manages the spatial storage.</td>
</tr>
<tr>
<td><strong>Create spatial index</strong></td>
<td>Checked by default. Creates an Oracle spatial index for the table containing the drawing, which makes certain Oracle spatial operations faster. Creates a Manifold spatial index when Manifold manages the spatial storage.</td>
</tr>
<tr>
<td><strong>Create sequence and triggers</strong></td>
<td>Checked by default. Creates a sequence object to generate values for the ID column, a trigger to fill values in the ID column for newly inserted records, and another trigger to update values in the Version column for changed records. Disabled when Manifold type is used since Manifold always creates sequences and triggers when Manifold manages the spatial storage.</td>
</tr>
</tbody>
</table>

**Note**

The default name of the identity column used when exporting a drawing to an Oracle database is **OID** to avoid naming collisions with the **ID** column that stores Manifold object IDs in Manifold drawings.

**Exporting Tables with Variable-Length Columns to Oracle**

Oracle tables cannot have more than one variable-length column. Attempting to export a drawing with more than one variable-length column to an Oracle database will fail with a message that lists the variable-length columns and advises converting one or more of these columns to fixed-length types, or unchecking them in the list of exported columns.

**Projections**

Manifold supports all Oracle projections (coordinate systems) although Oracle does not support all Manifold projections. When a component is imported or linked from an Oracle database it will automatically use that same projection within Manifold.

When a component is exported from Manifold to Oracle, Manifold will automatically choose the Oracle projection that is the best match, that is, the most similar to, the Manifold projection in use. Manifold export dialogs will
report the degree of similarity between the Manifold projection and the proposed Oracle coordinate system. If need be, Manifold will re-project the component on the fly into that Oracle projection system as part of the uploading process.

There are two nuances of interest in the case of components using a coordinate system that appears both in Oracle and in Manifold (that is, all Oracle coordinate systems):

- Although Manifold supports all coordinate systems used by Oracle, sometimes the names used for those coordinate systems are different. For example, the Latitude / Longitude projection used in Manifold is known as the TWD97 projection in Oracle when using the WGS 84 datum (the default for Latitude / Longitude).
- Manifold defines coordinate system presets using higher-precision parameters than those used in Oracle so even if the coordinate system is otherwise identical the Manifold settings have to be lowered in precision to match those used by Oracle. Manifold understands such precision-matching requirements when identifying the equivalent projection in Oracle and will automatically re-project data to account for precision differences. If this or any other re-projection is not desired, Manifold provides a Do not project data option (off by default) that may be checked on to prevent any re-projection of data.

**Errors**

If an export fails Manifold will display any error message returned by the Oracle server.

Exporting a drawing with the Create spatial index option turned on will postpone creating a spatial index until after all drawing objects have been uploaded. This is to assure that all uploaded data will stay in the database if index creation fails.

Example: Storing a Drawing in Manifold Spatial DBMS
Export Drawing - SDTS

Spatial Data Transfer Standard (SDTS) is a US Federal government format for spatial data interchange. SDTS may be used to export drawings in only a few projections (a limitation of the format): latitude / longitude, UTM, UPS and State Plane. If the drawing to be exported is not in one of these projections it should be re-projected into them before export to SDTS is attempted. Exporting a drawing into SDTS format that is not in one of the supported SDTS projections will convert the drawing into latitude / longitude projection automatically.

To export a drawing to SDTS format:

1. Open the drawing in a drawing window.
2. Choose File - Export - Drawing from the main menu.
3. In the Export dialog choose SDTS Files in the Save as type box and specify a filename to use. Press Save.
4. Check the fields that are to be exported. Buttons provide for Select All, Select None and Select Inverse to rapidly change which fields are to be exported for drawings containing many fields.
5. Optionally, specify the maximum number of coordinates that can make up a single line or area object and press OK.

Controls

- Select All - Check all fields. All data fields in the drawing will be exported.
- Select None - Uncheck all fields. No data fields will be exported. Tech tip: Use this to uncheck all fields before checking those desired.
- Select Inverse - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.

Use ring registration method

On by default. One of two allowed registration methods specified in the SDTS specification. Use this for compatibility with older SDTS-reading programs (like MicroDEM) that can only handle ring registration.

Limit line and area objects to …

coordinates

The maximum number of coordinates that can make up a single line or area object before it is split into multiple entities.

Although STDS is a fine format, it does have the limitation that individual objects (lines or areas) cannot be made up of more than approximately 5000 coordinates (also known as "inflection points" or "vertices" in some GIS packages). Some SDTS viewing programs set a maximum limit even lower than 5000 coordinates per object. The Manifold SDTS export dialog allows specification of the maximum number of coordinates allowed per object. Objects consisting of more than the given number of coordinates will be automatically split by Manifold into multiple entities in the saved SDTS file.

Exporting a surface to SDTS format will create a data quality module for compliance with the latest SDTS draft standard.
Export Drawing - SHP, Shapefiles

ESRI's .shp format, also known as "shape format" or "shapefiles," is used with ArcView, a popular GIS package of the early 1990's. Shape format has been openly published by ESRI and is widely used for data interchange in GIS. Shapefiles usually consist of three similar named files with differing extensions: a .shp, .shx and a .dbf file. The .dbf file is a dBase database system format file that is used to store data attributes for the drawing.

When Manifold exports to "shp" format it creates three files: a .dbf, a .shp and a .shx file. These work fine in all applications that can read "shapefiles" correctly. When providing the result of your export to shapefiles to someone else, don't forget to provide all three files and not just the .shp file. Because shapefiles cannot contain a mixture of areas, lines and points, when a drawing that contains a mix of areas, lines and points is exported to shapefile format Manifold must create shapefiles for the areas, shapefiles for the lines and shapefiles for the points.

When exporting drawings containing objects of only one type (only areas or only lines or only points) to shapefiles no postfixes will be appended to the filename. When drawings contain more than one type of object, Manifold will add "a," "l" and "p" postfixes to the filenames to indicate which shapefiles contain areas, lines and points.

Drawings exported as shapefiles should contain at least one data column in the drawing's table to avoid confusing unsophisticated shapefile-reading software. If there are no columns in the drawing's table or if we deselect all fields when exporting, then exporting the drawing as a shapefile will result in "shapefiles" that do not have a .dbf file. This may confuse some third-party software packages that do not understand how to read shapefiles with no .dbf files. Attempting to export a shapefile with no data columns will display a confirmation message warning of this risk that asks users to press Yes to continue.

To export a drawing to .shp format:

1. Open the drawing in a drawing window.
2. Choose File - Export - Drawing from the main menu.
3. In the Export dialog choose SHP Files in the Save as type box and specify a filename to use. Press Save.
4. Check the fields that are to be exported. Buttons provide for Select All, Select None and Select Inverse to rapidly change which fields are to be exported for drawings containing many fields.
5. Press OK.

Controls

- **Select All** - Check all fields. All data fields in the drawing will be exported.
- **Select None** - Uncheck all fields. No data fields will be exported. Tech tip: Use this to uncheck all fields before checking those desired.
- **Select Inverse** - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.

Shapefiles as most commonly occur do not save projection information. Recent extensions to ArcView allow the saving of projected data in additional files; however, most shapefiles that are published do not use this extension. Shape format is therefore best used to interchange data from unprojected drawings using degrees as the unit of measure. For maximum compatibility with other GIS applications it is strongly recommended that only drawings in Latitude / Longitude projection be saved to .shp format. To do this, before exporting the drawing use Edit - Change Projection to re-project the drawing into Latitude / Longitude projection if it is in a different projection.

The formal .shp specification includes use of dBase .dbf format. In Microsoft Windows operating systems, most applications use Microsoft drivers to read and write the .dbf part of shapefiles. Windows .dbf drivers normally support standard dBase format, which has a variety of legacy limitations. For example, .dbf files (and thus any shapefiles) should have have "8.3" style names, where the base name is at most eight characters, followed by a .shp, .shx, or .dbf extension. In addition, field names used within a shapefile should not be more than eight alphanumeric characters not beginning with a number.
Because Manifold and most other modern GIS software allows field names to be longer than eight characters and use special characters as well, it is a frequent occurrence that field names used within Manifold are too long or complex for use within shapefiles that are truly compliant with the .dbf standard used in Windows. Such field names should be renamed before export to .shp format is accomplished.

We realize that many users of shape files will rename files to longer than eight characters and also use field names greater than eight characters. This occurs especially often in UNIX environments where programs will at times use .dbf file drivers that are not consistent with dBase specification in that they relax the naming conventions used by dBase. However, writing to longer file names and using longer field names is a violation of the .dbf spec and may well cause failed interchange with other software that takes the spec seriously.

Because so many ESRI applications, both in UNIX and in Windows, do not respect Windows standards for .dbf, Manifold System does not use Microsoft drivers to read / write .dbf files when importing or exporting shapefiles. Instead, a custom set of Manifold drivers are used that accept nonstandard file and field names. In addition, the Manifold drivers will allow writing of long file and field names that violate the dBase standard but which are acceptable to various ESRI applications.

Manifold's shapefile export will preserve data types consistent with .dbf practice whenever possible. Variable-length text data is exported as fixed-length text with 254 characters (since ArcExplorer 2.x and some other programs do not seem to be able to handle memo fields).

**Internationalization**

Exporting a .dbf file (either by exporting a table as a .dbf or by exporting a drawing as a shapefile) will set the .dbf codepage field to the codepage used by the columns in the exported table. If the columns use conflicting codepages or if the codepage is not supported by .dbf format, Manifold will display a warning message.

Importing a .dbf file (either by importing a table from a .dbf or by importing a drawing from a shapefile) sets the codepage of each text column to that used in the .dbf file.

**Exporting Projected Shapefiles**

Because .shp format does not capture projection information it is unwise to export projected drawings into .shp format. However, if for some reason we absolutely must export projected data we should keep in mind the raw nature of data in projected form and the options used to represent locations in projected coordinate systems.

For example, suppose we have a drawing in some metric projection that uses local offsets of 100, 100 and local scales of 10, 10. Suppose we have a point the coordinates of which are 1, 2 in this coordinate system. When exporting this drawing as a .shp, sometimes we may want the coordinate numbers locating the point in the .shp file to be 1, 2 and sometimes 110, 120.

The Manifold .shp exporter does not transform the coordinate numbers in any way, so Manifold will always export 1, 2 for the coordinates of the point. If desired, we can force Manifold to export 110, 120 by first re-projecting the drawing into the coordinate system using local offsets of 0 and local scales of 1.

**Exporting a PRJ File**

To create a PRJ file to accompany the shapefiles for those software packages that can use ESRI PRJ files, use the Edit - Change Projection dialog's toolbar to save the coordinate information into a PRJ file. Name the file using the same name as the other shapefiles with the extension .prj.

**Troubleshooting**

It is tempting to use Manifold as a format converter, for example, to import from MapInfo .mif format and to save as .shp. However, since MapInfo like Manifold also allows longer file and field names than does .shp format it is very easy to import files that already contain field names or use file names incompatible with export to .shp. Such names must be renamed to fit into the limitations of .shp format before export.

If the results of .shp export from Manifold cannot be read by your .shp reading application, check the following:
Are all filenames in the "8+3" form? If not simplify the file names. Your application may not be able to handle long file names.

Are all field names no more than eight, simple alphanumeric (letters and numbers only) and not beginning with a number?

Have you used only simple database types (integers, fixed length text, etc.) for data attributes? Your application might not be able to recognize more sophisticated data types such as dates.

Edit - Change Projection

Export Image

Exporting Images

Export images from Manifold by right-clicking on the image in the project pane and choosing export, or by opening the image and then using the File - Export - Image dialog. In addition, images can be exported into databases using spatial DBMS technology can be exported by using the Data Source dialog. See the Example: Storing an Image in Oracle and Example: Storing an Image in Manifold Spatial DBMS topics for a typical example of exporting to a spatial DBMS as can also be done for DB 2 with Spatial Extender, PostgreSQL/PostGIS, SQL Server 2008, SQL Server 2005 with Manifold Spatial Extender, and just about any DBMS using Manifold's ability to provide generic spatial DBMS facilities.

When using the File - Export - Image dialog the Files of type choice acts as a filter for what is displayed in the browse pane in the Export dialog. Simple file types are exported directly from the Export dialog by choosing the desired type in the Files of type box. More complex exports into data sources such as databases are exported by choosing Data Sources () in the Files of type box and then using the Data Source dialog.

Images may be exported to various formats. In some cases, such as AI, EMF, PS and PDF the image export occurs not from an image window but rather from a print layout where the layout is exported as an image to the target format.

To export an image:

1. Open the image to be exported in an image window.
2. Choose File - Export - Image
3. Choose the desired format in the Save as type box.
4. Use the resulting dialog to choose export options and to export.

Manifold can export images to a variety of popular formats.

- **AI** Adobe Illustrator format. Exported from a print layout.
- **BMP** Windows bitmap format. Provides no compression at all.
- **ECW / JPEG2000** ERMapper ECW format using wavelet compression or in JPEG 2000 format depending upon the file name extension. Images of any size can be exported.
- **EMF** Extended Windows Meta File format. Often used for interchange with modern graphics packages like Adobe Illustrator.
- **GIF** Older format used for smaller web images. Manifold does not directly support saves to .gif due to Unisys patent threats. Third parties have published free extensions to Manifold that install the ability to write .gif as if it were a built-in capability. If you have such an extension installed you can write .gif.

   For saving images for the web, use .png instead, which can be read by all web browsers and is a much more efficient format than .gif. See the note on .gif usage.
Import and Export

**JPEG**
Classic and very efficient compressed format. Often used for web images that must preserve good appearance. Options include:
- **Quality** - Set to Low, Medium, High or Maximum to trade off image size for quality. The higher the quality the lower the compression and thus the larger the image.
- **Method** - Set to Baseline, Baseline Optimized or Progressive. When Progressive is chosen, set the number of Scans desire.

**KML, KMZ**
Google Earth XML-based KML or KMZ format.

**PDF**
Adobe Portable Document Format, an amusing spin on the word “portable” to mean exclusive use within Adobe’s world view. In all fairness, PDF is a rather handy way of publishing a print layout to an image file for redistribution. Exported from a print layout.

**PNG**
Simple graphics format that is a popular replacement for .gif in websites. PNG is cool. See the Just Say No to GIFs essay.

**PS**
PostScript PS format, a generic format used by many Adobe products. Exported from a print layout.

**TGA**
Targa TGA format. A Blast from the Past still in occasional use.

**TIFF**
Tagged image file format. When the Export projection info checkbox is checked will automatically write as a GeoTIFF format file. GeoTIFF files still use the .tif three letter extension as do ordinary .tif files and, in fact, are simply ordinary .tif files but with a few extra tags in them to store projection information.

**DB2 Data Sources**
Connect to IBM DB2 equipped with the DB2 Spatial Extender using IBM’s native spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**Oracle Data Sources**
Connect to an Oracle data sources using the Oracle Call Interface (OCI), the native Oracle interface for exchanging data. Exchanging images with Oracle data sources via OCI automatically maps images into Oracle GeoRaster form (if GeoRasters are supported by the Oracle product in use). A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**PostgreSQL Data Sources**
Connect to PostgreSQL equipped with the PostGIS spatial extender using native PostgreSQL connection technology. Connections made using this data source will have any password required masked so that later usage will not inadvertently expose the password. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**SQL Server Data Sources**
Connect to Microsoft SQL Server 2008 spatial DBMS facilities using native SQL Server 2008 spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**Important:**
Using a vendor’s native spatial DBMS connection technology (like those above) provides better performance and allows using features, such as built-in spatial DBMS facilities, not exposed through generic database interfaces such as ODBC, OLE DB and ADO .NET. At the present writing, only Oracle Spatial provides a built-in GeoRaster type. Other spatial DBMS products are supported using...
JPEG images are frequently used as images in web pages. Several different quality settings can be selected depending on the tradeoff desired between image size and image quality.

JPEG images can be arranged so that they load as one byte stream (Baseline) or as a sequence of updates (Progressive). If you've ever seen an image appear in a web page where initially a simplified view of the image appears and then more detail fills in via horizontal swaths you were likely looking at a Progressive JPEG image. The number of scans sets forth how many iterative updates are used to build the image. Progressive images are larger than Baseline images, but when served over a slow Internet connection can be more tolerable because the viewer sees at least a schematic view of the image right away.

The Baseline Optimized choice provides a higher quality JPEG at lower size than normal; however, some older web browsers are not able to display optimized JPEG images.

Image Storage within Databases

In addition to storage within Oracle Spatial databases, Manifold has a variety of means of storing images within external databases. See the Virtual Tables for Images and Surfaces topic, the Linked Images topic and the Queries and Images or Surfaces topic.

Manifold can automatically save images into databases using either vendor-supplied spatial DBMS technology as in the case of Oracle Spatial GeoRasters or with almost any DBMS using Manifold-managed spatial DBMS technology. Storing images in a fast DBMS is often the fastest way to handle large images.

Transparent Pixels and Export

GIF, PNG and TIFF support transparent pixels. GIF images do not have an alpha channel, so when exporting GIF files Manifold will render RGBa images over the background color specified in Tools - Options.

XML Files Created upon Export and Used on Import

Not all formats to which Manifold can export have the ability to correctly save projection information. As a safety measure to ensure that projection information is never lost, Manifold always writes an accompanying .xml file when exporting drawings, images, labels, maps or surface components to a file. The accompanying .xml file contains coordinate system information and some other metadata. The XML file is created for all formats, even those that correctly save coordinate system information.

When Manifold imports drawings, images, labels or surfaces, the system will check for an accompanying .xml file that might have been written by Manifold. If such an .xml file exists, Manifold will read it and use the information it contains to load a correct coordinate system.

See the XML Accessory File Format topic for details on the internal organization of this file.

A Note on GIF Usage

It is a great idea to avoid using .gif format. Use .png instead: it's faster, more efficient and it is not subject to moronic patent threats from Unisys. See Just Say No to GIFs for a quick history on the threat to .gif usage from Unisys.

Tools - Make Image
Export Image - AI, EMF, PS and PDF
Export Image - GeoTIFF
Export Image - Oracle
Export Image - PNG
Export Image - AI, EMF, PS and PDF

Manifold offers four quasi-vector graphics arts / imaging formats to use when exporting print layouts as "images."

- **AI** A graphics arts format read by Adobe Illustrator and other applications.
- **EMF (GDI)** Enhanced Meta File format, the 32 bit version of WMF (Windows Meta File) format. This option writes EMF using classic Windows GDI (Graphics Device Interface). Use the GDI version as a possible workaround only if the GDI+ version does not provide satisfactory results.
- **EMF (GDI+)** EMF written using GDI+. Microsoft’s GDI+ was developed for Windows XP and is installed by Manifold on all Windows systems if not already installed. The GDI+ version should be used by default, as GDI+ includes numerous improvements over GDI.
- **PDF** Portable Document Format, read by Adobe Acrobat Reader and other applications.
- **PS** Export to PostScript compatible files

**Options**

All four formats use a similar dialog to code the output image and include these options:

- **Pixel resolution** Used to save images and surfaces that are in the layout. Resolution must be greater than 1 DPI and less than 7200 DPI. Default is screen resolution, normally 72 DPI.
- **Vector resolution** Used to save drawings and labels as well as layout elements such as text or horizontal and vertical lines. Resolution must be greater than 1 DPI and less than 7200 DPI. Default is 300 DPI. If saving for subsequent work in some other program before printing choose a Vector resolution setting that is the same as the resolution of the printer that will be used. If printing to a 600 DPI printer, for example, use 600 DPI.
- **Ignore Styles** Export the image using default point, line, area and label styles.

In addition, the **Export PS File** dialog includes two more options used when exporting to PS:

- **Pixel Encoding** Choose Flat, ASCII HEX or Run-length. The default choice is Flat, which tends to produce smaller files. The other two choices are supplied as possible workarounds if encountering problems with other PS reading software.
- **Use explicit image mask for invisible pixels** Switches between two different methods for handling invisible pixels allowed in PS format. When checked (the default) each pixel includes an extra byte that specifies if the pixel is transparent or opaque. When not checked, invisible pixels are set to an infrequently used color (R:G:B = 0:0:1) that is then designated transparent. Unchecking the box will reduce file size for files containing large images, but may cause problems for inept PS reading software. AI format does not support invisible pixels.

In addition, the **Export PDF File** dialog includes options used when exporting to PDF:

- **Compress output** Use internal compression algorithms allowed in PDF format to reduce the size of the resulting PDF file.
Enabled by default.

**Use transparency**  Export using transparency, so that any partially transparent components will be rendered in the .pdf with partial transparency.

**Ignore styles**  Export using default styles for points, lines and areas.

The **Ignore styles** checkbox is an advanced option that forces Manifold to use default styles for exported objects. This can be useful when exporting for later use in vector-style graphics editors such as Illustrator because the default styles produce a relatively small number of simple vector objects per Manifold entity. In contrast, more complex styles available in Manifold can produce five to ten relatively complex vector objects per point. If the export is destined for use in Illustrator and the Illustrator operator prefers to work with simple objects check this box.

**Exporting Multipage Layouts**

Multipage layouts may be exported to **PDF** and **PS**, but not to **EMF**. However, a single page of a multipage layout may be exported to **EMF**. When a multipage layout is exported to **EMF**, the Export EMF File dialog will include a **Page** option that allows specification of which page in the multipage layout is to be exported.

When exporting a multipage layout to **PDF** or **PS**, a **Pages** option (called a **page filter**) appears that controls which pages from the layout appear in the exported image. Enter a series of page numbers or page ranges separated by commas. White space is ignored and reverse ranges are interpreted correctly. For example, Enter **1, 2, 5-8** or **1, 2, 8-5** and get the same results. See the Multipage Layouts topic for an example of using page filters.

**About GDI and GDI+**

Manifold uses Windows system routines wherever possible for maximum performance and continuing quality as Windows updates are released. The Graphics Device Interface (GDI) is a Windows subsystem used for a variety of utility tasks involving device-independent graphics, including export to EMF format. The original GDI has now been replaced by GDI+, which was developed with Windows XP and has been released by Microsoft in DLLs that developers can install on earlier Windows systems. Manifold automatically installs GDI+ on Windows systems other than XP.

The GDI+ version of the EMF exporter should always be used by default. If problems occur when using the resulting files in other programs, try using the GDI version to see if reverting to the earlier Windows technology solves the problem (as it might with some programs that were tested or developed using GDI and not GDI+).

**Compatibility**

Although the formats in this topic are often thought to be "universal," device independent formats the usage of these formats is no guarantee that the visual appearance of what one program writes will be recovered when the file is read by a different program. For example, **.emf** exports using ordinary **GDI** do support opacity for images and surfaces but not for drawings.

All four formats in this topic may be thought of as programming languages as much as they are formats. They operate not only by providing data but also by providing instructions on how a document is to be dynamically constructed based upon that data. Whenever a program reads one of these programs it must synthesize the desired document using the data and instructions contained in the file. The program must do its best to synthesize the desired document even if its capabilities or the facilities of its host system (such as fonts that might be available) may be less able than those in the system that wrote the file.

The full range of possibilities for describing a document within these four systems can be very complex and extensive and few programs (if any) that read or write these formats have implemented all of the capabilities that are theoretically possible. As a result, there can be considerable variation in how different programs interpret the instructions for synthesizing a document contained in these formats. Small differences in capability or interpretation can result in documents that are visibly different.
Export Image - ECW / JPEG2000

ECW and JPEG 2000 are two different formats that are handled by the same File - Export - Image choice in Manifold. Which format is written depends upon the three letter extension used for the file name. Manifold can export either ECW or JPEG 2000 images without limitations on size other than, of course, the capacity of the machine in use and the patience of the user.

ECW or JPEG 2000 format is strongly recommended for very large images. Manifold can link an image from an ECW or JPEG 2000 file with great speed. Images linked from these formats that are many gigabytes in size will load and display in just a few seconds.

ECW and JPEG 2000 are two different formats even though they are handled by the same exporter within Manifold. ECW is strongly preferred because it can store projection information (see notes below).

To export an image as an ECW file:

1. Open the image to be exported in an image window.
2. Choose File - Export - Image
3. Choose ECW / JPEG2000 in the Save as type box.
4. Enter a file name for the file ending in .ecw and press Save.
5. In the Export ECW / JPEG2000 File dialog enter a Compression ratio and press OK.

To export an image as a JPEG 2000 file:

1. Open the image to be exported in an image window.
2. Choose File - Export - Image
3. Choose ECW / JPEG2000 in the Save as type box.
4. Enter a file name for the file ending in .j2k, .j2c, .jp2, .jpc, .jpf, or .jpx and press Save.
5. In the Export ECW / JPEG2000 File dialog enter a Compression ratio and press OK.

Important: We must explicitly specify the three letter extension, either .ecw or one of the allowed three letter .j-- extensions, to tell the exporter whether we want an ECW file or a JPEG 2000 file. Do not forget to specify this extension (it is not something Windows users are accustomed to have to do) as forgetting to specify the extension will result, unpredictably, in the exporter choosing on its own which format to use.

Compression Ratio

Set the compression ratio desired, such as 1:10 or 1:20 or even greater in the export dialog and the ECW / JPEG 2000 routines will do their best to compress the image to the degree specified. ECW export supports all projections available within ECW files.

Note that wavelet compression can provide remarkable compression without apparent degradation of the image; however, both ECW and JPEG2000 are "lossy" formats and are not appropriate for certain types of remote sensing data where not even a single pixel can be change. These formats are best for visual data where appearance to the human eye is the main criterion.

Projections

ECW format can save projection information although the list of projections supported by ECW does not include all projections supported by Manifold. (Manifold has grown to support so many projections that virtually no other software supports such a long list of projections).

Although JPEG 2000 in theory can save projection information, in actual practice for the reasons given below it should not be treated as a projection-aware format. When Manifold writes a JPEG 2000 file it will also create an accompanying .xml file giving full projection information. In the special case of JPEG 2000 files written by Manifold that still are accompanied by the .xml accessory file, Manifold will be able to write and read projection information perfectly with JPEG 2000 files.
Import and Export

However, that capability of storing projection information will not extend to JPEG 2000 files written by other applications which we try to import into Manifold, nor is it likely that other applications will be able to read projection information from JPEG 2000 files written by Manifold. See the discussion below for reasons why.

**Good News and Bad News for Open Standards**

The ECW and JPEG 2000 code within Manifold System provides a living example of both the benefits and the curse of cooperation between companies using open source and open standards. First, the good news:

The export code to export to both ECW and to JPEG 2000 used within Manifold is open source code provided by ERM (Earth Resource Mapping, the makers of ERMapper) to the GIS community. ERM invented ECW and developed it into an effective format for storing compressed images. ECW is not only elegant from an academic, computer science perspective, it is also supremely practical in that it incorporates "real world" requirements such as the need to store projection information in a perfect, unambiguous form. Years of focused improvement under the guidance of expert remote sensing applications programmers have also given ECW extraordinary performance.

To help establish ECW as a universal format, ERM had the great presence of mind to provide source code to ECW to other GIS and remote sensing companies. In addition, ERM implemented the new JPEG 2000 "open" standard for compression within a common software development kit (SDK) for which freely available source code was openly provided. Having both formats supported by the same SDK with freely available source code removed any tension vendors might have as to which standard to support. It also showed that ERM had the confidence in ECW to allow the industry at large to make a choice even if the use of JPEG 2000 became free and effortless.

The ECW / JPEG 2000 SDK is now used throughout the GIS and remote sensing communities and is cooperatively maintained for use in UNIX, Linux and Windows by industry professionals with ERM managing the standard and taking the lead in UNIX and Manifold and others assisting with Windows notes. The objective is to have a single code base for all platforms to assure that the resulting ECW or JPEG 2000 files are fully interoperable.

Overall, the effort has been very successful, a shining example of how mutual support using access to source code can propel a commercial standard like ECW into universal acceptance by commercial vendors. About the only compromise required is that a side effect of using such shared code within Manifold for this exporter is the requirement to explicitly specify the three letter extension, either .ecw or one of the allowed three letter j-- extensions, to indicate whether an ECW or a JPEG 2000 is required. This small matter aside, the release of source code for the ECW / JPEG2000 SDK by ERM has resulted in superb performance and quality for ECW.

And now, the bad news of "open" standards:

Given ERMapper’s extensive experience in image compression, ERM had the experience to develop practical, effective and high quality JPEG 2000 code and has produced what is indisputably a best-of-breed JPEG 2000 implementation. The problem is that the JPEG 2000 standard itself has been weakened by too many "design by committee" compromises instead of a solid focus on practical software implementation and use. Those compromises may have been well-intentioned but they have resulted in a format that does not work as well for GIS use as ECW.

In particular, the JPEG 2000 standard attempts to incorporate too many different approaches in the matter of projections information storage and so succeeds in being darn near useless in this key area. It allows several different methods to store projection information in a JPEG 2000 file.

With different ways of storing projection information JPEG 2000 opens itself up to a Tower of Babel phenomenon where no two packages are likely to use the same method in exactly the same way. Even in the case of packages that attempt to support multiple methods or the same method the intrinsic ambiguity of the methods usually chosen for JPEG 2000 make it unlikely that projection information interchange will be accomplished in all cases. We can see why by looking at the best of the methods allowed in JPEG 2000, EPSG codes.

The most useful of projection storage methods within JPEG 2000 is the use of EPSG codes. These are also used by OGC (the inventors of famously incompetent "standards" like GML) for things like OGC WMS / WFS and are used by Manifold for the Manifold IMS implementation of OGC WMS / WFS as well.

For all the merits of EPSG, the available EPSG codes do not cover a sufficient number of projections. A further problem is that EPSG codes are not defined in a single, unique set and so different applications can end up using code sets that are not identical. As a result, even the use of EPSG codes imposes great limitations on what can be inside a JPEG 2000 and how that information can be interchanged. As the industry moves to greater standardization and a single set of EPSG codes this situation should be improved.
The JPEG 2000 inability to make decisions in a unifying way can be seen from the very nature of JPEG 2000 filenames. A standard which cannot make up its mind which three letter extension to use and instead compromises by allowing six different names for essentially the same thing (.j2k, .j2c, .jp2, .jpc, .jpf, or .jpx) obviously from the very beginning has a serious problem with squishy thinking. If the standard cannot even standardize its own name there is little hope it will do better on more contentious issues, such as methods for encoding projections.

Note that in no way do we suggest that JPEG 2000 is not well intentioned. It's actually a great project done for all the right reasons with the best of intentions. But as anyone who has ever participated in one of the committees that earnestly come up with such things can attest, it is good intentions that pave the road to you-know-where. It could well be that the press of evolution and the indisputable talent of the many people who work on JPEG 2000 will take a hand in guiding JPEG 2000 into more useful form. Perhaps there will emerge a JPEG 2007 or JPEG 2010 that one day will equal ECW in effectiveness. Until then, GIS professionals with a job to do will reach first for ECW.

Because source code for ECW is now freely available within the GIS and remote sensing vendor community, users and vendors can trust that ECW will continue to serve as the de facto standard for "real world" GIS and remote sensing applications. For the reasons set forth above, manifold.net strongly encourages Manifold users to employ ECW in preference to JPEG 2000.

Tech Tip

JPEG 2000 may be squishy about filenames but that doesn't mean you have to be. If for some reason you choose to save files into JPEG 2000 format, consider always using the .j2k three letter extension. There's no particular reason for this advice except that .j2k looks like a more memorable mnemonic for JPEG 2000 than, say, "jpc" or the others. Although the original suggestion for JPEG 2000 was to use .jp2 as an extension, it appears that .j2k is now slightly more popular than the other choices. Within the Manifold community, we may as well voluntarily "standardize" on .j2k.

Compressed Images
Export Image - GeoTIFF

To export a georegistered image to GeoTIFF format, use the File - Image - Export dialog using TIFF in the Save as type box.

TIFF is Adobe’s copyrighted “tagged image file format” that provides a surprisingly rich set of extensions. It is often used to save simple images without any georegistration. However, it also provides for added information through the inclusion of extra tags. Software that does not understand how to use extra tags simply ignores them.

The GeoTIFF organization has defined a set of standard tags that can be used to embed projection / georegistration information within TIFF files. When a TIFF file includes such tags it is said to be a GeoTIFF file.

When Manifold reads an existing GeoTIFF it automatically reads the projection tags and will import the GeoTIFF with correct coordinate system info. When Manifold writes a TIFF, by default, Manifold will export projection information tags into a TIFF so that it is automatically made a GeoTIFF. There is no separate File - Export - Image setting to write a "GeoTIFF" because writing a TIFF always creates a GeoTIFF if the Export projection info box has been checked in the export dialog.

To export an image as a GeoTIFF file:

1. Georegister the image if it is not already georegistered.
2. Open the image to be exported in an image window.
3. Choose File - Export - Image
4. Choose TIFF files (*.tif, *.tiff) in the Save as type box.
5. Enter a file name for the file and press Save.
6. Choose Intel (IBM PC) in the byte order box.
7. For maximum interchangeability, choose None in the compression box.
8. Check the Export projection info box and Press OK.

Options

- **Byte Order**
  - Intel (IBM PC) - Use for all PC clones (AMD, Intel, etc.).
  - Motorola (Mac) - Use for Apple Mac products.

- **Compression**
  - None - Best choice for interchange. Not all software products can read compressed TIFF files.
  - JPEG, PackBits, LZW, ZIP - Various compression methods in common use with GeoTIFF files. Not all software packages can read these.

- **Export projection info**
  - Checked by default. Export projection info tags into the TIFF. This makes it a GeoTIFF. Don’t uncheck unless you want to create an ordinary TIFF that contains no projection tags.
TIFF export does not currently support JPEG compression for palette images. This is a bit odd, since JPEG export itself supports palette images. To create a JPEG compressed GeoTIFF from a palette image, first convert the image to RGB or grayscale for export. See the Image Types topic.

**XML Files Created upon Export and Used on Import**

Not all formats to which Manifold can export have the ability to correctly save projection information. As a safety measure to ensure that projection information is never lost, Manifold always writes an accompanying .xml file when exporting drawings, images, labels, maps or surface components to a file. The accompanying .xml file contains coordinate system information and some other metadata. The XML file is created for all formats, even those that correctly save coordinate system information.

When Manifold imports drawings, images, labels or surfaces, the system will check for an accompanying .xml file that might have been written by Manifold. If such an .xml file exists, Manifold will read it and use the information it contains to load a correct coordinate system.

See the XML Accessory File Format topic for details on the internal organization of this file.

**Tech Tip**

Keep inexpert users away from your GeoTIFFs because such users cannot seem to resist killing those GeoTIFFs by opening them with some brainless consumer graphics editing package. See the comments in the Import Image - TIF [Various types] topic.

If you do have a GeoTIFF killed by an inexpert user and that GeoTIFF was created by Manifold, if you still have the auxiliary XML file created by Manifold the situation can be saved. Place the GeoTIFF and its accompanying XML file in the same folder so that when you open the former GeoTIFF the projection information will be restored. Save the GeoTIFF again and the projection information will be re-embedded into what will be once again a GeoTIFF when it is saved. The inclination of inexpert users to kill GeoTIFFs was one of the main reasons Manifold introduced an auxiliary XML file to save projection information, just in case.
Export Image - KML, KMZ

KML is an XML-based format used by Google Earth for "annotations" in Google Earth displays. KML can be used for showing points or other vector objects from a GIS format drawing as well as for images. Manifold includes the ability to export a drawing or an image as a Google Earth KML file provided the component is in Latitude / Longitude projection using the WGS 84 Auto datum. It's a quick and convenient way of publishing your GIS data for use with Google Earth.

To export an image to KMZ format:

1. Open the image. Images must be in Latitude / Longitude using the WGS 84 Auto datum for export to KML or KMZ, so re-project the image into Latitude / Longitude using the WGS 84 Auto datum if necessary.
2. Choose File - Export - Image from the main menu.
3. In the Export dialog choose KMZ Files in the Save as type box and specify a filename to use. Press Save.

Creating KMZ or KML Files

The Manifold KML / KMZ exporter will create .kmz files if the extension for the filename given ends in .kmz and it will create .kml files if the filename given ends in .kml. KMZ format is simply a "zipped" version of KML.

Use KMZ when exporting images because then the image itself will be embedded within the .kmz file that is created. If KML is used, then Manifold will create both a separate image file and also a .kml file. These must be kept together for display in Google Earth. Given the possibility that the image file might not always accompany the .kml file that uses that image, it is wise to always use .kmz in such circumstances to make sure the image always accompanies the relevant KML.

About the WGS 84 Auto Datum

This is a special datum based on the standard WGS84 datum that has automatic fine adjustment to account for different image servers or applications that use WGS84. When projection a component for ultimate export to KML or KMZ, use the WGS 84 Auto datum.

Caution

Export to Google KML and KMZ is an experimental capability due to the constantly evolving and poorly documented nature of Google Earth itself. Google Earth appears to have been designed mainly for visual overview by consumers and not as a rigorous GIS application for use by professionals requiring full precision. Of special importance is that essential documentation on the use of projections and the data composition methods used to prepare raster data for display by Google's mapping services is absolutely lacking.

Therefore, while Manifold export to KML and KMZ makes it easy to create striking visual displays with very little effort, users should not expect that at very detailed zoom levels the objects exported by Manifold will line up perfectly with images generated by Google Earth. The Manifold objects will be placed to absolute precision given the limits of whatever data source has provided those objects, but Google may not always be in agreement with data sources such as USGS, the Census Bureau or US military data sources.

Because Google provides little information on how it cobbles up a particular visual display, it is not possible to diagnose why a particular Google image sometimes does not match commonly accepted, authoritative sources of GIS data that are written to KML or KMZ using the information provided by Google.

Given the relative newness of Google Earth and the focus on consumer viewing, it is possible that it is simply not a matter of concern for the application that some imagery might have shifts of a few meters or even a few dozen meters as compared to GIS data from other sources. After all, since the announced goal of the application is consumer "mash ups" showing things like the locations of one's favorite beer halls it is more important that points of interest may be declared in a simple and easy-to-apply format than it that such points appear with accuracy better than a few meters. One suspects that tight integration with the many sources of professional GIS data might be such a low priority matter that Google itself may not at the present time have investigated all details necessary to resolve data compatibility issues as can be done within dedicated GIS applications.

Given Google's often-stated commitment to supporting "open" development by the Google user community we expect Google Earth to evolve and be improved in many ways, including support for closer matches between user-supplied data and Google Earth displays when using KML and KMZ. Should Google Earth or KML and
KMZ format change before the next edition of Manifold becomes available, it is possible that new versions of export to KML and KMZ format might become available as add-ins to Manifold System.

Tech Tip

The general Google definitions for KML and KMZ are broader than what might be the capabilities of a particular Google product that uses these formats. Users intending to employ these formats with Google products should take time to read Google's technical documentation in detail to understand how to do so correctly for each particular Google technology.

Linked Images from Google Servers
Export Drawing - KML, KMZ
Import Drawing - KML, KMZ
Export Image - Oracle

Requires Manifold Enterprise Edition or above. This topic provides a typical example of exporting an image to a spatial DBMS using Oracle. The same procedure can also be used to export images to any spatial DBMS using Manifold's ability to save images using generic spatial DBMS capability.

Manifold Enterprise Edition or higher editions can export images into Oracle's GeoRaster database storage technology as found within Oracle Spatial and other GeoRaster capable Oracle products. This is a very fast storage medium that is excellent for very large images and can be utilized by any application that is Oracle GeoRaster compatible. Oracle Spatial scales very well: whether stored images are a few hundred megabytes, a few gigabytes or even a terabyte the database response is fast.

The Oracle server in use must have GeoRaster capability. Note that some Oracle products, such as Oracle Express Edition, have Locator spatial capability but **do not** provide GeoRaster capability. If the Oracle server in use does not have GeoRaster capability, Manifold can still save images into the database using Manifold spatial facilities. Manifold image storage is also very fast, although it cannot scale across Oracle clusters the way GeoRaster can.

To export an image into an Oracle Spatial database we must have access to that database and have write permissions.

**To export an image to an Oracle database:**

1. Open the image in an image window.
2. Choose *File - Export - Image* from the main menu.
3. In the *Export* dialog choose *Data Sources ()* in the *Save as type* box.
4. Connect to the desired Oracle data source, creating a data source for the Oracle server desired if one has not already been created in the Data Source dialog.
5. Provide the information required in the *Export Image* dialog. Choose *Oracle* in the *Type* box to export using Oracle GeoRaster if available. Choose *Manifold* in the *Type* box to use Manifold image storage within the database. Check the other options as desired.
6. Press OK.
Type  Either Oracle or Manifold. Choose Oracle in the Type box to export using Oracle GeoRaster and Oracle spatial facilities. Choose Manifold in the Type box to use Manifold-managed image storage.

Name  Name of the new table to create in the server in which this image will be stored. By default, Manifold will try to construct a valid Oracle name from the name of the image.

Projection  The projection to use when storing the image, which is chosen by default from the projections supported by the server. Manifold will use the same projection used by the image if it is supported by the server (nearly always possible) or whichever is the most similar projection available on the server. Press the [...] to manually alter the projection chosen by Manifold. Using a projection on the server different than that used by the image will require re-projecting the image, which can take a significant amount of time for large images. Disabled when Manifold type is used since Manifold always stores an exact match when Manifold manages the spatial storage.

Do not reproject data  Off by default. Check to prevent re-projection of data on export, as might be required to match the projection in use by Manifold to an available Oracle projection. Disabled when Manifold type is used since Manifold always stores an exact match when Manifold manages the spatial storage.

Create pyramids  Create intermediate level images to enable much faster zooming and panning. Always leave this checked unless you are a maximum Oracle GeoRaster expert and have some specialized reason not to create pyramids.

Split data into tiles  On by default. If checked, will split image data into tiles of the specified size instead of sending image data in one chunk. Disabled when Manifold type is used since Manifold always uses tiles.

Tile size  Size of image tile to use in pixels. The value estimated by Manifold is usually the best choice.

Compression  Disabled within Oracle since GeoRaster uses Oracle's own technology. Enabled when Manifold type is used and effectively always on by default since compression is faster than not and is lossless.

Projections

Manifold supports all Oracle projections (coordinate systems) although Oracle does not support all Manifold projections. When a component is imported or linked from an Oracle database it will automatically use that same projection within Manifold.

When a component is exported from Manifold to Oracle, Manifold will automatically choose the Oracle projection that is the best match, that is, the most similar to, the Manifold projection in use. Manifold export dialogs will report the degree of similarity between the Manifold projection and the proposed Oracle coordinate system. If need be, Manifold will re-project the component on the fly into that Oracle projection system as part of the uploading process.

There are two nuances of interest in the case of components using a coordinate system that appears both in Oracle and in Manifold (that is, all Oracle coordinate systems):

- Although Manifold supports all coordinate systems used by Oracle, sometimes the names used for those coordinate systems are different. For example, the Latitude / Longitude projection used in Manifold is known as the TWD97 projection in Oracle when using the WGS 84 datum (the default for Latitude / Longitude).
Manifold defines coordinate system presets using higher-precision parameters than those used in Oracle so even if the coordinate system is otherwise identical the Manifold settings have to be lowered in precision to match those used by Oracle. Manifold understands such precision-matching requirements when identifying the equivalent projection in Oracle and will automatically re-project data to account for precision differences. If this or any other re-projection is not desired, Manifold provides a Do not project data option (off by default) that may be checked on to prevent any re-projection of data.

Example: Storing an Image in Oracle
Export Image - PNG

To export an image to PNG format, use the **File - Image - Export** dialog using PNG in the **Save as type** box. After a filename is provided and we press OK a secondary **Export PNG File** dialog will be raised with options.

Options

- **Interlaced**: If checked, will interlace the resultant image so that it can download progressively when used in web publishing. Using interlaced images will slightly expand the image size, but it is psychologically easier on visitors to web sites when large images are served because the visitor can see the large images being downloaded progressively.

- **Embed description info**: If checked, write text properties into the .png image using the component name as the **Title** property, the component's description text property as the **Description** property and the **Software** property set to the "Manifold System..." identification string displayed in the **Help - About** dialog.

The **Embed description info** option is a useful way of embedding copyright slogans: enter the copyright text or whatever other text you want embedded into the image into the component's **Description** property and it will be embedded into the .png image that is exported. Since very few people know that the .png format can contain embedded text information, virtually no one who copies the resultant .png image will realize that you have, in effect, "watermarked" it with embedded .png text properties.

**Notes**

.png is fine format for web publishing and for graphics arts, but it does not preserve georeferencing and projection information. Use GeoTIFF to preserve projection info. It is the ethical duty of all webmasters to do their best to replace .gif format with .png.

Export Layout

Exporting Layouts

Print Layouts are used to arrange jobs for printing. They may also be exported to file formats. To save the layout to a file, we choose **File - Export - Image**. The **File - Export - Image** menu pathway is used for all formats, including those, such as .pdf, which are quasi-vector in nature.

To export a layout to a file:

1. Create the layout and open it.
2. Choose **File - Export - Image**.
3. In the **Export** dialog, browse to the folder in which the file is to be saved, choose a filename and in the **Save as type** box choose the file format to be used. Press **Save**.
4. Formats such as .emf, .pdf, and .ps will raise another **Export ... File** dialog. Choose options desired and press **OK**.

**File Types**

- **AI**: A graphics arts format read by Adobe Illustrator and other applications.
- **EMF (GDI)**: Enhanced Meta File format, the 32 bit version of WMF
Import and Export

(Windows Meta File) format. This option writes EMF using classic Windows GDI (Graphics Device Interface). Use the GDI version as a possible workaround only if the GDI+ version does not provide satisfactory results.

**EMF (GDI+)**
EMF written using GDI+. Microsoft’s GDI+ was developed for Windows XP and is installed by Manifold on all Windows systems if not already installed. The GDI+ version should be used by default, as GDI+ includes numerous improvements over GDI.

**PDF**
Portable Document Format, read by Adobe Acrobat Reader and other applications.

**PS**
Export to PostScript compatible files

Compatibility

Although the .ai, .emf, .pdf and .ps formats are often thought to be "universal," device independent formats the usage of these formats is no guarantee that the visual appearance of what one program writes will be recovered when the file is read by a different program. For example, .emf exports using ordinary GDI support opacity for images and surfaces but not for drawings.

The .ai, .emf, .pdf and .ps formats in this topic may be thought of as programming languages as much as they are formats. They operate not only by providing data but also by providing instructions on how a document is to be dynamically constructed based upon that data. Whenever a program reads one of these programs it must synthesize the desired document using the data and instructions contained in the file. The program must do its best to synthesize the desired document even if its capabilities or the facilities of its host system (such as fonts that might be available) may be less able than those in the system that wrote the file.

The full range of possibilities for describing a document within these formats can be very complex and extensive and few programs (if any) that read or write these formats have implemented all of the capabilities that are theoretically possible. As a result, there can be considerable variation in how different programs interpret the instructions for synthesizing a document contained in these formats. Small differences in capability or interpretation can result in documents that are visibly different.

Export Layout - Ai

Export a print Layout to an Ai file. Ai is a graphics arts format read by Adobe Illustrator and other applications.

To export a layout to an Ai file:

1. Create the layout and open it.
2. Choose File - Export - Image.
3. In the Export dialog, browse to the folder in which the file is to be saved, choose a filename and in the Save as type box choose Ai file format. Press Save.
4. In the subsequent dialog, choose options desired and press OK.

Options for Ai export

Pixel resolution Used to save images and surfaces that are in the layout. Resolution must be greater than 1 DPI and less than 7200 DPI. Default is 72 DPI.

Vector resolution Used to save drawings and labels as well as layout elements such as text or horizontal and vertical lines. Resolution must be greater than 1 DPI and less than 7200 DPI. Default is 300 DPI. If saving for subsequent work in some other program before printing choose a Vector resolution setting that is the same as the resolution of the printer that will be used. If printing to a 600 DPI printer, for example, use 600 DPI.

Pages Export only specified pages from a multipage layout.

Convert text to vector shapes When turned on (default), text elements are converted to vector shapes, as happens when outlining fonts in Illustrator. When off, text elements will be exported as text using the defined font whenever possible but will use the system font (Helvetica) instead of the original font if preservation of fonts is not possible. Using vector shapes results in a larger file but one that is faithful to the appearance of fonts originally used in all circumstances. Not converting text to vector shapes preserves the font for possible editing in Illustrator using Illustrator's text tools.

Ignore Styles Export the image using default point, line, area and label styles.

The Ignore styles checkbox is an advanced option that forces Manifold to use default styles for exported objects. This can be useful when exporting for later use in vector-style graphics editors such as Illustrator because the default styles produce a relatively small number of simple vector objects per Manifold entity. In contrast, more complex styles available in Manifold can produce five to ten relatively complex vector objects per point. If the person who will be operating Illustrator prefers to work with simple objects check this box.

Default Resolutions for Export

Screen resolution is normally 96 DPI on most monitors. The default resolution for layout exports is set to 72 DPI because at 72 DPI one point is one pixel. For example, at 72 DPI an 8 pt Tahoma font will be 8 pixels wide.

Exporting Layouts

Layouts
Export Layout - EMF

Export a print Layout to an EMF file. EMF is Enhanced Meta File format, the 32 bit version of WMF (Windows Meta File) format. It may be written in Manifold using either GDI or GDI+ engine.

To export a layout to an EMF file:

1. Create the layout and open it.
2. Choose File - Export - Image.
3. In the Export dialog, browse to the folder in which the file is to be saved, choose a filename and in the Save as type box choose either the EMF (GDI+) file format (recommended) or EMF (GDI). Press Save.
4. In the subsequent dialog, choose options desired and press OK.

Options for EMF export

- **Pixel resolution**: Used to save images and surfaces that are in the layout. Resolution must be greater than 1 DPI and less than 7200 DPI. Default is 72 DPI.
- **Vector resolution**: Used to save drawings and labels as well as layout elements such as text or horizontal and vertical lines. Resolution must be greater than 1 DPI and less than 7200 DPI. Default is 300 DPI. If saving for subsequent work in some other program before printing choose a Vector resolution setting that is the same as the resolution of the printer that will be used. If printing to a 600 DPI printer, for example, use 600 DPI.
- **Page**: Export only the specified page from a multipage layout.
- **Ignore Styles**: Export the image using default point, line, area and label styles.

The Ignore styles checkbox is an advanced option that forces Manifold to use default styles for exported objects. This can be useful when exporting for later use in vector-style graphics editors such as Illustrator because the default styles produce a relatively small number of simple vector objects per Manifold entity. In contrast, more complex styles available in Manifold can produce five to ten relatively complex vector objects per point. If the person operating Illustrator prefers to work with simple objects check this box.

Default Resolutions for Export

Screen resolution is normally 96 DPI on most monitors. The default resolution for layout exports is set to 72 DPI because at 72 DPI one point is one pixel. For example, at 72 DPI an 8 pt Tahoma font will be 8 pixels wide.

About GDI and GDI+

Manifold uses Windows system routines wherever possible for maximum performance and continuing quality as Windows updates are released. The Graphics Device Interface (GDI) is a Windows subsystem used for a variety of utility tasks involving device-independent graphics, including export to EMF format. The original GDI has now been replaced by GDI+, which was developed with Windows XP and has been released by Microsoft in DLLs that developers can install on earlier Windows systems. Manifold automatically installs GDI+ on Windows systems other than XP.

The GDI+ version of the EMF exporter should always be used by default. If problems occur when using the resulting files in other programs, try using the GDI version to see if reverting to the earlier Windows technology solves the problem (as it might with some programs that were tested or developed using GDI and not GDI+).

Exporting Layouts

Layouts
Export Layout - PDF

Export a print Layout to a PDF file. PDF is Portable Document Format, read by Adobe Acrobat Reader and other applications.

To export a layout to a PDF file:

1. Create the layout and open it.
2. Choose File - Export - Image.
3. In the Export dialog, browse to the folder in which the file is to be saved, choose a filename and in the Save as type box choose PDF file format. Press Save.
4. In the subsequent dialog, choose options desired and press OK.

Options for PDF export

- **Pixel resolution**: Used to save images and surfaces that are in the layout. Resolution must be greater than 1 DPI and less than 7200 DPI. Default is 72 DPI.
- **Vector resolution**: Used to save drawings and labels as well as layout elements such as text or horizontal and vertical lines. Resolution must be greater than 1 DPI and less than 7200 DPI. Default is 300 DPI. If saving for subsequent work in some other program before printing choose a Vector resolution setting that is the same as the resolution of the printer that will be used. If printing to a 600 DPI printer, for example, use 600 DPI.
- **Pages**: Export only specified pages from a multipage layout.
- **Compress output**: Use a compression algorithm to save space.
- **Convert text to vector shapes**: When turned on (default), text elements are converted to vector shapes. When off, text elements will be exported as text but will use the system font (Helvetica) instead of the original font. Using vector shapes results in a larger file but one that is faithful to the appearance of fonts originally used.
- **Use layers**: Use .pdf layers.
- **Use transparency**: Enable transparency to correctly render transparent colors.
- **Ignore Styles**: Export the image using default point, line, area and label styles.

The Ignore styles checkbox is an advanced option that forces Manifold to use default styles for exported objects. This can be useful when exporting for later use in vector-style graphics editors such as Illustrator because the default styles produce a relatively small number of simple vector objects per Manifold entity. In contrast, more complex styles available in Manifold can produce five to ten relatively complex vector objects per point. If the person operating Illustrator prefers to work with simple objects check this box.

Default Resolutions for Export

Screen resolution is normally 96 DPI on most monitors. The default resolution for layout exports is set to 72 DPI because at 72 DPI one point is one pixel. For example, at 72 DPI an 8 pt Tahoma font will be 8 pixels wide.

Tech Tip: Printing a Layout to PDF

There are two ways to create a PDF file from a layout: exporting a layout to a PDF as described within this topic or "printing" the layout via File - Print using a PDF virtual printer driver, which mimics a printer to capture any printing activity as a PDF.
Printing a layout to a virtual printer driver that produces PDF feeds the layout through an ordinary GDI / GDI+
rendering pipeline, which issues "dumb" printing commands that are then captured by the driver. Exporting a
layout directly as a PDF feeds the layout through the Manifold PDF rendering engine, which optimizes printing
commands. In general, the results of exporting a layout as a PDF will almost always be better than the results of
printing the same layout to a virtual printer driver.

Note also that printing a layout to a via **File - Print** exposes you to the risk of whatever that PDF printer driver
vendor has in mind. For example, it could easily produce different results depending on the installed version of
Acrobat if that is what is used for a PDF printer driver. In contrast, exporting a layout to a PDF via **File - Export -
Image** will be consistently the same.

Export Layout - PS

Export a print Layout to a PS file. PS is a PostScript compatible format.

To export a layout to a PS file:

1. Create the layout and open it.
2. Choose File - Export - Image.
3. In the Export dialog, browse to the folder in which the file is to be saved, choose a filename and in the Save as type box choose PS file format. Press Save.
4. In the subsequent dialog, choose options desired and press OK.

Options for PS export

- **Pixel resolution**: Used to save images and surfaces that are in the layout. Resolution must be greater than 1 DPI and less than 7200 DPI. Default is 72 DPI.
- **Vector resolution**: Used to save drawings and labels as well as layout elements such as text or horizontal and vertical lines. Resolution must be greater than 1 DPI and less than 7200 DPI. Default is 300 DPI. If saving for subsequent work in some other program before printing choose a Vector resolution setting that is the same as the resolution of the printer that will be used. If printing to a 600 DPI printer, for example, use 600 DPI.
- **Pages**: Export only specified pages from a multipage layout.
- **Pixel Encoding**: Choose Flat, ASCII HEX or Run-length. The default choice is Flat, which tends to produce smaller files. The other two choices are supplied as possible workarounds if encountering problems with other PS reading software.
- **Use explicit image mask for invisible pixels**: Switches between two different methods for handling invisible pixels allowed in PS format. When checked (the default) each pixel includes an extra byte that specifies if the pixel is transparent or opaque. When not checked, invisible pixels are set to an infrequently used color (R:G:B = 0:0:1) that is then designated transparent. Unchecking the box will reduce file size for files containing large images, but may cause problems for inept PS reading software.
- **Ignore Styles**: Export the image using default point, line, area and label styles.

The Ignore styles checkbox is an advanced option that forces Manifold to use default styles for exported objects. This can be useful when exporting for later use in vector-style graphics editors such as Illustrator because the default styles produce a relatively small number of simple vector objects per Manifold entity. In contrast, more complex styles available in Manifold can produce five to ten relatively complex vector objects per point. If the person operating Illustrator prefers to work with simple objects check this box.

Default Resolutions for Export

Screen resolution is normally 96 DPI on most monitors. The default resolution for layout exports is set to 72 DPI because at 72 DPI one point is one pixel. For example, at 72 DPI an 8 pt Tahoma font will be 8 pixels wide.

Export Surface

Exporting Surfaces

Export surfaces from Manifold by right-clicking on the surface in the project pane and choosing export, or by opening the surface and then using the File - Export - Surface dialog. In addition, surfaces can be exported into databases using spatial DBMS technology can be exported by using the Data Source dialog. Surfaces are exported into spatial DBMS as if they were images. See the Example: Storing an Image in Oracle and Example: Storing an Image in Manifold Spatial DBMS topics for a typical example of exporting to a spatial DBMS as can also be done for DB 2 with Spatial Extender, PostgreSQL/PostGIS, SQL Server 2008, SQL Server 2005 with Manifold Spatial Extender, and just about any DBMS using Manifold's ability to provide generic spatial DBMS facilities.

When using the File - Export - Surface dialog the Files of type choice acts as a filter for what is displayed in the browse pane in the Export dialog. Simple file types are exported directly from the Export dialog by choosing the desired type in the Files of type box. More complex exports into data sources such as databases are exported by choosing Data Sources () in the Files of type box and then using the Data Source dialog.

Surfaces may be exported several different formats. If Enterprise Edition is installed, a surface may be exported to ESRI .e00 format as well. Formats supported include:

- **BIL**: ESRI BIL surfaces/terrain elevation
- **ESRI E00**: Surfaces in ESRI .e00 format. [Requires Manifold System Enterprise Edition]
- **ESRI ASCII Grid**: ESRI grid / surface files using ASCII encoding.
- **ESRI Float Grid**: ESRI grid / surface files using binary encoding.
- **KML, KMZ**: Google Earth XML-based KML or KMZ format. Similar to image export: see the Export Image - KML, KMZ topic.
- **Raw Binary Files**: Export the surface to a generic, raw binary format. Creates a data file with the pixels and an XML file with metadata, which includes the coordinate system, dimensions, and type of the surface.
- **SDTS**: Surfaces in SDTS format.
- **Surfer 6 GRD**: Surfer version 6 GRD format
- **Surfer 7 GRD**: Surfer version 7 GRD format
- **Surfer ASCII GRD**: Surfer ASCII GRD format
- **XYZ**: Comma-delimited ASCII files containing X, Y and Z coordinates.
- **DB2 Data Sources**: Connect to IBM DB2 equipped with the DB2 Spatial Extender using IBM's native spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.
- **Oracle Data Sources**: Connect to an Oracle data sources using the Oracle Call Interface (OCI), the native Oracle interface for exchanging data. Exchanging images with Oracle data sources via OCI automatically maps images into Oracle GeoRaster form (if GeoRasters are supported by the Oracle product in use). A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.
- **PostgreSQL Data Sources**: Connect to PostgreSQL equipped with the PostGIS spatial extender using native PostgreSQL connection technology. Connections made using this data source will have any password required masked so that later usage will not inadvertently expose the password. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.
- **SQL Server Data Sources**: Connect to Microsoft SQL Server 2008 spatial DBMS facilities using native SQL Server 2008 spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires
Import and Export

Enterprise Edition or above.

**Important:** Using a vendor's native spatial DBMS connection technology (like those above) provides better performance and allows using features, such as built-in spatial DBMS facilities, not exposed through generic database interfaces such as ODBC, OLE DB and ADO.NET. At the present writing, only Oracle Spatial provides a built-in GeoRaster type. Other spatial DBMS products are supported using Manifold-managed image and surface storage.

To export a surface to ESRI .bil format:

1. Open the surface to be exported in a surface window.
2. Choose **File - Export - Surface**
3. Choose **BIL Files (*.bil, *.hdr)** in the **Save as type** box.
4. Enter a file name for the file and press **Save**.

The procedure for exporting a surface to SDTS or .e00 is similar.

When exporting a surface to SDTS, the **Export SDTS Data Set** dialog will be raised with one option, a **Use ring registration method** checkbox. On by default, this checkbox selects one of two registration methods allowed by the SDTS specification. Use this for compatibility with older SDTS-reading programs (like MicroDEM) that can only handle ring registration. Exporting a surface to SDTS format will create a data quality module for compliance with the latest SDTS draft standard.

When exporting to .bil format, in addition to the .bil file Manifold also creates .blw (world file), .hdr (header file), .prj (projection file) and .stx (statistic file) files.

**Exporting to Raw Binary**

The .xml file created when exporting to raw binary will be the name of the exported file with an .xml extension. To learn what fields are included, export a sample surface (such as the Montana Mountain example surface included on the Manifold CD) and then open the .xml file using Notepad.

**Importing from Raw Binary**

If a raw binary surface file is accompanied by an .xml file giving metadata, Manifold will automatically use it to pre-load the **Import Raw Binary File** dialog. See the Import Surface - Raw Binary topic.

**XML Files Created upon Export and Used on Import**

Not all formats to which Manifold can export have the ability to correctly save projection information. As a safety measure to ensure that projection information is never lost, Manifold always writes an accompanying .xml file when exporting drawings, images, labels, maps or surface components to a file. The accompanying .xml file contains coordinate system information and some other metadata. The XML file is created for all formats, even those that correctly save coordinate system information.

When Manifold imports drawings, images, labels or surfaces, the system will check for an accompanying .xml file that might have been written by Manifold. If such an .xml file exists, Manifold will read it and use the information it contains to load a correct coordinate system.

See the XML Accessory File Format topic for details on the internal organization of this file.

**Exporting a GSR File**

To create a GSR file to accompany files written for Golden Software applications like Surfer, use the Edit - Change Projection dialog's toolbar to save the coordinate information into a GSR file. Name the file using the same name as the other files with the extension .gsr.

Edit - Change Projection

Export Table

Exporting Tables

Export tables from Manifold by right-clicking on the table in the project pane and choosing export, or by opening the table and then using the File - Export - Table dialog. In addition, tables can be exported into databases by using the Data Source dialog.

When using the File - Export - Table dialog the Files of type choice acts as a filter for what is displayed in the browse pane in the Export dialog. Simple file types are exported directly from the Export dialog by choosing Data Sources () in the Files of type box and then using the Data Source dialog.

Any table in Manifold can be exported to common database file formats. Tables can also be exported to ADO.NET, ODBC and OLE DB data sources as well as to Oracle databases using OCI.

<table>
<thead>
<tr>
<th>ADO .NET Data Sources</th>
<th>ADO .NET data sources. Exported using the Data Source dialog.</th>
</tr>
</thead>
<tbody>
<tr>
<td>CSV</td>
<td>Comma separated text files. Use this choice and specify the full filename in the File name box complete with extension to save to .asc, .csv, .tab or .txt format. Options allow writing an end comma for each record and quotes around all field values (not just for text fields).</td>
</tr>
<tr>
<td>DB</td>
<td>Paradox .db format.</td>
</tr>
<tr>
<td>DBF</td>
<td>dBase and FoxPro .dbf format.</td>
</tr>
<tr>
<td>HTML</td>
<td>Write as a table within an .htm (HTML) format file, ready for publishing on the web.</td>
</tr>
<tr>
<td>MDB</td>
<td>Microsoft Access .mdb file format.</td>
</tr>
<tr>
<td>ODBC Data Sources</td>
<td>ODBC data sources. Exported using the Data Source dialog.</td>
</tr>
<tr>
<td>OLE DB Data Sources</td>
<td>OLE DB data sources. Exported using the Data Source dialog.</td>
</tr>
<tr>
<td>WKx</td>
<td>Lotus WK tables</td>
</tr>
<tr>
<td>XLS</td>
<td>Microsoft Excel .xls spreadsheet file format.</td>
</tr>
<tr>
<td>DB2 Data Sources</td>
<td>Connect to IBM DB2 equipped with the DB2 Spatial Extender using IBM's native spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.</td>
</tr>
<tr>
<td>Oracle Data Sources</td>
<td>Connect to an Oracle data sources using the Oracle Call Interface (OCI), the native Oracle interface for exchanging data. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.</td>
</tr>
<tr>
<td>PostgreSQL Data Sources</td>
<td>Connect to PostgreSQL equipped with the PostGIS spatial extender using native PostgreSQL connection technology. Connections made using this data source will have any password required masked so that later usage will not inadvertently expose the password. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.</td>
</tr>
</tbody>
</table>
Import and Export

above.

**SQL Server Data Sources**
Connect to Microsoft SQL Server 2008 spatial DBMS facilities using native SQL Server 2008 spatial connection technology. A spatial DBMS connection accessed through the Data Source dialog. This option requires Enterprise Edition or above.

**Important:** Using a vendor's native spatial DBMS connection technology (like those above) provides better performance and allows using features, such as built-in spatial DBMS facilities, not exposed through generic database interfaces such as ODBC, OLE DB and ADO .NET. For example, exchanging data with Oracle data sources via OCI automatically maps geometry columns into Oracle SDO_GEOMETRY data and will likewise map geometry columns into the native geometry types used by DB2, PostgreSQL and SQL Server 2008.

Export dialogs for **DBF, DB, MDB, WK** and **XLS** include a **Subtype** choice box allowing choice of specific variations within those formats. This is used, for example, to select Access 2000 or Access 97 versions of .mdb format. Export dialog controls include:

**Subtype** Choose format subtype for compatibility with older applications.

- **Select All** - Check all fields. All data fields in the table will be exported.
- **Select None** - Uncheck all fields. No data fields will be exported. Tech tip: Use this to uncheck all fields before checking those desired.
- **Select Inverse** - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push **Select Inverse**.

**Fields pane** Check the fields to be exported.

**Note:** Exporting a table to a data source that supports NULL values makes intrinsic, rank and script columns (that is, Active columns) NULL-able. That is, the table in the external data source may contain NULL values. In general, exporting a table to an external data source makes all exported columns except the identity column (ID) NULL-able.

**Formatting in Exported Tables**

Tables export to the target format using whatever native field types map best to those in use within Manifold. In general, it is not possible to preserve formatting information such as the number of significant digits to show after a decimal point.

Export to text formats such as .csv or HTML is the exception. Manifold will always export data to these formats as strings formatted using whatever column formats have been applied to the table. This includes use of extra characters such as, for example, the percent character, " %" when it is used as a column formatting style to show a percentage field.

Manifold supports the usual conventions when exporting tables to text files. For example, the first line of the file should contain the field names to be used for the data in the subsequent lines.

**Exporting Tables with Variable-Length Columns to Oracle**

Oracle tables cannot have more than one variable-length column. Attempting to export a drawing with more than one variable-length column to an Oracle database will fail with a message that lists the variable-length columns and advises converting one or more of these columns to fixed-length types, or unchecking them in the list of exported columns.
Important Note when Using 64-bit Manifold Editions

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKx format files. This includes no access to the MDB parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut.

Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.
Export Table - ADO .NET / ODBC / OLE DB

ADO .NET, ODBC and OLE DB are database technologies for connecting to a wide variety of database sources. We can connect to databases using these database connection technologies by using the Data Source dialog, creating a new data source in the dialog if necessary.

Exporting a table to an ADO.NET, ODBC, OLE DB or native Oracle data source allows selecting which columns we would like to export.

When exporting a table to an ODBC data source, Manifold tries to preserve, if possible, the signed / unsigned variations of integer types when matching them to the types supported by the data source.

The Data Source Dialog
Export Table - CSV

CSV refers to a family of ASCII (plain text) formats that save tabular data in the form of one line per record with the values for each field in that record separated by a comma, hence the name Comma Separated Value (CSV) format.

There is considerable variation in how different programs work with "CSV" format. Some programs like to see a comma at the end of each line and others do not. Most programs expect to see only string field values enclosed in quotes, but some like to see all values enclosed in quotation marks whether they are strings or not. Manifold's CSV exporter provides options to deal with both situations.

To export a table to .csv format:

1. Open the table in a table window.
2. Choose File - Export - Table from the main menu.
3. In the Export dialog choose CSV Files in the Save as type box and specify a filename to use. Press Save.
4. Check the fields that are to be exported. Buttons provide for Select All, Select None and Select Inverse to rapidly change which fields are to be exported for tables containing many fields.
5. Check the ending comma and quotes boxes as desired.

Controls

Select All - Check all fields. All data fields in the table will be exported.
Select None - Uncheck all fields. No data fields will be exported. Tech tip: Use this to uncheck all fields before checking those desired.
Select Inverse - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.

Fields pane

Write ending comma
Place a comma at the end of each line. Off by default.

Write quotes around non-text fields
Enclose all values within quotation marks even if they are not text fields. If not checked, only text fields will be surrounded by quotation marks. Off by default.

When exporting data to CSV format one loses fine control over how numeric fields are represented. Values end up being either text fields or numbers. A better choice for data interchange in the Microsoft world is to export to Microsoft's .mdb format whenever possible.

When Text Fields Contain Commas

Although the "comma separated values" format is intended to use commas as delimiting characters to separate field values, at times people would like to use different characters. Normally this desire is prompted by text fields that contain commas as part of the data.

Manifold's CSV importer can read "csv" files that use characters other than commas as delimiters but Manifold's CSV exporter only exports using commas (otherwise, it would be somewhat inaccurate to refer to the resulting file as a "comma separated" file). Suppose we do have text fields that contain commas in our table. What can we do? The best approach would be to use .mdb or some other modern format, but if we must export the data into a text file format like CSV there is a workaround:

The usual technique is to open the table and use Edit - Replace to replace all commas with an otherwise unused character, such as the ^ character. Save using the Export Table - CSV command. Open the resulting .csv file with Notepad or some other text editor and replace the commas with the desired delimiter character of choice.
such as a pipe | character or some otherwise unused character. Finally, search and replace all ^ characters with commas. The result will be a "comma separated value" file that uses pipe characters instead of commas.

**See Also**

Import Table - CSV
Export Table - DB

DB refers to a family of formats originally used with the Borland Paradox database management system, with slightly different formats for different versions of Paradox.

To export a table to .db format:

1. Open the table in a table window.
2. Choose File - Export - Table from the main menu.
3. In the Export dialog choose DB Files in the Save as type box and specify a filename to use. Press Save.
4. Check the fields that are to be exported. Buttons provide for Select All, Select None and Select Inverse to rapidly change which fields are to be exported for tables containing many fields.

Controls

Subtype  Choose the Paradox version .db file that is to be created.

- Select All - Check all fields. All data fields in the table will be exported.
- Select None - Uncheck all fields. No data fields will be exported. Tech tip: Use this to uncheck all fields before checking those desired.
- Select Inverse - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.

Important Note when Using 64-bit Manifold Editions

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKx format files. This includes no access to the MDB parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut. Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.
Export Table - DBF

DBF refers to a family of formats originally used with the dBase database management system. The format is now used with Microsoft's FoxPro DBMS as well as in many Windows and UNIX/Linux DBMS applications that can save database tables. Unfortunately, there is no universal standard for what constitutes a ".dbf" file. The original dBase format limits field names to eight alphanumeric characters not beginning with a number. It also limits file names to eight alphanumeric characters plus a three-letter extension. More recent ".dbf" drivers will allow nine or eleven character filenames and field names. Some UNIX drivers may impose no limitation on file or field names.

To export a table to .dbf format:

1. Open the table in a table window.
2. Choose File - Export - Table from the main menu.
3. In the Export dialog choose DBF Files in the Save as type box and specify a filename to use. Press Save.
4. Check the fields that are to be exported. Buttons provide for Select All, Select None and Select Inverse to rapidly change which fields are to be exported for tables containing many fields.
5. Check use dBase format for greatest compatibility with older databases; however, if this box is checked and field names or file names are longer than 8 simple alphanumeric characters the export will not succeed.

Controls

Subtype Choose dBase or FoxPro .dbf format for compatibility with older applications.

Select All - Check all fields. All data fields in the table will be exported.

Select None - Uncheck all fields. No data fields will be exported. Tech tip: Use this to uncheck all fields before checking those desired.

Select Inverse - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.

Fields pane Check the fields to be exported.

One problem with .dbf formats is that the specific nature of what is allowed or disallowed in the format varies greatly depending on the drivers or applications that are used. In particular, some applications can use longer names for files and fields than can other applications using a ".dbf" format. Manifold will use whatever .dbf drivers are available on the host Windows system, by default installing the FoxPro and .dBase .dbf Microsoft drivers.

For maximum compatibility it is best to use filenames and fieldnames that are eight characters or fewer in length. Use only letters and numbers in the name and do not start a filename or field name with a number. Do not use any special characters such as spaces, parentheses or underscores. Most modern drivers will allow 11 character filenames and field names, as do the default .dbf drivers installed with Manifold. However, it is wise to truncate file and field names to only 8 characters if you plan on exchanging data with other ".dbf" capable applications.

Because of the wide variation in drivers and field and file naming conventions in common use, .dbf is not a good choice for reliable data interchange unless it is limited to the least common denominator of using very restricted field and file names. However, such a primitive approach to naming is very costly because it denies us the ability to use descriptive field and file names that are self-documenting.

A better choice for data interchange in the Microsoft world is to export to Microsoft's .mdb format whenever possible.

Internationalization
Exporting a .dbf file (either by exporting a table as a .dbf or by exporting a drawing as a shapefile) will set the .dbf codepage field to the codepage used by the columns in the exported table. If the columns use conflicting codepages or if the codepage is not supported by .dbf format, Manifold will display a warning message.

Importing a .dbf file (either by importing a table from a .dbf or by importing a drawing from a shapefile) sets the codepage of each text column to that used in the .dbf file.
Export Table - MDB

MDB refers to the .mdb formats used with Microsoft's Access database products. These formats have been made available in the Microsoft "Jet" database engines (the same used within Access) that may be used royalty-free by developers working with Microsoft development products such as Visual Studio. As a result, many thousands of third party applications can read and write .mdb formats.

To export a table to .mdb format:

1. Open the table in a table window.
2. Choose File - Export - Table from the main menu.
3. In the Export dialog choose MDB Files in the Save as type box and specify a filename to use. Press Save.
4. Check the fields that are to be exported. Buttons provide for Select All, Select None and Select Inverse to rapidly change which fields are to be exported for tables containing many fields.
5. Check use Access 97 format for greatest compatibility with other applications.

Controls

Select All - Check all fields. All data fields in the table will be exported.

Select None - Uncheck all fields. No data fields will be exported. Tech tip: Use this to uncheck all fields before checking those desired.

Select Inverse - Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.

Fields pane  Check the fields to be exported.

Access 97 and Access 2000 .mdb Formats

Until Access 2000, all .mdb capable applications could exchange data without any problems. However, with the introduction of Access 2000 and Jet 4.0, Microsoft changed the .mdb format slightly so that the "new" .mdb cannot be read either by Access 97 or by any applications using Jet versions prior to Jet 4.0. In particular, Manifold System Release 4.50 uses Access 97 format.

Manifold’s export to .mdb will write to the "new" .mdb by default. A checkbox option allows writing to the Access 97 .mdb format if desired. Since Access 2000 and Jet 4.0 based applications can read the older Access 97 / Jet .mdb formats, a good strategy to assure maximum compatibility with all ".mdb" applications is to check the Use Access 97 format box if the files will be used for interchange, exchanged with Manifold System 4.50 users or otherwise widely published.

Important Note when Using 64-bit Manifold Editions

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKx format files. This includes no access to the MDB parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut.

Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

Although Microsoft is slowly moving forward towards 64-bit operation of Office and the JET components used by Access and Excel, at the present writing (2010) this is such a total kludge that while it is possible to get 64-bit
access to Access or Excel it is just easier for most to continue using the 32-bit versions. See comments in the 32-bit and 64-bit Manifold Editions topic.
Export Table - XLS

XLS refers to the .xls formats used with Microsoft's Excel spreadsheet products. Routines to read and write these formats have been made available in the Microsoft "Jet" spreadsheet engines that may be used royalty-free by developers working with Microsoft development products such as Visual Studio. As a result, many thousands of third party applications can read and write .xls formats.

Keep in mind that .xls formats are spreadsheet formats. For general database table exchange it is usually wiser to use a database format like Access .mdb.

To export a table to .xls format:

1. Open the table in a table window.
2. Choose File - Export - Table from the main menu.
3. In the Export dialog choose XLS Files in the Save as type box and specify a filename to use. Press Save.
4. Choose the Excel subtype to use.
5. Check the fields that are to be exported. Buttons provide for Select All, Select None and Select Inverse to rapidly change which fields are to be exported for tables containing many fields.
6. Press OK.

Controls

- **Subtype**: Choose which version of Excel format to use. Newer versions of Excel use slightly different .xls formats than earlier versions.
- **Select All**: Check all fields. All data fields in the table will be exported.
- **Select None**: Uncheck all fields. No data fields will be exported. Tech tip: Use this to uncheck all fields before checking those desired.
- **Select Inverse**: Uncheck all previously checked fields and check all previously unchecked fields. This is a fast way to check only a few columns out of many: uncheck those desired and then push Select Inverse.

Fields pane: Check the fields to be exported.

Extra Sheets

Manifold System uses Microsoft's own OLE DB drivers to write Excel format. This provides perfect compatibility with Microsoft's .xls format since Microsoft's own code is used to write the .xls files. Unfortunately, Microsoft's OLE DB driver has an interesting "feature" in that it automatically creates an extra, unnecessary sheet in the Excel file. There is no way to prevent the OLE DB driver from creating this extra sheet.

If Excel is installed on the system, Manifold is able to take extra steps to get rid of the extra sheet. If Excel is installed, Manifold launches an automation routine that locates and instantiates Excel, opens the newly exported file with Excel, turns off confirmations and then deletes the extra sheet. Expert programmers or system administrators may notice an Excel process launching when exporting to .xls - it is being used to eliminate the extra sheet created by the OLE DB driver.

If Excel is not installed on the system, Manifold will be unable to launch Excel to clean up the extra sheet deposited by the OLE DB driver. In that case, each .xls file created by exporting a table will include an extra sheet.

Important Note when Using 64-bit Manifold Editions
Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKx format files. This includes no access to the MDB parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut. Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

Although Microsoft is slowly moving forward towards 64-bit operation of Office and the JET components used by Access and Excel, at the present writing (2010) this is such a total kludge that while it is possible to get 64-bit access to Access or Excel it is just easier for most to continue using the 32-bit versions. See comments in the 32-bit and 64-bit Manifold Editions topic.
Projections

Projections are a very important idea in GIS and mapping. If you are not familiar with projections, please begin by reading the Projections Tutorial topic.

This documentation provides several paths through the general subject of working with projections in Manifold. Some material is repeated in the various topics so that essential material is covered no matter which path the reader takes through the Help system.

- Experts may jump directly to the Projections Quick Reference topic for a terse introduction.

- If you are a new user and are working completely within Manifold System, read this topic and then proceed to the Projecting a Map topic. Very little expertise in the inner workings of projections is required to make simple projections when working within Manifold System.

- To permanently re-project a specific component we open it in a window and apply the Edit - Change Projection command. If the component appears in a map and we would like to re-project it to use the same projection as the map, we can right click its tab in the map and choose Project to Map.

- If you must deal with maps in legacy formats such as ESRI .shp or AutoCAD .dxf, please read the Projections and Legacy Formats topic. Because legacy formats do not normally save information on projection parameters used, importing maps saved in legacy formats can require extensive knowledge of projections and coordinate systems.

- If you are new to projections and coordinate systems in GIS and would like to learn more about the general concepts involved, consult the Projections Tutorial and subsequent topics.

- The Projections Readings topics provide a classical introduction to projection concepts together with a guide to selecting projections based on the writings of John Parr Snyder, one of the greatest enthusiasts of map projections ever.

- The Manifold Projections topics discuss the specific characteristics in summary form of various families of projections available within Manifold System. This is a reference section that should be consulted for summary information on a specific projection.

- A topic related to projections is Georegistration, the process of matching an image or drawing to the geographic location and projection of a "known good" reference drawing, image, or map. If you wish to use an image within a geographic map please read the Georegistration topic.

- Experts may specify custom units of measure, ellipsoids, datums and even customized coordinate systems (projections) by specifying customized projection presets. See the Customization topic.

- **Very Important:** Do not use the Edit - Assign Projection dialog in an attempt to change the native projection of a component. This dialog is used only to complete the import of a projected component from a format that does not
correctly save projection information. Instead, use the Edit - Change Projection dialog to re-project a component.

- Maps are a special case because they are viewports that show their contents in whatever temporary projection is desired. They don't change their contents, they simply show them in a different form. The projection used by a map to display its contents is set in the Edit - Assign Projection dialog.

**Why Use Projections?**

In Manifold, projections are used for three main reasons:

- To provide a more natural looking map,
- To enable measurements of areas and lengths in printed maps.
- To enable easy measurement in linear units such as meters when performing analyses.

**Better Appearance**

Geographic projections are confusing to many people but the idea is quite simple. Because the Earth is a round, three-dimensional body it's not possible to show the shapes of large entities such as continents on a flat sheet of paper or a flat computer monitor without distorting their shapes. Anyone who has tried to flatten a deflated basketball knows that a rounded 3D surface cannot be perfectly flattened without distorting shapes on the surface.

"Geographic projections" are simply ways of transferring the shapes of things from a sphere onto a flat sheet of paper (or, the same thing, onto a flat computer monitor screen) in a way that minimizes distortions. The idea is to show an image that looks like what one would perceive if one were looking at a globe.

The simplest "projection" is sort of a non-projection: take the longitude and latitude coordinates of objects and plot them as if they were X and Y coordinates. This is a "cylindrical" projection of sorts. Along the Equator and middle latitudes, the distortion is not so bad. More northerly objects are very distorted. Manifold uses this "projection" by default because it is the simplest conceptually. If we are working with small-scale maps such as a map of a particular county near the Equator, we might never need to use another projection. However, if we are working with larger maps such as the entire United States or all of Europe we will probably wish to convert the map to a projection that shows the region in a closer approximation to the way it would appear if seen on a globe.

It is very important to note that no projection can show the entire world without distortion, and every projection to a greater or lesser extent causes some distortion within the map. All projections are therefore approximations. Various projections have been designed for different purposes so when they are used for the intended purpose they do a better job of minimizing distortions that are important for that purpose. For example, some projections are better at minimizing distortions when used to display broad, rectangular regions such as the continental United States. Other projections are better at displaying circular regions such as the Antarctic continent or oceanic coverage of the entire Pacific Ocean.

See the readings in projections provided in this documentation, including General Projections Concepts, The Earth as an Ellipsoid and Guide to Selecting Map Projections for more information on various projections and their uses.
**Accurate Measurement**

Projections are also used to create flat maps from which measurements can be made. Many people are familiar with the idea of taking a ruler to a paper map and measuring the distance between two points, perhaps by comparing the measured distance of a pencil line to a scale printed at the edge of the map. This is a simple and straightforward idea when the map shows a very small rectangle of the Earth’s surface because in such cases even a clumsy projection does not introduce distortions that are greater than the intrinsic accuracy of the map.

When maps cover larger areas of the Earth one must be more careful to choose a projection for the map so that the distortions introduced in the process of projection do not make it impossible to measure distances in the map reliably. The larger the area, the more difficult it is to draw a rectangular, flat map that will enable accurate measurements of length and area to be made at all locations in the map.

The usual solution is to use a projection that is mathematically arranged so that the area of a figure drawn on the globe (such as a country) is the same as that of the equivalent figure on the flat, rectangular map within the area of interest. If lengths are more important than areas, one chooses a projection that does a good job of preserving accurately measurable lengths in the region of interest. If measurement is not required because the map will be used for "thematic" presentation, one is free to use a projection such as the Robinson that allows no accurate measurement at all but that nonetheless delivers a pleasing aesthetic impression.

For work done on the computer screen Manifold will automatically compute areas and lengths of items that appear on screen so one can use whatever projection is desired for visual effect without losing the ability to measure lengths or areas. Because Manifold knows what the true Earth coordinates are supposed to be of every map, the system can re-compute on the fly what the correct areas and lengths should be if the items were laid out on the real, three-dimensional, ellipsoidal Earth.

For measuring lengths using the Tracker tool, Manifold will always compute the tracker length by great circle distance, that is, a straight line between the two points indicated as laid out over the surface of whatever Earth ellipsoid is currently specified as the map datum.

Projections are still important when printing maps because users may attempt measurements from the printed map. In such cases it is important to pick the projection which best preserves lengths or areas in the intended usage.

**Projecting a Map**

Once drawings have been imported into Manifold it is easy to show them in a map and to show the map within any projection desired. To do so, we open the map and use the Edit - Assign Projection dialog to change the projection to any projection desired.

Note that even though a map can show its layers in whatever projection desired, re-projecting the layers on the fly if their components are in a projection different from the one used by the map, at some point the reprojection on the fly process will take so long that users will be unhappy with the resultant performance of the map window for panning and zooming. We can make the map window work faster if both the map window and any large components it contains use the same projection.

See the Projecting a Map topic for more information.
Projections and GIS Formats

Manifold can work with data saved in both projected and unprojected coordinate systems from all standard GIS formats. Unprojected maps are usually easy to import automatically no matter how geographically unaware the GIS format. GIS data saved as projected maps might require user intervention in some cases if the format does not save the projection parameters necessary to use the data.

Once a drawing is imported, the projection parameters in use for that drawing may be seen at any time by viewing its coordinate properties. Click on the drawing in the project view to highlight it and then choose the Edit - Assign Projection dialog for that component. The coordinate properties tell Manifold how to interpret the data in that drawing. If these properties are changed, they simply change how Manifold uses the existing data. Changes in this dialog do not change the data itself. To change the native projection of the drawing, we use the Edit - Change Projection dialog.

Some GIS formats are "smart" and automatically save the projection parameters in use together with the data. During import, Manifold will fetch all necessary parameters from such "smart" formats automatically and will load the coordinates properties with the correct parameters necessary to use the data. Cool!

Other GIS formats (such as ESRI .shp "shapefile" format as commonly used) are legacy formats and do not save the projection parameters in use. When legacy formats are used to save projected maps they require users to keep track manually of the projections used in the file. This is usually done by accompanying the GIS data with a readme.txt file or other "metadata" documentation that specifies what projection parameters should be used with the file. Users must read the file's documentation to know what parameters to use. If we download the file and neglect to fetch the documentation that says how to use it we are in trouble. Ugly!

Since no one wants the hassle of keeping track of projection parameters manually, most people will use legacy formats only to save unprojected data. GIS data in legacy formats therefore is usually unprojected data that may be imported into Manifold with no special user intervention.

On those rare occasions when we encounter a projected map saved using a legacy format there is usually no warning within the format that the data it contains must be interpreted in a way known only to its author. When importing from legacy formats we should always keep in mind the possibility that the file being imported contains projected data. If we suspect projected data is involved we should keep an eye out for a readme.txt or other "metadata" documentation file that might explain what projection parameters are to be used with the file.

To use projected data from a legacy format we first import the drawing using default settings. We then manually add the projection parameters required. To do this, click on the new drawing to highlight it in project view, and then open the Edit - Assign Projection dialog. This will display the (wrong) parameters used during default import. We then enter the correct parameters intended to be used with that data. We only need do this once and then forever more Manifold will keep track of all projection parameters for us automatically.

Note: It's always a good idea to download any accompanying documentation when downloading GIS data from the web even when "smart" formats are used. This will help us speak accurately about the sources of data being used in our projects.

Verifying Projections
Once a component has been correctly imported into Manifold, the system will automatically manage projections from then on. The catch is getting a drawing or image or other component correctly imported into Manifold in the first place if it must be imported from a format that does not reliably capture projection information. Surprisingly many formats for drawings and images used in GIS work are very old formats that do not reliably capture projection information.

It is so important to make sure that a projection has been correctly assigned that Manifold tries to ascertain when a component is imported from a format that does not store projection information. In such cases, Manifold will take special measures to ask us to verify the projection assigned. The first time such a new component is opened, Manifold will overlay an info bar onto the window telling us that the projection used by the component has not yet been verified, and inviting us to click on the info bar to verify the projection.

Clicking on the info bar will launch the Edit - Assign Projection dialog. We should take a moment to review the settings shown by that dialog to verify that the projection is indeed what it should be. If it is, we can click OK and thereafter Manifold will not nag us about verifying the projection. If the projection is not what it should be, we can specify the desired projection. Once we verify the projection assigned, we can open the component without Manifold nagging us to verify the projection.

We can get rid of the info bar without launching the Assign Projection dialog by clicking the X sign at the right side of the info bar; however, Manifold will know that we've not yet verified the projection of this component and the info bar will appear again the next time the component is opened in a window.

If we do not want to verify projections of new components, once we acquire enough expertise not to want to verify projections anymore unless it is absolutely necessary, we can get rid of the info bar by changing the Prompt to verify projections of new components option in the Tools - Options dialog.

Conversely, if we would like Manifold to remind us to verify the projection of all new components, even those imported from formats that correctly store projection information, we can uncheck the Suppress prompt for non-default projections option in the Tools - Options dialog.

**Note:** The rule of thumb used by Manifold to decide if a component has been imported from a format that does not store projection information is to simply raise the info bar whenever a new component's projection is Orthographic, the default used for imports from formats that do not provide coordinate information, or if the component has been imported in Latitude / Longitude with coordinate locations outside the expected range (+/- 90 latitude and +/- 180 longitude).

That leads to some unnecessary use of the info bar as occasionally we will import a component from a perfectly expert GIS format where the component just happens to have truly been stored in Orthographic projection, but for a short hand rule of thumb it works surprisingly well.

More worrisome is that the rule of thumb will miss occasions when formats have some projection information but not complete projection information. The classic case is shapefiles using incomplete .prj accessory files or some image formats accompanied by "world" files. In that case, there may be enough information to cause a projection other than Orthographic to be used, so that the rule of thumb does not cause the info bar to be raised, but not sufficient information from the format to have all projection parameters correctly assigned. In that case, we have be alert enough as users to manually launch the
Assign Projection dialog to verify the projection and to accurately specify all parameters if needed.

Beginning GIS users working with formats such as shapefiles or graphics formats using "world" files may want to uncheck the Suppress prompt for non-default projections option in the Tools - Options dialog so that they are reminded by Manifold to always verify projections on all new components.

Changing Projections of Drawings and Images

Changing the coordinates properties of a drawing or image simply changes how Manifold interprets the internal coordinate numbers that comprise the actual data set. The only time we would do this manually is if we import a projected drawing or image from a legacy format and need to tell Manifold (manually) what parameters are supposed to be used. When importing a projected map from a legacy format, the internal coordinate numbers are already correct but there is nothing in the format that can be imported as correct properties. We must add this information manually.

Changing the native projection within which the coordinate numbers are computed requires us to change the actual coordinate numbers themselves. To re-project a drawing or image into a new coordinate system we open the drawing or image and use the Edit - Change Projection dialog. The dialog opens with the projection parameters currently in use. If the drawing was imported correctly these parameters will be the exactly correct parameters required for the coordinates required in the drawing to make sense.

When we use the Edit - Change Projection dialog to change these properties to cast the drawing into new projection, Manifold will re-compute the coordinates within the drawing to the equivalent numbers required by the new projection. All of this happens automatically. Henceforth, when we open either the projections dialog we will see the new parameters to match the new coordinate numbers. Re-projecting a drawing in this way permanently changes the internal coordinates used to define the drawing.

Because drawings are normally seen through map view within maps, it is not normally necessary to re-project them from whatever projection they were in when imported. Specifying the projection used by a map does not change any data - it simply changes the way the data is seen by computing "on the fly" how the drawing should look in the projection requested of that map view.

The only time we would re-project a drawing is to speed up map view. Map windows works much faster if the drawings they contain use the same projection requested of the map. This is especially true if many, large drawings and images are used in the map. If we re-project a drawing into the same projection used by our map we should make sure that the projection used for the drawing also uses the same parameters as the map. For example, using the same azimuthal projection with the same center latitude and longitude but using different datums is not using the same projection.

Very important: The above discussion of Edit - Change Projection assumes the drawing was correctly imported in the first place. A regrettable trap for the unwary is the use of some older formats, such as ESRI .shp or AutoCAD .dxf, to publish GIS data in projected form. Because these formats do not save projection information, the user must manually enter such information using the Edit - Assign Projection dialog. If you are importing projected data from such formats you must use the Edit - Assign Projection dialog to specify the correct information the format is unable to provide. Until you provide such information the drawing may appear visually correct but it is not yet correctly imported.
Formats such as ESRI .shp or AutoCAD .dxf should not be used to publish projected data but regrettably this is done all the time. See Projections and Legacy Formats for more information in this area.

Images

Although idea of projection is the same in both cases we tend to work differently with images and projections than we do with drawings and projections.

- Images are often re-projected to achieve greater speed in a map view, because images usually contain many more pixels than drawings contain objects.
- Images are usually highly localized views shot from directly overhead or very nearly so. They thus are already in Orthographic projection or are very close to Orthographic. In contrast, most drawings or imported maps are in Latitude / Longitude coordinates and are not in any specific geographic projection.
- Images are often slightly off Orthographic projection, or they are shot at angles that result in a Tilted Perspective or Space Oblique projected view in the image; however, it is very rare that we have actual numeric parameters corresponding to a particular image.

Manifold deals with the above by providing a collection of interactive tools for simple image movement and distortion to transform an image into a correct projection by matching the image to a known good drawing. This process is often called georegistration and allows the use of images with drawings and surfaces in correct geographic position.

A Projections Strategy

For most interactive editing and map preparation work in middle latitudes a good strategy is to keep all drawings in Latitude / Longitude form and to work with them in maps using the Latitude / Longitude projection. This is the name given to the "unprojection" that uses simple degrees latitude and longitude instead of any other projection. Most GIS data is published in this form, so it’s likely that this will be the native “projection” used by most drawings on import.

Use the map in Latitude / Longitude projection for most interactive editing. For fine-tuning the appearance of the map for presentation purposes, create a map that shows the project in whatever projection is desired for presentation.

Maps involving images such as aerial photographs can be conveniently kept in Orthographic projection because the images by default will be in Orthographic projection and because Orthographic provides a typical "view from space" appearance that most people associate with overhead imagery. If speed is an issue, the drawings involved in the map should also be re-projected into the same Orthographic projection.

One limitation of Orthographic is that the projection is defined only for the sphere datum. If other datums are to be used, an alternative "view from space" projection is the Stereographic projection.

If you have an especially fast system or are working with smaller maps you can simply keep drawings in whatever projection they were imported and use whatever projection you like in maps.

XML Files Created upon Export and Used on Import
Not all formats to which Manifold can export have the ability to correctly save projection information. As a safety measure to ensure that projection information is never lost, Manifold always writes an accompanying .xml file when exporting drawings, images, labels, maps or surface components to a file. The accompanying .xml file contains coordinate system information and some other metadata. The XML file is created for all formats, even those that correctly save coordinate system information.

When Manifold imports drawings, images, labels or surfaces, the system will check for an accompanying .xml file that might have been written by Manifold. If such an .xml file exists, Manifold will read it and use the information it contains to load a correct coordinate system.

In addition to the .xml file that is automatically created, Manifold projections dialogs such as the Edit - Change Projection dialog provide toolbar commands to manually write or read projection information from accessory files using generic XML, Golden Software GSR or ESRI PRJ files.

**Automatic use of Custom Datum Transformations**

Manifold uses high accuracy coordinate transformation mathematics when re-projecting data from one coordinate system to another. In certain parts of the world, custom transformation formulae are routinely used (and, at times mandated by law for certain uses) to convert datums during re-projection. If the **Use custom datum transformations** option is checked in the Tools - Options - Miscellaneous pane (checked by default) Manifold will use such custom datum transformations when available.

Currently, NADCON formulae are used to convert between NAD27 and NAD83 in North America and NTv2 formulae are used to convert Canadian, Australian and New Zealand datums supported by NTv2.

If a converted location is outside of the conversion domain supported by such custom methods, no datum conversion is done and Manifold will display a message box to that effect after the attempted re-projection. If desired, such a re-projection can be undone, the data set edited to fall entirely within the region supported by the custom method and re-projection attempted once more.

**Note:** the message box mentioned above appears only when a component is re-projected using **Edit-Projection**. It does not appear when a component is re-projected on-the-fly for display as part of a map view.

In general, if we attempt to make a datum conversion between any of the datum pairs shown below and the datum is not converted, that tells us part of the data set we are attempting to convert falls outside the service area of the custom transformation formulae.

**Datum Pairs supported by Custom Transformations**

- North American 1927 (mean for CONUS) &gt; **NADCON**
- North American 1983 (mean for CONUS)
- North American 1927 (mean for Canada) &gt; **NTv2**
- North American 1983 (mean for CONUS)
- Australian Geodetic 1966 (Australia, Tasmania) &gt; **NTv2**
- Australian Geocentric 1994 (GDA94)
Custom datum transformations will be invoked only when converting between the above pairs in either direction. For example, they will be used when converting NAD27 to NAD83, or when converting from NAD83 to NAD27. Pairs shown above are listed using their full names as they appear in the datum box in Manifold projection dialogs, not using the abbreviated form commonly used. For example, North American 1983 (mean for CONUS) is referred to as NAD83 in abbreviated form.

The names of the above datums are significant, not the parameters used. For example, if we convert GRS80 (the parameters of which are identical to NAD83 so it is the same datum) to NAD27 (mean for Canada), Manifold will not use the custom NADCON conversion formulae. This is done on purpose, so we can use NAD83 as the name of the datum for conversion-sensitive North American data (so that the custom transformation will be used) and GRS80 as the name of the datum for all other data where we would like to use the general purpose routines.

Custom Datum Pairs for NTv2

Additional datum pairs may be added to those supported by Manifold for use in NTv2 transformations through customization. See the Custom Datum Grids for NTv2 topic for details.

A Technical Note on Datums

This technical note is intended for experts.

The most commonly used datums for many purposes (such as the default datums used by GPS devices) are WGS84 worldwide and NAD83 in North America. While in almost all cases these datums may be thought of as fixed, well-defined datums not subject to change, that is not true in all cases as sometimes the definitions of those datums will vary from the "standard" definitions embedded within Manifold's XML file definition and as used by virtually all GIS applications and almost all hardware (such as most GPS devices).

In actual fact both the WGS84 datum and the NAD83 datum change slightly over time to account for changes such as those caused by movements of tectonic plates. The working definitions of these datums as used in some high-precision applications will therefore change from the "standard" definitions of these datums.

To use a working definition for either WGS84 or NAD83, create a custom datum from the working definition and use that instead of the WGS84 or NAD83 datum built into Manifold. Such working definitions are not published within this documentation or with Manifold because the point of those definitions is that they change over time. Therefore, the user must find out exactly how such "working" datums are defined within the particular usage that employs them. This can be a major annoyance, especially if someone uses such an atypical definition for a very common standard like WGS84 without alerting users that something unusual is going on.

The need for such custom datums usually arises when working with GPS devices that employ working definitions of such datums instead of the prevailing standard definitions.

For example, certain Trimble devices equipped with WAAS will use a working definition of NAD83. To use data from such devices in Manifold, first find out what working definition is used by that device. Create a custom datum from that working definition using a distinct name of your choosing, such as "NAD83T."
Next, create a drawing in latitude / longitude using the standard NAD83 datum. Accept data from the Trimble device into that drawing. To correct the coordinate system used, launch the Edit - Assign Projection dialog and change the datum to use your custom NAD83T datum.

Note that some Trimble devices not equipped with WAAS will use a working definition of WGS84 instead of the "standard" WGS84 definition. These may be dealt with by using a custom datum created from the working WGS84 definition used by Trimble.
Projecting a Map

This topic assumes all we want to do is project a map using drawings or images that have been imported into Manifold correctly. When using drawings or maps in Manifold format or other modern GIS format that correctly saves information about projections there is no need to understand the internal workings of projections. There are also few difficulties when we import unprojected data.

If you are struggling with the import of a projected map (say, in UTM or State Plane Coordinate System) using data in some ancient format such as ESRI .shp, please jump to the Projections and Legacy Formats topic and then follow the links to all the ugly stuff you must consider.

To project a map, we take note of some map characteristics and then we use the Edit - Assign Projection dialog.

Step 1: Note the Center of the Map

Most projections require a center for the projection. That's the latitude / longitude location at the center of the region to be projected. Before launching the Edit - Assign Projection dialog we should note the center and some other parameters in case we want to set projection parameters manually. Manifold has a Suggest button in the projection dialog that will set parameters for us but it is often helpful to note them in advance so we can compare the suggested parameters to what we might choose to set on our own.

To determine the center of the map move the mouse cursor to the center of the region and note the latitude / longitude numbers given in the status bar. For larger regions, round up to some reasonably even number. For example, a reasonable center for maps of the US made in Lambert Conformal Conic is 40 degrees latitude and -100 degrees longitude.

Step 2: Choose the Right Projection

Launch the Edit - Assign Projection dialog and choose the projection desired. The projection to use depends mainly on the region to be mapped and the intended purpose of the map. The suggestions below work well in almost all cases and are based on the region to be mapped.

There are so many projections available within Manifold that they are organized within a tree diagram. All of the following are in the Standard category. The subcategories are noted in parentheses where the name of the projection itself does not make it clear to which subcategory it belongs.

Most users will use only a few projections over and over. For general use, the Manifold team recommends the following:
Region to be Mapped | Suggested Projections
--- | ---
Whole Earth | Robinson (pseudocylindrical) or Miller Cylindrical. Robinson seems to be fashionable for thematic maps. Any of the pseudocylindrical projections will be fine if you like their appearance better.
Hemispheres | Orthographic (azimuthal) for a "view from space" look, and Lambert Azimuthal Equal Area for thematic maps where the relative size of countries near the edge of the projection is to be preserved.
Continents | Use Lambert Conformal Conic for North America and Eurasia. Use Lambert Azimuthal Equal Area or Orthographic for South America and Africa. Use Orthographic for Australia, and Antarctica.
E-W Countries or Regions | Use Lambert Conformal Conic for US, Canada, Russia, and China. Use either Lambert Conformal Conic or Orthographic for Europe. Use Orthographic or Lambert Azimuthal Equal Area otherwise.
Polar Regions | Orthographic or Lambert Azimuthal Equal Area.
Oceans | Orthographic or Lambert Azimuthal Equal Area.
Smaller Countries or Regions | Orthographic.
N-S Countries, Oblique Regions | Long, thin countries aligned North-South such as Chile are one of the few times we would use Transverse Mercator. Oblique regions like the Alaska panhandle are mercifully rare: Use the Oblique Mercator in such cases.

Other than personal taste in visual appearance there are only three reasons not to use one of the above projections:

- A specific projection is required to match other data available or to exchange data with other users.
- The technical characteristics of a particular projection such as preservation of scale or relative area are required for creating a paper map or other presentation.
- A specific technical characteristic, such as datum used, is not a a good match to the data.

As an example of the latter point, one limitation of Orthographic is that the projection is defined only for the sphere datum. If other datums are to be used, an alternative "view from space" projection is the Stereographic projection.

Manifold provides a very wide array of projections in addition to the standard projections mentioned above.

**Step 3: Project the Map**
In the **Edit - Assign Projection** dialog specify the projection selected using the tree diagram and the center for the projection and other parameters. When specifying latitudes and longitudes remember that **west** longitudes are **negative** numbers and that **south** latitudes are also **negative** numbers.

Some projections will require other parameters. For example, when using Conic projections two "standard" latitudes (also known as "standard parallels") are required. These should be about one fifth of the way down and one fifth of the way up the map for greatest visual fidelity, but most people will round these values to memorable numbers. For the US, many people use 35 degrees as the first standard latitude and 45 degrees as the second standard latitude. The **Suggest** button will automatically load reasonable values for standard parallels into the projection's parameters.

The **Suggest** button will cause the system to estimate the center of the map based on the size of the largest drawing rectangle that participates in the map. Manifold will then load the estimated, rounded center into the **Center Latitude** and **Center Longitude** parameters together with estimates of "reasonable" values for the other parameters. These may then be edited as desired.

There's no need to worry about the **Datum** unless we are exchanging projected data from old formats or are using Manifold to convert GIS data between different projections or datums. If we use **World Geodetic 1984 (WGS84)** as our standard datum we'll be in great shape to utilize GPS data and other modern instrumentation, almost all of which use WGS84.

If we need to match a particular projection used by other data or required for data exchange we must find out what datum is necessary and pick it from the list of datums available. Manifold includes virtually every datum that has been used anywhere in the world for mapping.

The projection dialog includes several options for use by experts. These are changed only in special cases, such as manual georegistration. See the **Edit - Change Projection** dialog topic.

**Additional Notes on Choosing a Projection**

For showing small regions of the Earth, such as a hiking trail within a park almost any projection is acceptable. Any distortion of shape, area or scale for such small regions caused by the projection will likely be less than the intrinsic accuracy of the data. In small regions almost all applicable, correctly centered projections are visually indistinguishable even to experts.

We suggest the Orthographic projection because it provides a natural appearance of mapped shapes from an overhead view. It is also the "default" projection used with images and abstract CAD drawings when they are first imported into Manifold. This will enable fast usage of images within maps when all use the same projection.

For mapping larger regions, such as countries or continents, learning about a handful of frequently used projections is enough. The main choice is between projections that provide better appearance and accuracy of East-West regions (like the US), North-South regions (like South America) or circular regions (like Antarctica or the Pacific Ocean). In almost all cases a choice between Lambert Conformal Conic (for East-West regions) or Orthographic (for South America or Africa) is a good choice. The Lambert Conformal Conic projection uses two additional standard latitudes as described in the Lambert Conformal Conic projection's topic.
For showing the entire world at once, there is no single projection that adequately minimizes distortion while preserving accurate representations of area or scale. Maps of the entire Earth are used almost exclusively for thematic presentation purposes and not for measuring purposes such as navigation. In such maps the main objective is a visual appearance that preserves in a subjective way the relative sizes of countries, with rough preservation of shapes.

Most users will gravitate toward one of the standard cylindrical or pseudocylindrical whole-world projections and will tend to use it over and over. It is almost exclusively a matter of personal taste. We suggest either the Robinson because it is currently a fashionable projection or the Miller Cylindrical because it provides straight lines for parallels and meridians. Many users will prefer the Mollweide or another choice.

The only projection for whole Earth use one should absolutely, positively avoid is the Mercator projection. The Mercator projection was intended for marine navigation. Its main positive feature is that it has straight rhumb lines, an essential requirement for marine navigation. As a whole Earth projection it is one of the worst possible choices due to the great distortion of regions not near the Equator.

**Why So Many Projections?**

If only a handful of projections are recommended, why does Manifold provide so many other projections? Manifold provides so many projections because many projections are in common use. To import data from those many different projections Manifold must understand them all.

Many projections are in common use because most mapping of the Earth was done before the era of fast and cheap computers. In earlier times paper maps were the living instruments used to measure the Earth. The specific technical characteristics of projected maps such as scale preservation are extremely important if paper maps using such projections will be used as measuring instruments. Different map projections were required for different countries and regions so that mechanical measuring and plotting on paper maps for different purposes could be easily achieved.

With modern computer software none of that is necessary any more. Measurements of distance or area within a GIS on a computer can be done with far greater precision than by using a straight-edge and compass on a paper map. As a result paper maps are less frequently used as precision measuring instruments. In modern times paper maps are used for presentation and for visual estimates of relationships.

There is no longer any reason to restrict our projection methods because they are easy to compute by hand. For presentation purposes computers can instantaneously create a custom-centered projection of a data set to suite whatever specific view is required. With computers and software like Manifold we can use relatively few different map projections and simply set the parameters so the projection is always a good match for the view desired. However, since the world's database of digital maps was created mainly from the legacy archive of paper maps the numerous different projections created for use with paper maps continue to be prevalent in the digital era.

This is not necessarily a negative thing, since different projections provide different artistic impression and even a different conceptual feel. Having a rich set of projections from which to choose is like having a nice collection of fonts to use in one's text documents. Different projections can be used to good effect for improving the visual appearance of presentations.
For more on choosing projections, see the Projections Tutorial, General Projections Concepts and the Guide to Selecting Map Projections.

For more on datums see The Earth as an Ellipsoid.

**Re-projecting Drawings, Images and other Components**

The above procedure describes re-projecting a map. To permanently re-project a specific component we open it in a window and apply the Edit - Change Projection command. If the component appears in a map and we would like to re-project it to use the same projection as the map, we can right click its tab in the map and choose **Project to Map**.

**Differences between Assign Projection and Change Projection**

- **Assign Projection** appears both with map windows and with individual component windows. When used with map windows it changes the projection used in the map view without actually changing the data in the components. Map windows have dynamic projections that can show their contents in whatever projection is desired regardless of the native projections of what is inside them. When used with component windows, this dialog changes the projection assigned to be used to interpret the coordinate data within the component.
- **Change Projection** appears only with individual component windows such as drawing windows or image windows. This command changes the actual coordinate data in the component into a new coordinate system. It can only work correctly if the starting projection assigned to that component was correctly assigned, so before we can use **Change Projection** to change a projection we must use **Assign Projection** to verify that the projection originally assigned was correctly assigned.

**Problems with Drawings from Legacy Formats**

Failing to import a projected drawing correctly will lead to unpredictable effects when the drawing is used in a map. If we import a projected drawing from a geographically unaware format such as `.shp` or `.dxf` we must tell Manifold the correct projection to use to interpret that data since the format does not save this important information. It is, of course, a blunder to publish projected drawings using formats such as `.shp`, but this is done all the time.

To import a projected drawing or image from a geographically unaware format:

1. Import the drawing or image using **File - Import**. Use default settings.
2. Open the drawing or image.
3. Use the Edit - Assign Projection dialog to specify the projection information that should be used.

The **Edit - Assign Projection** dialog allows us to manually provide the correct projection information into the coordinates properties. Manifold will then be able to make sense of the data just imported.

Do not confuse the use of a chosen projection view in a map window (via Edit - Assign Projection) with the use of Edit - Assign Projection in a drawing window to specify projection information missing from legacy formats. If a projected drawing is imported from, say, `.shp` format and you fail to tell Manifold the correct projection to use, that drawing has not yet been correctly imported. Subsequent use of the drawing in maps may
cause bizarre effects or lengthy delays as the system attempts to compute a new projection for the map based on fundamentally inaccurate coordinates.
Projections Quick Reference

This topic provides a summary of key coordinate information for experienced GIS users.

If you are a new user and are working within Manifold System only, jump to the Projections topic and the Projecting a Map topic. Very little expertise in the inner workings of projections is required to make simple projections when working within Manifold System.

If you must deal with maps in legacy formats such as ESRI .shp or AutoCAD .dxf, please read the Projections and Legacy Formats topic. Because legacy formats do not normally save information on projection parameters used, importing maps saved in legacy formats can require extensive knowledge of projections and coordinate systems.

If you are new to projections and coordinate systems in GIS or would like a refresher on coordinate systems and projections consult the Projections Tutorial and subsequent topics followed by a quick return to this topic as a summary.

- Manifold maintains all coordinates using double-precision, floating-point numbers. This allows mapping the Earth with accuracy to 16 decimal digits of accuracy. If we divide a meter (about a yard) into two hundred and fifty million parts, Manifold's accuracy is better.

- A map shows any combination of drawings or images reprojected "on the fly" into whatever projection is used in that map. Use Edit - Assign Projection to specify the projection a map uses. This changes the projection used by the map without changing the native projections of any drawing or image used in the map. Because a map window allows multiple layers it is the preferred window for work in Manifold.

- Drawings and images are shown in drawing windows and image windows using their native coordinate systems. Drawings and images may be reprojected so their internal coordinates are already transformed into a specified projection. If a particular projection will be frequently used with drawings or images in a map it is wise to convert them into that projection so there is no need to reproject them on the fly.

- Use Edit - Change Projection to transform the coordinate numbers inside a drawing or image into their equivalents for the desired new projection. This is a permanent alteration in the internal coordinates used to create a drawing or image. This dialog allows export of projection information to XML, Golden Software GSR or ESRI PRJ formats (as well as import from those formats) to allow for easy creation of accessory files when exporting components for use in other software package. The dialog also allows quick fetching and reuse of coordinate information specified for other components, to avoid having to manually re-enter coordinate information whenever possible.

- Images that originate in raster data are normally not re-projected since doing so invariably adds or removes pixels via interpolation. Instead, raster data images are re-projected on the fly in Map view to achieve the desired effect. In contrast, images used purely for visual effects are often re-projected using the Edit - Change Projection dialog so maps that use them will display rapidly.

- CAD-style drawings created using linear coordinates such as meters or inches are interpreted by default as using the Orthographic projection centered on the 0,0 origin of the Prime Meridian and the Equator. If not otherwise georeferenced, images also are placed with their lower left-hand corner at that geographic 0,0 origin and are taken to be in Orthographic projection. Manifold's internal accuracy is so high that
images scanned at over 4800 DPI can have a distinct geographic location for each pixel.

- Since images shot from aircraft or satellites are often overhead views of very small portions of the Earth, they may be conveniently used within the default Orthographic projection used for images. This allows them to be used in a casual way in map layers with cartographic drawings that also use Orthographic projection centered on the current view. This is a fast setup where Map view can operate without any re-projection on the fly. We can use the various image georegistration tools to adjust such images so they are a good match to the vector drawings.

- All drawings using projections other than degree-based "Latitude / Longitude" are based on linear measures, usually meters, centimeters or feet as units of measure. When importing from a "smart" format the coordinates properties for such drawings will be automatically set by Manifold during import.

- Legacy formats like ESRI "shape files" are not normally used for saving maps in projected form. If we have the misfortune of encountering a projected map saved in a legacy format we must make all efforts to locate and grab any documentation that accompanies the file to see what projection parameters were used. We will need this information to tell Manifold what to do with the numbers being imported. After such maps are imported into Manifold as drawings, we must manually change the coordinates properties for that drawing using the Edit - Assign Projection dialog to specify the correct projection parameters based on what we read in the metadata. Note that even if the shapefile is in unprojected Latitude / Longitude coordinates we will have to specify which datum is used using this dialog.

- The Edit - Assign Projection dialog is normally used only once when importing projected drawings from legacy GIS formats. Requisite parameters may be manually added with this dialog after importing the drawing. Changing the projection properties of a drawing does not change the raw coordinate numbers that define the drawing's objects. It simply changes the way the numbers are interpreted by the system.

- It's often the case that images used in mapping will not be a perfect overhead view of the subject. We will often receive such images in geographically-mute image formats such as .jpeg that have nothing to say about the projection used. Technically, such images are often in Tilted Perspective or Space Oblique projection but with unknown parameters. In Manifold, we deal with such images by assuming they are Orthographic and then we use Manifold georegistration tools to warp the image to fit a "known good" vector drawing or set of lat/lon coordinates. In effect, we are re-projecting the image into Orthographic by nudging its scale and position while warping it. This georegistration process is usually easy and very satisfactory in the case of near-overhead images.

**Very Important**

To re-project a component, use the Edit - Change Projection dialog. Do NOT use the Edit - Assign Projection dialog. This latter dialog is a specialized dialog that is used to manually correct the projection assigned to a component imported from a format that is unable to provide projection information.

**Customization**
Experts may specify custom units of measure, ellipsoids, datums and even customized coordinate systems (projections) by specifying customized projection presets. See the Customization topic.
**Projections and Legacy Formats**

Projections are used in maps for two main purposes:

- To provide a more natural looking map, and
- To enable measurements of areas and lengths in printed maps.

Projections can be extremely simple to use, with little knowledge required if one works exclusively within Manifold using digital maps saved in modern formats. Using Manifold, one can make pretty projections with a point and a click. It's fast and it's fun.

To project a map, use the Edit - Assign Projection command to choose whatever projection you like. The map will show its contents in that projection no matter what the "native" projections of the components it contains. To change the projection used in a drawing, image or surface permanently, open the component in its own window and use the Edit - Change Projection dialog to re-project it. If that's all you would like to do, read the Projections topic and then jump straight to Projecting a Map.

The situation becomes considerably more complex when importing data into Manifold that was created using older GIS systems and saved in formats that are not well suited for publishing maps. Complexity also rears its ugly head when importing geographic images and surfaces from formats that do not save projection data. We can use such data in Manifold, but to do so we will have to learn more about projections and follow a more complex import process.

Most digital map data is published in unprojected form to assure the greatest possibility of accurate interchange between various GIS systems and to reduce hassles for users. Users can then cast the map into whatever projection is desired using the facilities of their GIS package. Occasionally one encounters digital map data published in projected form. Dealing with projected maps that are published in old formats can be a real nightmare.

If you must deal with maps in legacy formats such as ESRI .shp or AutoCAD .dxf you probably will have to learn a lot about projections and coordinate systems. At a minimum, you must learn enough to be able to tell whether the digital map being imported was saved as a projected or as an unprojected map. Because legacy formats are geographically mute when it comes to projection information, users must acquire a considerable level of understanding just to be able to tell if they are dealing with a projected or unprojected map.

The situation becomes even more complex if a legacy format is used to save maps using old-fashioned projections such as UTM. In such cases one can be pulled into a confusing sequence of tasks requiring deep technical knowledge of the inner workings of map projections cast within ancient GIS formats. Not only is it a conceptual mess, it requires learning a quasi-technical lexicon of obsolete words, such as "false easting" and "false northing." It is as if to purchase a hamburger at McDonald's one needed to learn the farming methods and jargon of 1940's cattlemen.

Learning about projections in detail requires learning about coordinates and numerous other technical topics. This is not easy for non-mathematical people. It is especially difficult if the overall concepts are muddied by the tactical hassles involved in importing data created in older software using older formats. For this reason, it is a good idea to begin by learning to use projections exclusively with maps from the Manifold downloads site (start at the Projecting a Map topic and continue with the Projections Tutorial topic).

Once you understand how to use projections within Manifold without the complications of dealing with legacy formats or old-fashioned methods you can dive into extended reading on projections and coordinates topics, beginning with the Coordinates topic.
Older File Formats and Projections

Manifold saves maps in a project file together with all technical parameters required to manipulate the data regardless of what projection is used. One may combine data from such maps in a completely free-form way and Manifold will automatically make all adjustments necessary. In a modern system such as Manifold, everything will always appear in the expected latitude / longitude coordinates everyone understands are used to identify locations on the Earth’s surface.

Older GIS software was not always so flexible, and formats used to create maps in older systems are often unable to store important information about the projection in their file formats. Part of the user-unfriendly nature of older software and formats is that the user is expected to manually keep track of important information such as projection parameters. Quite literally, the user is expected to make notes on paper or in some sort of readme.txt file that accompanies the digital map files so that the GIS can be told what projection parameters to use with that file.

In modern times we recognize that requiring users to manually keep track of which projection parameters were used to create a particular file is a formula for endless hassles and errors. However, older GIS formats that require this of users continue in service within organizations that produce many digital maps we would like to use. In at least one case (ESRI .shp format) a format unsuited for publication of projected maps continues in use as the main format behind the most widely distributed GIS software within US government and universities. In another case, a CAD format, AutoCAD .dxf, is widely used to publish both projected and unprojected maps even though .dxf is highly unsuited for geographic map publication of any kind.

When governments and universities publish maps in unprojected form using ESRI .shp or other old formats there is usually little harm done except for the ordinary limitations of old formats such as limited file names. Even the difficulties presented by AutoCAD .dxf usually involve no more than minor hassles when unprojected maps are involved. In contrast, major problems arise when formats unsuited to the saving of projected maps are used to publish maps in projected form.

When formats like .shp and .dxf are used to save maps in projected form, one must know technical details about the projections used because one must manually provide information the format is unable to save. This introduces another conceptual minefield for users, the need to know enough about the technical internal details of various projections to be able to recognize and write down the necessary key details. This is not always easy, since some projections are themselves relics from the dawn of time. The Stereographic projection, for example, was known to the ancient Egyptians.

Many maps have been created using projections that are reflections of the limitations of the technology of their day and not because they are the best projections to use for a given purpose or are the most user-friendly. The notorious Universal Transverse Mercator (UTM) system, for example, was created in part in recognition of the limits of computation when doing arithmetic with hand-cranked calculating machines. Even though UTM was created before desktop computers were imagined it persists into the present day to wreak havoc among GIS novices. Because many maps were created in such systems and because technologically static governments have adopted some obsolete systems (like UTM) as the basis for legal norms they persist as living fossils into modern times.

If we use digital maps from many different sources or if we wish to exchange mapping information with colleagues using legacy systems, sooner or later we will need to understand projections and the coordinates within them at a seriously detailed technical level. This will be very frustrating for the new user. At times, as with UTM, the bizarre
technical limitations of a living fossil projection presented within a living fossil data format such as .dxf will try the technical patience of even professional cartographers. However, if we persist and gain the technical understanding required we will be able to decode ancient formats we find on contemporary government and university web sites. We will be able to get many free maps and we will then be able to combine map data from such maps with other maps. We will be able to communicate with organizations still stuck in the technological amber of an earlier day.

It must be emphasized that there is no reason why in modern times most users of a GIS system should need to know the internals of how projections and coordinates work. This is all a result of legacy data and legacy formats. Manifold provides a very rich set of tools for dealing with such relics when they are encountered, or for the expert usage of cartographers who desire direct control over all aspects of their data. However, knowledge of internals is only required when working with legacy map data and not because of anything intrinsic to Manifold.

Problems with Drawings from Legacy Formats

Failing to import a projected drawing correctly will lead to unpredictable effects when the drawing is used in a map or other usage within Manifold. If we import a projected drawing from a geographically unaware format such as .shp or .dxf we must tell Manifold the correct projection to use to interpret that data since the format does not save this important information.

Manifold will remind us of this need by always raising an info bar the first time a new component that was imported from a geographically unaware format is opened. The info bar reminds us to verify the projection assigned to that component.

Note: The rule of thumb used by Manifold to decide if a component has been imported from a format that does not store projection information is to simply raise the info bar whenever a new component's projection is Orthographic, the default used for imports from formats that do not provide coordinate information, or if the component has been imported in Latitude / Longitude with coordinate locations outside the expected range (+/- 90 latitude and +/- 180 longitude).

To import a projected drawing from a geographically unaware format:

1. Import the drawing with File - Import. Use default settings.
2. Open the drawing.
3. Use the Edit - Assign Projection dialog to specify the projection information that should be used.

The Edit - Assign Projection dialog allows us to manually provide the correct projection information into the coordinates properties. Manifold will then be able to make sense of the data just imported. The Edit - Assign Projection dialog is normally used only once immediately after importing the drawing to specify correct projection information that the drawing's original format was too stupid to provide. It is not used to re-project the drawing. To re-project the drawing, use the Edit - Change Projection dialog.

Do not confuse the use of a chosen projection view in a map window (via Edit - Assign Projection) with the use of Edit - Assign Projection in a drawing window to specify projection information missing from legacy formats. If a projected drawing is imported from, say, .shp format and you fail to tell Manifold the correct projection to use, that drawing has not yet been correctly imported. Subsequent use of the drawing in maps will cause bizarre effects, lengthy delays or other incorrect operation as the system attempts to deal with the drawing based on fundamentally inaccurate coordinates.
Also, do not confuse the one-time use of **Edit - Assign Projection** with the regular use of **Edit - Change Projection**. Changing the internal understanding of a drawing's coordinate numbers by using **Edit - Assign Projection** will not re-project the drawing. To re-project the component, use **Edit - Change Projection**.

**Notes**

The classic "ancient" formats are ESRI **.shp** and AutoCAD **.dxf**. Neither saves projection information as commonly used. Use these formats for unprojected data only. There is a recent hack to the **.shp** format that will save projection information; however, it is so recent it does not help with the great mass of legacy data already published in **.shp** format. If you have a choice when getting projected legacy data, use **MapInfo .mid/.mif** format. Mid/mif is a reasonably modern format that saves projection information within the map files. Avoid **.dxf** at all costs.

When importing from **.shp** format, even when importing an unprojected shapefile keep on the lookout for any information that tells you what datum was used in that file. Importing an unprojected shapefile will by default import the shapefile using **Latitude / Longitude** projection using the **WGS 84** centroid. Such imports will be acceptable for many GIS purposes; however, for full accuracy one should find out what centroid / ellipsoid / datum (three words with slightly different meanings but often used as synonyms) was used for the shapefile being imported and use the Edit - Assign Projection dialog to specify it for the imported drawing.

The classic "living fossil" projections that confuse new users are UTM, State Plane Coordinate System and Gauss Kruger. If you have a choice between receiving projected data in these systems or receiving unprojected data, always choose the unprojected data.

If you have no choice but to receive data in old formats remember to stay alert for any "readme.txt" file or any other documentation that accompanies the data files. With luck, the author of the data will have provided some notes on projection parameters or other information used within the map.

If you are not sure whether or not a **.shp** format or other old format file is a projected or unprojected map, an easy way to find out is to import it using default settings for the importer. One can then overlay the imported drawing as a layer in a map with a layer imported from a "known good" drawing from the Manifold downloads site. If the imported drawing appears where it should geographically, it almost certainly imported OK and was quite likely an unprojected map. If it does not appear in the correct geographic context then the original file most likely contained a projected map. In such cases, the projection parameters to be used with the file must be tracked down.

Using **.shp** for projected maps and **.dxf** for anything causes such hassles during interchange that one is tempted to say bad things about publishers who do such things. However, it is often the case that the publishers themselves are trapped by organizational politics into using inappropriate formats. In some cases they might not have enough time to convert data from old formats and are simply trying to get data out to the public for better or for worse. If you find yourself in this position as a publisher please do your best to publish **unprojected** data sets. If you must publish projected data sets, please try to provide clear documentation for the projections that were used.

In this topic we refer to "drawings" because most projected data sets saved in legacy formats are drawings. Images and surfaces are also occasionally found as projected data as well. For that matter, images are often encountered that are "whole Earth" images in latitude / longitude projection and published using non-geographic formats such as **.jpg**.
See the Cookie Cutter a Large Image with Transfer Selection topic for an example of how one uses **Edit - Assign Projection** to complete the import of such images.

Some images are accompanied by "world files" that are said (by the uninformed) to contain full projection information allowing automatic import of georegistered images. Regrettably, that is not true: world files contain only partial projection information and still require manual intervention. See the Importing Images topic for a complete discussion.

The use of .prj files together with shapefiles (as a sort of machine-readable "readme" file) to specify projections is a recent development that, unfortunately, has come into play without any definitive standards being published to precisely specify how the .prj should code its contents. Although the use of .prj files works most of the time, it is something of a haphazard system. If a shapefile is accompanied by a .prj file Manifold will analyze the .prj to try to determine what projection and projection parameters are intended for the shapefile.

Manifold recognizes over 500 projection types used in .prj files and so will be able to extract the projection information in almost all cases, reading more different types of .prj than almost all other software packages that can read shapefiles. However, because .prj files do not use standardized nomenclature for projections it is possible that in some cases it will not be possible to read the desired projection even if the shapefile is accompanied by a .prj file. manifold.net is always on the lookout for .prj files containing previously-unknown standards to add to our "zoo" of strange examples. If you encounter a shapefile using a .prj that does not import into Manifold correctly, please contact tech support for instructions on how to FTP it to manifold.net for examination.

Projections Tutorial
This is the introductory topic on geographic projections for users new to GIS and mapping. It is a good refresher for experienced users wishing to understand how Manifold deals with projections.

Geographic projections are a way of showing the curved surface of the Earth on a flat surface like a piece of paper or a computer monitor.

For over two thousand years educated people have known that the Earth is round and have realized as a matter of elementary geometry that any flat map showing the surface of our curved Earth will in some way change the shape of what it portrays. For over two thousand years geographers have been inventing ways of using flat maps to show the curved surface of the Earth in ways that minimize such distortions.

Imagine we make a globe out of a flexible material with a world map painted onto the material. Now, let’s cut the material and try to flatten it. If you’ve ever tried to flatten a deflated ball you know this is not possible to do without stretching the flexible material in some areas and compressing it in others. If we deform the peeled "skin" of our atlas globe in this way to make it flat we will end up changing the shape of continents and other items illustrated in our world map.

There is no one way of projecting the curved surface of the Earth onto a flat sheet that does not cause some distortion, and there is no one projection that is suitable for all purposes for which people use maps. However, for virtually every usage there are projections that minimize distortions of importance for that task. For example, if one needs to measure areas in a flat map there are projections that will guarantee the area contained by various shapes is correct even if the shapes of the objects shown appear quite differently than they do on a globe. Other projections do a good job of showing continents in a shape similar to that seen on a globe even though they do not allow for accurate measurement of areas.

Note: We refer to the Earth as a sphere in this topic even though it is a slightly flattened ellipsoid.

How Projections Work

Any shape that is curved in only one direction can be unrolled into a flat map without distorting the appearance of objects drawn on it. For example if we take a cylinder and cut it lengthwise we can unroll the cylinder into a flat map. The trick to any elementary projection is to place the Earth within such a shape and to "project" lines out from the Earth onto the shape to show where to draw the projected outlines of items on the globe. We can then "unroll" the shape and see our projected map on a flat surface.
The first and most obvious such projection to use is a simple cylindrical projection. Place the Earth inside a big cylinder that touches the Equator and then transfer points on the globe to the cylinder. The simplest way to do this is to imagine the cylinder is graph paper with 360 boxes in circumference and 180 boxes up and down.

If we use the longitude and latitude coordinates in degrees of a place on the sphere and transfer it to our cylindrical roll of graph paper we end up with a map like the above. Since one point needs to be the center of the unrolled cylinder, nearly universal usage is to use the intersection of the Equator with the zero Meridian running through Greenwich, England. We can then count degrees plus and minus 180 degrees in longitude and plus and minus 90 degrees in latitude.

The above presentation is called the **Geographic** or Latitude / Longitude projection. We can think of it as our default projection. It produces a good effect in areas near the Equator, but results in immense distortion close to the poles.

There are other ways of transferring points from the surface of the globe onto an enclosing cylinder. Most of these, such as the Mercator projection, use some mathematical formula to alter the ratio between degrees of latitude on the globe and vertical measurements on the cylinder. What they all have in common is that accuracy is good near the Equator where the cylinder is very close to the globe. To a greater or lesser degree all cylindrical projections centered on the Equator fall off in accuracy as distance from the Equator increases.

If we wish to make maps of places along the Equator we could use a cylindrical projection and just show those regions. What would be shown in those maps would be relatively free of distortion. One problem with this is that the Equator for the most part lies over water whereas the greatest demand for maps is in populated zones. A quick glance at a world map shows that most populated zones occur in a North-South direction.

Turning the cylinder so that it is tangent to the Earth along a meridian (longitude line) instead of tangent to the Equator results in what is called a **transverse** cylindrical projection. We can now make local maps anywhere along the darker, North-South line of
tangency and if the maps are not too big they will be relatively free of distortion. However, this only works along the line of tangency. If we pick a North-South line running through Athens we can make maps all the way from Scandinavia down the length of Africa, but any maps using this projection in North and South America would be hopelessly distorted.

One possible solution is to use not one projection, but many transverse cylindrical projections with the cylinder rotated slightly along the Equator. In fact, one scheme of mapping the Earth called the Universal Transverse Mercator (UTM) plan does just this. UTM maps the Earth with a transverse cylinder projection using 60 different lines, each of which is a standard "UTM Zone". By rotating the cylinder in 60 steps (six degrees per step) UTM assures that all spots on the Earth will be within 3 degrees of the center, tangent line of one of the 60 cylindrical projections. (The Gauss Kruger system is a European system akin to UTM that also uses a transverse cylinder rotated in six degree steps).

To map any spot on Earth in UTM, one picks the UTM Zone centerline that is closest to it and then makes a map using that cylindrical projection.

The illustration above shows a small section of the earth near the tangent line projected onto the cylinder, and then the cylinder being unrolled into a flat sheet. If we want to save the X,Y locations of points on our flat sheet we can now measure them as though the flat sheet were graph paper and use the resulting coordinates in a digital, flat map.

The above illustration shows a key concept that often proves confusing to GIS newcomers: although "unprojected" data about locations on the Earth are specified in degrees, all projected maps specify the coordinates of the objects on them using X,Y coordinates using meters, feet or other linear measures. These coordinates are computed relative to some origin on the flat sheet established by the projection in use.

Computer files that contain projected maps therefore contain coordinates like
and not longitude, latitude coordinate numbers such as

-110.3484, 44.2856
-110.3463, 44.2889
-110.3511, 44.2902

Latitude, longitude coordinates are normally in decimal degrees as above, while the coordinate numbers in projected files are most often meters in X and Y directions from some origin known to the projection. It is as if the green sheet in the illustration above were an enormous piece of graph paper on which the map is drawn “full size” and then measured off in meters.

In a well run GIS system the internal coordinates of projected maps may be hidden from the user because the GIS software will automatically translate the internal map drawing coordinates into Latitude/Longitude values on the fly. Manifold, for example, will show cursor position in a projected map view using Latitude and Longitude values. What is going on is that Manifold is automatically translating internal projected coordinates like 44030984,38403080 into the equivalent Longitude and Latitude values.

Conic Projections

The main problem with cylindrical projections is that they do a poor job of minimizing distortion except for very close to the line of tangency. They are a poor choice for mapping large countries (such as the US or Russia) that have great East-West extents.

A better choice for mapping such regions is a conic projection, which projects shapes from the Earth’s sphere onto a cone. Cones, of course, can be unrolled into a flat sheet without any deformation. Locations near the line where the cone is tangent to the Earth will be relatively free of distortion. By using taller cones we can move the line of tangency nearer to the Equator and by using fatter, more open cones we can move the line of tangency closer to the pole.

We can see the practical effect of a conic projection by considering a map of North America shown in the Latitude / Longitude projection. This is an “unprojection” that simply takes each coordinate in degrees and plots it using equal sized X and Y degrees at all locations:
The geographic cylindrical projection greatly overstates the size of northern regions.

Using a conic projection, we can transfer the shape of North America to the cone (in the region marked in red on the cone) and then unroll the cone to make a flat map. That flat map can then be used as "graph paper" to measure off coordinate locations with which we could build a flat, digital map.

The resulting flat map provides a much better impression of the true shape of North America. It is interesting to note that since most schoolchildren are taught geography from maps using cylindrical projections that greatly distort Northern regions, the average person thinks Alaska and Greenland are many times larger than they really are. The above conic projection uses a tangent line cutting through the "lower 48" US states and so optimizes their appearance while understating the apparent size of Alaska.
When both are viewed in Lambert Conformal Conic projection using parameters midway between the "lower 48" and Alaska and Alaska is moved over the "lower 48" US and rotated to preserve apparent meridian angles, it's clear that Alaska is very large, but not as large as is commonly thought.

**Azimuthal Projections**

Azimuthal projections show one hemisphere of the Earth at a time by projecting lines upward from the globe onto a flat disk tangent to the globe at one point.

By centering the disk over any particular point on the Earth, one can achieve a view of the Earth as it appears from space from high over that point. The Orthographic projection is the classic "view from space" azimuthal projection of the Earth.

**Projections and Projection Parameters**

Virtually all projections in common use fall into one of the above three categories. They are either cylindrical (regular or transverse), conic or azimuthal projections as customized by slightly different projection parameters. Projection parameters are options in how the projection is arranged.

For example, the Orthographic projection can be centered on any point on Earth by specifying the latitude and longitude of the desired central point. Conic projections may be customized by specifying the parallel of latitude at which the cone should be tangent.

Specifying a projection together with various optional parameters will drive the mathematical conversion of longitude, latitude degree coordinates into the numbers used within the projected coordinate system. When we encounter a computer file with projected data numbers such as…

44030976, 38403088
44030984, 38403080
...we will not be able to make geographic sense of these numbers unless we know in which projection with which optional parameters they are intended to be used.

Some GIS formats are "smart" and automatically save the projection parameters in use together with the data. During import of drawings from such formats, Manifold will fetch all necessary parameters from such "smart" formats automatically and will load the coordinates properties for that drawing with the correct parameters necessary to use the data.

When importing projected drawings from legacy GIS formats that do not save the projection information with the data we will need to know what projection and parameters should be used with that drawing. We will then have to enter this information manually into that drawing's coordinate properties so Manifold can use the data as intended.

Projections dialogs in Manifold are set up so they automatically present available options for the projection in use. Some specialized projections allow specification of an elaborate set of optional parameters.

**False Easting and False Northing**

Once a map is constructed using a given projection, the map is a flat surface. Distances on that flat surface may be measured as X and Y rectangular coordinates, with the X coordinate being the distance to the right of the vertical line passing through the origin or the center of a projection. A negative X coordinate represents distance to the left. In practice a false X or false easting is frequently added to all values of X to eliminate negative numbers.

Likewise, the Y rectangular coordinate is the distance above the horizontal line passing through the origin or center of a projection, with negative Y being the distance below. In practice, a false Y or false northing is frequently added to all values of Y to eliminate negative numbers.

The use of false easting and false northing is a relic of days when map projection computations were done by hand, so that computation with negative numbers was less convenient. In modern times we let computers do all the computational drudgework so false easting and northing are no longer essential. However, they continue to live on within projected digital maps created using older methods. Manifold allows use of false easting and false northing with many projections.

**A Historical Note on the Round Earth**

![Christopher Columbus](image)

**Christopher Columbus** by Sebastiano del Piombo
School children are often wrongly taught that Columbus sailed Westward to China to prove that the Earth is round. Once launched on his journey Columbus is often portrayed as heroically pressing on despite the opposition of his sailors, who feared their little fleet would fall off the edge of a flat Earth. That is almost the exact opposite of the truth.

Most educated people in Columbus's day knew the Earth was round. In fact, they not only knew the Earth was round they knew the size of the Earth as well. Almost everyone except Columbus accepted the estimate for the radius of the round Earth computed by Eratosthenes of Cyrene (276-195 B.C.). Eratosthenes figured the Earth's radius to be about 6267 kilometers, a figure remarkably close to the modern mean of about 6371 kilometers. In the 1490's educated people had known for over one thousand five hundred years the actual size of the round Earth. Since ancient days cartographers had even created projections to deal with the representation of a round earth on flat maps.

Even many uneducated people knew the Earth was round. Among uneducated people sailors especially believed the Earth to be round because of the frequent observation at sea that tall points such as mountains come into view above the horizon as the distance to an objective becomes closer. Many "round Earth" visual effects incompatible with a flat Earth are easily seen by the human eye at sea.

Columbus met much opposition at Court to his plan precisely because people knew the Earth was a very large sphere. The ships of Columbus's day were so slow that they could not be loaded with enough food and water to voyage directly to China westward from Europe. Without the then-unknown continents of North and South America to use as re-supply points the direct voyage would be so long that the crew would die before making landfall.

Columbus based his plans for his voyage on the argument that the Earth is smaller than it truly is. Educated people were unimpressed with what they regarded as his chain of wishful-thinking assumptions that "proved" Eratosthenes was wrong and that a Westward voyage was just barely feasible. When Columbus launched across the Atlantic his sailors were fearful that in the event his estimate of the Earth's size was wrong and everyone else was right they would expire of thirst and starvation.

As it turns out Eratosthenes was right and Columbus was wrong about the size of the Earth. Columbus simply had the good fortune of rediscovering a New World (it was first discovered and then forgotten by the Norsemen) before he and his crew died proving the true size of the round Earth. In all fairness it should be pointed out that despite his flawed belief in a small world Columbus was a master admiral of unparalleled skill, intelligence and personal courage. A failed and quarrelsome administrator on land, Columbus is indisputably one of the greatest leaders who ever took to sea. He is alone among the early voyagers in executing and surviving four successful voyages to the New World.

Coordinates

Objects in drawings are defined by the coordinates necessary to draw them. **Coordinates** are simply the numbers for each X and Y position that defines the object.

Consider a drawing that contains an area, a line and three points.

The objects are defined by the coordinate numbers that are used to draw them in a "connect the dots" fashion. The area, for example, is nothing more than a list of five coordinates in a computer file:

```
3 7
2 9
3 10
5 9
5 8
```

Through various clever means Manifold knows how to interpret the above list of coordinates as an area and how to draw the area knowing correctly what is the inside and what is the outside of the area.

By themselves the raw coordinate numbers describe only the relative position and shape of objects within the drawing. We don't know, for example, if the "3" in the area is supposed to be three centimeters or if it is three degrees of longitude. If the "3" is not degrees of longitude we don't know from the number by itself if it is supposed to represent an unprojected coordinate in a CAD drawing or if it is a number that has some meaning within some specific geographic projection.

The coordinate numbers that specify objects are given meaning (such as scale and geographic positioning) by the parameters specified in the drawing's Edit - Assign Projection dialog. Manifold files save this additional information along with the
coordinates needed to draw objects so that when a Manifold file is opened the coordinates properties are automatically loaded with the correct values. This is all done automatically so we never have to worry about internal coordinates.

If we work only within Manifold we do not need to know much about coordinates nor will we need to use the Edit - Assign Projection dialog. It is typically used only once when importing projected drawings from legacy GIS formats such as ESRI .shp or AutoCAD .dxf. It is not used when importing unprojected drawings nor is it normally used for drawings created within Manifold or imported from "smart" formats. Such drawings will automatically be created or imported with the correct settings for coordinates properties.

Projected drawings imported from older formats such as those used by some legacy GIS systems will at times require manual entry of their coordinates properties within the Edit - Assign Projection dialog. To use this dialog sensibly we must understand how coordinates work in general and how they are utilized within Manifold.

If you are new to coordinate systems in GIS or would like a refresher on coordinate systems and projections, consult the Coordinates Tutorial, the Projections Tutorial, and the Coordinates in Projected Maps topics followed by a quick review of the Projections Quick Reference as a summary.
Coordinates Tutorial
This topic explains coordinates for users new to GIS. Experienced users may begin with the Projections Quick Reference topic.

Overview

Drawings and images come to us for use in Manifold from many different sources. Drawings come in many different sizes using different scales. Images can be everything from a photograph scanned on a desktop scanner at 1200 DPI, where one pixel is less than a thousandth of an inch in size, to a data set acquired by satellite where every pixel is supposed to represent a square kilometer of the Earth’s surface.

It's obvious that if we want to use different drawings or images together in a map we will often ask the system to enlarge or reduce them in some way so their scales match up. If we want to use drawings or images together in a map, we will also need some way of specifying the desired geographic position of the images so that Manifold can draw them correctly aligned together with drawings or other images in a map window.

In the illustration above showing Highway 101 in Palo Alto, we will have to not only match the sizes of the drawing and the image but also to place each in correct geographic context in a Map. This will allow us to add other drawings and images and see them correctly overlaid as well.

Coordinates in Drawings

Drawings are for the most part simply lists of the X,Y coordinates needed to draw the objects they contain. Let's consider a simple example to see how this works:
Imagine taking a sheet of paper and sketching the layout of a chair, a side table and a table with our computer setup and telephone.

If we drew this on a piece of graph paper with a fine grid, we could measure the X, Y coordinate of every corner point of every rectangle by counting the little boxes from the origin in the lower left corner of the paper.

For example, the lower left corner of the table is forty units in the X direction and 20 units in the Y direction so the coordinates of this spot are 40,20. The four coordinate pairs needed to draw the table rectangle might be:

40,20
80,20
80,50
40,50

We could measure off each and every coordinate location in our example drawing above and create a file containing the coordinates necessary to draw a plan of our office setup. Digital drawings in almost any format are simply vast collections of numbers like these that specify the location of every coordinate needed to create the drawing in a "connect the dots" fashion.

**Specifying Size**

The list of coordinates will allow us to reproduce the drawing in the future, but it does not tell us the size of the paper used or what each "unit" is intended to represent in real life. For example, if we originally used graph paper with a one millimeter mesh to measure coordinates and then one day re-created our drawing using graph paper that had a 1/8-th inch mesh the two drawings would not be the same size. Likewise, it makes a big difference if each unit is supposed to represent one inch or one centimeter. A table 30 inches deep is passable while one 30 millimeters deep is not so good.

Units of measure don’t matter if we simply want an abstract view of the arrangement but they matter a lot if we wanted to combine this drawing with a different drawing to compare the relative sizes of tables, or if we wanted to use the drawing to make measurements that we would apply in real life.
We could add some metadata ("data about the data") to the drawing by writing in a note: "one drawing unit equals one inch" to tell us the scale. This would allow us to make measurements in our drawing and to compare those measurements to real life. "Smart" drawing formats used to save digital drawings will save the intended scale together with the lists of coordinates. This allows programs that read such formats to automatically reckon the correct scale. Surprisingly many formats fail to take this simple step.

**Specifying Location**

Looking at our sample drawing we may wonder why the chair is drawn above the table and not the other way around. We can specify which way our desk arrangement faces in "real life" by assuming that North is always up in the drawing. To do this, we can assume that Y coordinates going in the positive direction are headed North and that positive X coordinates are headed East.

We could also add metadata that specify where the drawing is located on the Earth.

For example, we could attach a note that the origin in the lower left-hand corner is precisely located at the longitude/latitude location of -122.1635, 37.4452. A mapping system could then know where to place it on a map of the Earth. If we could layer the drawing into a map, we could zoom far in and see that the desk is located at the old Microsoft Silicon Valley ISV center in Palo Alto.

"Smart" formats used for drawings and maps use a variety of ways to specify where a drawing should be located. One way is to use a standard geographic projection for drawing coordinates and to embed a note on the projection and projection parameters used within the drawing format. See the Projections topic for details on projections.

When importing a drawing from a format that does not provide information on the desired geographic location, we can georegister the drawing to the desired location. See the Georegistration topic for information on how to do this.

**Coordinates in Manifold Drawings**

Every drawing in Manifold includes embedded information about scale and location that describes the intended use of the X,Y coordinates it contains. This information is attached to the drawing when it is created or imported and can be seen at any time by looking at the drawing’s coordinate properties. If a drawing is imported from some "smart" mapping format the required information will automatically be imported with the drawing.
Drawings created using degrees, radians and other angular units are assumed to be Earth geographic degrees and will be displayed with the drawing centered on a 0,0 origin at the intersection of the Prime Meridian and the Equator.

Unless some other projection is specified, drawings created using any linear units of measure (inches, meters, kilometers, etc) will be created using Orthographic projection with the lower left-hand corner, the origin, also centered at the intersection of the Prime Meridian and the Equator.

**CAD Usage of Drawings**

Computer Aided Design (CAD) packages such as AutoCAD are used to create blueprints and other drawings without tying those drawings to specific geographic locations. We can do this in Manifold, as well.

We may wish to create drawings without specifying where they are located on Earth. For example, we might wish to use Manifold to create generic drawings of proposed factory layouts. We will probably want to specify the scale of the drawing, but perhaps we will not want to specify the geographic location of the drawings since we don't know in which location they will be used. No problem!

All drawings in Manifold, even drawings that are intended as CAD documents using meters as a unit of measure, are created by default using the Orthographic ("view from space") projection using a 0,0 origin at the intersection of the Prime Meridian and the Equator. This convention does not get in the way of CAD usage while it does provide a simple means of georegistration CAD drawings in a geographic context should the need arise.

If we are using Manifold as a CAD editor, it really doesn’t matter where the system thinks is the default geographic location of the drawings. The geographic location of the 0,0 origin of the drawing remains a theoretical matter buried in the drawing properties as long as we are doing "pure" CAD. It doesn’t surface as a consideration unless we wish to place the drawing somewhere within a geographic map. At that point it becomes a handy default placement.

So long as we are doing "pure" CAD, the only thing that matters is that the scale is accurate and that all the drawings are based on the same common position of the X, Y origin. There is no deformation from projection factors either, since the drawings used in our CAD project share a common meaning for their coordinates.
Suppose we create our desktop drawing in a Manifold drawing view using one inch per unit. We've illustrated a red cross at the lower left corner to emphasize the idea that the drawing uses internal coordinates based on X,Y displacement from that origin. Manifold does not actually show red crosses at the coordinate origin of drawings.

If we look at this drawing in a map it appears the same; however, if we switch the cursor X,Y readout indicator in the status bar to read in Latitude/Longitude instead of in X/Y coordinates, we'll see that the system thinks the lower left corner is at the intersection of the Prime Meridian and the Equator.

Suppose we create another drawing to show the arrangement of cubicles in the office room in which our desktop lives:

If we open this drawing in Map view it too will appear with the lower left-hand corner georeferenced to our map origin.

If we opened both drawings together in the Map view we would see the above situation. The scale is correct, since our desk set is supposed to fit in one of the cubicles. Now that...
we are looking at two drawings at the same time we need to show where they are positioned in relation to each other. To do this we simply select the desk set drawing objects and move them to where they are supposed to be:

![Desk set drawing objects moved](image)

There, that's better! Now we show our desk set where it belongs, in the second cubicle over by the left-hand doorway. Doing the edit in this way changes the internal coordinates used to make the desk set drawing so that every time we open it the desk set will appear in the right location when overlaid on the cubicle plan.

**Notes:** We've added the drop shadows and drawing outlines in the illustrations above to make it more clear in this documentation what is going on. Manifold does not show drawings in maps with drop shadows.

**CAD Style Drawings in Maps**

Normally, if we wish to create drawings for use in geographic maps we would begin with some geographic basemap drawing as a template. If desired we can always take CAD-style drawings originally created in a non-geographic CAD environment and see them in a geographic setting if we choose.

We can do all the CAD style editing we wish in a map using multiple drawings as multiple layers without ever caring that the lower left corner happens to be georeferenced to a spot off the coast of Africa. However we can exploit this default georegistration when mixing up drawings originally intended for CAD settings with drawings that have geographic content.

To see this effect, we can simply insert a world basemap drawing into the Map view we are using to view our "CAD" drawings.

The first effect is that we wouldn't see our CAD drawings any more because they would be a tiny dot off the coast of Africa and too small too see when the whole world is in view. (A drawing the size of our desk set is invisible at the scale of the entire world!) However, we could zoom far into that point and, like magic, see our desktop drawings appear in the size of our office setup at exactly zero latitude and longitude, apparently floating in the ocean off Africa.

We can make the desk set more visible by editing coordinates properties of our desk set drawing so that one unit is equal to 100 kilometers instead of 1 inch:
Suddenly the drawing appears as if our desk is 8000 kilometers wide instead of 80 inches wide. If we view this drawing in a map view together with a world map, we would see the lower corner of the desk is now 4000 kilometers (40 units x 100 kilometers per unit) to the right of the origin. Note that we haven’t changed the data in the drawing (it still contains numbers like 40, 20, etc), we have simply changed the way we want the system to interpret that data.

Because the default georegistration for drawings is to the 0,0 world Longitude/Latitude origin, this convention is a useful way of doing “quick and dirty” georegistration. Through a process of zooming in, selecting objects in a drawing, zooming out and moving the objects we can move objects to any position we desired. The Georegistration topic describes faster and far easier ways of accomplishing georegistration in Manifold, but this “thought experiment” is nonetheless a useful way of understanding how coordinates work in drawings.

**Coordinates in Images**

Images consist of adjacent pixels arranged in rows. There are no "coordinates" within images except those that may be inferred from the size of the image and its placement at some geographic location, if desired.

Just as the raw numbers within a drawing do not tell us what size the drawing is unless we know what size (inch, meter, etc.) the units used represent, we don’t know what the intended size is of an image unless we know how big the pixels are supposed to be. If we have an image that is 600 pixels wide and 900 pixels high, we don’t know what the
The intended size of the image is unless we know the physical size represented by each pixel. We can specify what size the pixels are supposed to be using any one of several methods.

In the case of scanned or other photographic images, the size of the pixels is usually specified by the dots per inch (DPI) resolution at which the image was created. If it was scanned at 300 DPI, there are supposed to be 300 pixels per inch so that each pixel is 1/300 inch in size. An image that is 600 pixels wide and 900 pixels tall that was scanned at 300 DPI is intended to be two inches wide by three inches tall.

DPI is fine for small images that have many pixels per inch. For images representing very large sizes we will most often specify the size of each pixel in meters or kilometers. For example, the very best commercial space satellite photographs will display an area one meter square for each pixel. If we had an image from such a satellite that was 600 pixels wide by 900 pixels tall, it would represent an area that was 600 meters by 900 meters.

When creating or importing an image in Manifold, we will be prompted to tell the system what size this image is supposed to be, either by specifying DPI or by specifying the size of each pixel. By default, Manifold will import images in geographic image formats using whatever scale factor is specified for the image. For non-geographic formats, Manifold will import the image using the screen resolution (typically, about 72 DPI) for the image. We can change this property at any time to rescale the image without losing any accuracy.

Until the image is georeferenced in a more sophisticated way, Manifold places it geographically with the lower left hand corner at the 0,0 origin at the intersection of the Prime Meridian and the Equator. Manifold's internal accuracy is so high that a 1200 DPI image can use the same system of 0,0 origin as drawings do by default and still be able to assign a specific lat/lon coordinate to each pixel, even though different pixels are only 1/1200 inch apart.

It is slightly ludicrous to think of a photographic image (like the detail above) being built up pixel-by-pixel using latitude and longitude coordinates; however, because Manifold does this internally when an image is used in a map it gives us great flexibility. We can mix images and drawings in a "CAD style" environment and know that an image scanned at 600 DPI from a letter-sized or A4-sized paper sheet photo will look exactly the correct size when layered in a map that includes a drawing made on the same scale.

Note that whereas drawings are made up of coordinates, images are made of pixels that are coordinate-free: coordinates of pixels are simply implied by the announced size of the pixels, their arrangement adjacent to each other in rows and the location of the image overall. While it is possible to reproject a drawing to change the coordinate values without any significant loss of accuracy, it is not possible to reproject an image without adding or deleting pixels. See Projections and Images for visual examples of this effect.

For this reason, to maintain accuracy we would not normally re-project an image that represents a raster data set because re-projecting the image changes the actual data by virtue of the interpolation necessary to change the shape of the image data into a new projection. If we are using the image for purely visual effect, of course, or if the interpolation is acceptable to us for the intended use of the raster data then we should feel free to re-project the image to match the desired map's projection.

Additional Reading

Experts should scan the Projections Quick Reference topic.
If you are new to coordinate systems in GIS or would like a refresher on coordinate systems and projections, consult the Projections Tutorial and the Coordinates in Projected Maps topics followed by a quick review of the Projections Quick Reference topic.
Coordinates in Projected Maps
Before proceeding with this Topic, please read the Coordinates topic and Projections Tutorial topic first.

In the Coordinates topic we saw how a drawing can be created on graph paper with a sequence of X,Y coordinates measured from the origin showing how to draw every object in the drawing. Drawings are just computer files filled with sequences of coordinates that are used to make the drawing in a “connect the dots” fashion.

To create a “flat” digital map, we use the same approach we did in drawing a plan of our office desk set in the Coordinates topic.

Recall the illustration of a cylindrical projection from the Projections Tutorial topic. It showed how a small part of the surface of the Earth could be “projected” onto a section of cylinder, which could then be unrolled into a flat sheet. If we want to save the X,Y locations of points on our flat sheet we can now measure them as though the flat sheet were graph paper to create a diagram of geographic features, just as we created a diagram of our desk set on a sheet of graph paper.

The above illustration shows a key concept that often proves confusing to GIS newcomers: although “unprojected” data about locations on the Earth are specified in degrees, all projected maps specify the coordinates of the objects on them with X,Y coordinates that are numbers representing meters, feet or other linear measures. These coordinates are computed relative to some origin established by the projection in use.

Computer files that contain projected maps therefore contain coordinates like

44030976, 38403088
44030984, 38403080
...and not longitude,latitude coordinate numbers such as

-110.3484, 44.2856
-110.3463, 44.2889
-110.3511, 44.2902

Latitude,longitude coordinates are normally in decimal degrees as shown above, while the coordinate numbers in projected files are most often meters in X and Y directions from some origin known to the projection. It is as if the green sheet in the illustration above were an enormous piece of graph paper on which the map is drawn "full size" and then measured off in meters.

In a well run GIS system the internal coordinates of projected maps may be hidden from the user because the GIS software will automatically translate the internal map drawing coordinates into Latitude/Longitude values on the fly. Manifold, for example, will show cursor position in a projected map view using Latitude and Longitude values. What is going on is that Manifold is automatically translating internal projected coordinates like 44030984,38403080 into the equivalent Longitude and Latitude values. Manifold allows "toggling" the status XY indicator between native units and lat/lon.

New GIS users are often fooled by the system's "translation on the fly" into thinking that their projected maps still contain coordinates in latitude/longitude degree form. This is not the case, since once a drawing is projected out of Latitude / Longitude into a different projection it will be in meters or other linear measure even though many Manifold dialogs will show the contents in degrees for the convenience of the user.

**Projected Coordinates and Projection Parameters**

The particular set of coordinate numbers in a projected file will make sense only if used within the projection parameters and projection within which they are intended to be interpreted. The projection parameters in use for a drawing may be seen at any time by viewing its coordinate properties. Click on the drawing in the project view to highlight it and then choose the Edit - Assign Projection dialog to open the properties dialog for that component. The coordinate properties tell Manifold how to interpret the data in that drawing. If these properties are changed, they simply change how Manifold uses the existing data. Changes in this dialog do not change the data itself.

For example, if we imported the following sequence of coordinate numbers...

44030976, 38403088
44030984, 38403080
44030900, 38403077

...from an ESRI "shapefile" they would make no sense if the coordinates properties were set to use Latitude / Longitude with coordinates interpreted as degrees. If we knew these coordinates were created for use with some particular UTM zone projection parameters we could open the Edit - Assign Projection dialog and enter those UTM zone parameters. The drawing would then make sense within Manifold.

Note that there is nothing about the raw numbers that says how they should be interpreted. "Smart" GIS formats will always save the required projection information with the file containing the coordinate numbers. When importing drawings from such formats
Manifold can automatically grab the required projection information and use it for that drawing's coordinate properties.

Legacy GIS formats do not save the necessary projection information with the files containing projected coordinates. This poses a big problem if one acquires a file full of projected coordinates without knowing what projection was used. ESRI's "shapefile" format is a classic legacy format that does not include projection information. It's best to use this and other legacy formats only for unprojected maps that require no elaborate projection parameters.

**Changing Projections**

Changing projections in a Manifold map is easy: we simply use the Edit - Assign Projection dialog to specify whatever projection we want and Manifold will automatically display all drawings and images in that map within that projection. There's no change to the native projections used by the drawings and the images since map windows in Manifold re-project their contents on the fly.

Because drawings are normally seen through map view within maps, it is not normally necessary to reproject them from whatever projection they were in when imported. Specifying the projection used by a map in map view does not change any data - it simply changes the way the data is seen in that particular map view. If desired, we can see the same drawings simultaneously through different map views using different projections in each map view.

The only time we might need to reproject a drawing is to speed up map view. Map view works much faster if the drawings it contains use the same projection requested of map view. This is especially true if many, large drawings and images are used in the map.

The X,Y coordinates in a projected drawing make sense only within the "grid" coordinate system used by that particular set of projection parameters. If we wish to change the projection within which the drawing exists we need to re-compute the numbers into their equivalents in the new projection.

Manifold does this via the Edit - Change Projection dialog. Specifying a projection with any optional parameters in this dialog will cause the coordinate numbers within the file to be changed into their equivalents in the new projection. The **Edit - Assign Projection** dialog will also be updated with the new interpretation.
Projections and Images

Images in Manifold may be projected as well as drawings. Images may be projected on the fly within maps or they may be re-projected within their native coordinate systems. Images are also re-projected automatically when they are georegistered to match a reference map, drawing or image.

Images have an implied coordinate system given by the row and column arrangement of their pixels. If an image is imported from a geographically aware image format such as GeoTIFF, it is automatically georeferenced to the correct location on Earth in geographic coordinates.

If an image is imported into Manifold from a geographically mute format such as .bmp or .jpeg, it is projected using Orthographic projection and placed with its lower left hand corner at the intersection of the Prime Meridian and the Equator (0 latitude and 0 longitude). This default georegistration decision together with size information about each pixel makes a specific choice as to where that image is located, what size it is and thus where the "center" of each pixel is located.

Just like a drawing, the coordinate properties currently in use for an image may always be seen in the Edit - Assign Projection dialog for that image. Changing any settings in this dialog does not change any pixels within the drawing - it simply changes how Manifold interprets the pixel data that already exist. To change an image's projection, we need to use the Edit - Change Projection dialog.

Although projection in images and drawings is conceptually similar, we tend to work differently with images and projections than we do with drawings and projections.

- Images used for visual effects are often re-projected to achieve greater speed in a map view. Images usually contain many more pixels than drawings contain objects. The cost of re-projecting an image on the fly in a map window is therefore often much higher than the cost of re-projecting a drawing on the fly.
- Images are usually highly localized views shot from directly overhead or very nearly so. They thus may be treated as already being in Orthographic projection. In contrast, most drawings or imported maps are in Latitude / Longitude coordinates and are not in any specific geographic projection.
- For geographic use, drawings are most frequently imported from formats that provide a known geographic location. Images are most frequently imported from formats that provide no geographic context. Images therefore will usually need to be georeferenced.
- Images are often slightly off Orthographic projection, or they are shot at angles that result in a Tilted Perspective or Space Oblique projected view in the image; however, it is very rare that we have actual numeric parameters corresponding to a particular image. Images will therefore often need to be adjusted through irregular geometric or numeric methods to fit a known good map. Drawings, in contrast, usually are transformed only through specific formulae from one known projection into another known projection.
- Any re-projection of an image will add or subtract pixels whereas re-projecting a drawing will neither add nor subtract objects. For this reason, images that present raster data where the value of each pixel represents important data will not usually be re-projected.

Georegistration

Georegistration is the process of moving, re-sizing and re-projecting an image to match the geographic region it is supposed to represent. This is done using control points to
match features in the image to locations in some reference map, drawing or image that is already in correct geographic context. This isn't necessary if we receive an image in a geographically aware format that automatically results in import into correct georegistration.

If we intend to use the image within a particular map it is wise to georegister the image using that map or using a drawing that employs the same projection used in that map. Doing so will georegister the image using same projection used by the map. This will eliminate the need to re-project the image "on the fly" when it is used within the map and will improve map display performance.

Once an image is georegistered to a known good geographic location and projection, we can use it like any other geographically accurate component.

**Visual Images and Raster Data Images**

Image formats are often used to deliver raster data such as terrain elevation or remote sensing information where the specific arrangement and value of pixels is very important. Any changes to such data sets (such as by interpolation required to change their shape into a desired projection) will add and subtract data not in the original data set.

Other types of image data are basically photographic images intended for human perception as visual images. In such cases, how the image looks to the human eye is more important than whether individual pixels are added or subtracted or otherwise changed. In many cases an overall change to the data such as improving contrast will improve the visual perception of the image.

Re-projecting an image invariably "warps" it in a way that adds or subtracts pixels. For visual images this is no problem. However, for images that represent specific raster data it may be unacceptable to change the data even if a very clever interpolation is used.

Within Manifold, we will therefore often re-project visual images without a second thought while taking care not to re-project certain types of raster data. Re-projecting photographic images into the same projection as a map view will allow the map view to operate rapidly. In the case of raster data set images we can always rely on the map view to re-project the image on the fly should it be necessary to show the raster data in a projected view. This will be slower but we will know the data has been unchanged.

To preserve the data accuracy of raster data images, they must be georegistered manually by altering their coordinate properties and not by re-projection through the georegistration process. To preserve unmodified data accuracy, raster data images must already be in some "natural" geographic projection such as Latitude / Longitude or be so close to a projection that no re-projection is necessary. Manual georegistration of such images requires opening the Edit - Assign Projection dialog and altering parameters there so the image is correctly interpreted.

**Why Re-projecting an Image Adds or Deletes Pixels**

All images imported into Manifold are rectangular because all raster image formats by definition have pixels arranged in rows and columns. Image windows show images as rectangles in the "native" coordinates implied by the row and column arrangement of pixels.
For example, images shot from oblique space vehicle trajectories and published as "north up" images will be shown in a rectangular format, usually with black pixels padding the extra regions needed to make the image a perfect rectangle. The image above is a Landsat 7 shot of the region near San Francisco Bay.

Although images are received as rectangles, re-projecting an image invariably changes its shape and leads to interpolation that changes the data. Re-projecting an image is, in effect, creating a new image.

Consider an image in its original rectangular format. All pixels are in locations adjacent to each other.

If we now re-project the image into some new projection (such as tilted perspective) we can imagine that the implied pixel locations will be pushed together in some regions and pulled apart in others. When shown in a map window within some projection the image will thus no longer be rectangular in shape. We should keep in mind this is only a thought experiment since images always consist of pixels adjacent to each other. Although we
can imagine that pixel locations are pushed together or pulled apart in real life an image always consists of a rectangular array of pixels.

When re-projecting an image, Manifold must take the implied locations of the pixels in the new form and transfer them to a new rectangular array of pixels. The color for each pixel in the new array is determined by sampling those color values at the implied projected points within it.

When georegistering or projecting images the **Size** parameters specify what size the new image is supposed to be. Using fewer pixels in height and width will result in re-sampling that averages down the image. Using a higher number of pixels in height and width will provide finer sampling. By default, Manifold tries to guess at a reasonable **Size** setting that will preserve the approximate overall size of the image when re-projection does not result in radically different shapes.

Note that increasing the number of pixels in height and width of the re-projected image can not increase detail or improve resolution beyond that in the original image. Increasing the number of pixels in height and width beyond the size of the original image simply re-samples the same "big" original pixel over and over within adjacent new pixels.
The result of re-projection is an image that has visible pixels in the appropriate locations and otherwise has invisible pixels. Using invisible pixels is more flexible than always using black pixels to "pad" the uneven edges of images to save them in rectangles. If desired, the Paint Bucket tool can always be used to pour black color into the invisible pixels.

Note that unlike re-projecting images, re-projecting vector drawings does not involve additions to or deletions from the data set. Even though re-projecting a vector drawing changes the shapes of objects it does not add or subtract objects from the drawing nor does it add or subtract from the number of coordinate pairs used to draw each object. The shapes of all objects in drawings are defined by the coordinates used to draw those objects. Re-projecting a drawing simply changes the coordinates into different numbers but it neither adds to nor subtracts from the coordinate pairs used to draw objects.

Note: The images above are simulations and are not actual screen shots because Manifold shows images in projected views too smoothly for a real screen shot to show the effects above.

Re-projecting for Speed in Maps

When an image is displayed in a map view using a projection other than the native image projection, the map view will automatically interpolate on the fly to add and delete pixels as necessary. This can be a time-consuming process for large images and will slow down map view in such cases. Note that even though the map window is showing the image in a new projection it is not changing the actual image data. It is simply re-computing on the fly how the image would appear in the new projection.

If we get tired of a slow map window when large images must be re-projected we can open the image in an image window and permanently re-project it to the new projection using the Edit - Change Projection dialog. When the native projection used by an image is changed the image will be re-computed and pixels will be added or subtracted as necessary for the new shape. Manifold will "pad" the new, non-rectangular shape of the image with invisible pixels to maintain a rectangular format. This will speed up map view if the new projection is exactly the same as that used in the map. This is a permanent change in the actual image data.

Mystery Projections

We will often encounter images that are close to, but not quite, a direct overhead view of a geographic scene where we do not know the exact circumstances under which the image was created. Such images are effectively in a Tilted Perspective projection where we don't know the parameters - a mystery projection, as it were.
We can deal with this situation by using georegistration to warp the image with control points to make it fit into some known good drawing. Instead of using ellipsoidal trigonometric formulae to achieve a perfect mathematical transformation between two projection coordinate systems as is done with projections in drawings, this method simply uses "best fit" algorithms to distort the image so that it is a good fit as directed by the control points.

**Tech Tip**

When an image is used in a map, for speed of operation the map usually is specified to have the same projection as the image. This is automatically accomplished when creating the map by using the image as the first component in the map. Sometimes the map is created first, an image is added to the map and then we would like to re-project the image so it has the same projection as the map. This is easily accomplished by right clicking on the image's layer tab and choosing **Project to Map**. This will re-project the image to use the same projection as the map.

**For advanced users:** Expert users might notice that sometimes doing a **Project to Map** will result in an image that looks slightly different when seen in its own component window than it appears when seen in a map. The reason for this is that **Project to Map** tries to preserve the original resolution of the image by modifying the values of the local scale parameters, in some cases choosing values for X and Y that are different for a better match to the original resolution. (To be exactly precise, **Project to Map** also modifies the values of local offsets as well, although this will not change the appearance).

As a result of the modifications in local scale parameters there can occur situations where an image component window and a map window showing the same image will not look exactly the same after re-projecting an image component to a map using the **Project to Map** command.

To make both windows look exactly the same, follow this procedure:

1. Open the image window and choose **Edit - Change Projection**.
2. Select the coordinate system to be the same as the map.
3. Press the **Suggest** button to let the system compute optimal values for local scales and offsets. These are the same values that would be used by the **Project to Map** command, were it to be used.
4. Modify the values of the local scale parameters so that they are equal to each other. There is no need to modify the values of local offset parameters.
5. Press **OK** to re-project the image.

**See Also**

**Changing a Component's Projection**
Changing a Component’s Projection

To permanently change a component's projection, choose the Edit - Change Projection command. This dialog permanently changes the projection used for a drawing or image. With drawings, it changes the coordinate numbers within the drawing to their equivalents in the new projection, and then updates Manifold's coordinate properties for that drawing. With images or surfaces, it will re-compute the image by interpolating to add or delete pixels as necessary to match the image shape to the required projection.

**Projection Dialog**

The dialog opens with a display of the current projection in use. Changing values in this dialog and then pressing apply will cause Manifold to re-compute the coordinate numbers within the component into their equivalents in the new projection. It is a permanent way of casting the data that define the drawing, image, surface or labels component into a new projection.

The dialog includes these controls:

- **Load from File** - Load projection information from a file using XML, Golden Software GSR or ESRI PRJ files.
- **Save to File** - Save projection information to a file using XML, Golden Software GSR or ESRI PRJ files.
- **Recent settings** - Choose a projection setting to reuse from a list of recently-used projections employed in this Manifold session.
- **Load from Component** - Load projection settings from another component in this project.

**Projection**

A tree diagram providing numerous projections within various types of projections.

**Datum**

A list of standard datums that incorporate various Earth ellipsoids and standard offsets.

**Parameters**

One or more optional parameter settings, if used by this particular projection. Double-click into the values boxes to change them. Press Enter after changing a value.

**Units box**

Choose the unit of measure. All "unprojected" maps are in Degrees, Arc Minutes or Arc
Seconds. Most projected maps are in meters.

**Local offset**  
Shifted version of the external coordinate system peculiar to this component. Specifies shift in X (longitude) and Y (latitude) direction in the given units. With images or surfaces, the Local offset stores the offset to the left-bottom corner of the left-bottom pixel of the image or surface.

**Local scale**  
Scaled version of the external coordinate system peculiar to this component. Specifies scale factor to be applied to external coordinate system.

**Scale correction**  
Controls scale of the external coordinate system. For example, 0.9996 for UTM.

**False easting/northing**  
Shift of the external coordinate system. For example, 500,000 meters for UTM. Some projections (such as UTM) add values to the "true" X and Y coordinates so that all coordinates stored are positive numbers. This avoids the use of the minus sign in primitive formats. The value added to X is the Easting and that to the Y is the Northing.

**Adjust for units**  
Automatically adjust easting/northing values when units of measure are changed. Not checked by default.

**Clip coordinates**  
Enabled for projections like Orthographic: clip those parts of objects that extend past the projection extent.

**Autosuggest local values**  
Enabled for images and surfaces: Automatically adjusts the values of local scale and local offset parameters after we change the coordinate system or alter one of the parameters in the parameter list. Checking Preserve local values overrides this box and keeps local values as they are.

**Preserve local values**  
Normally, choosing a projection from the projections pane will reset the values of Local offset, Local scale and units to the preset values for that projection. Checking this box will preserve any existing values in these local fields even when a new projection is selected. It is not checked by default in the Edit - Change Projection dialog because usually when re-projecting a component we want to use the preset local values associated with a new projection.

**Suggest**  
Suggest values for projection parameters based on the view in the component window. Used with projections with user-specifiable parameters.

This dialog should be a relatively infrequently used dialog since drawings and images are normally viewed as layers within maps. Because maps can show drawings and images in
whatever projection is requested of the map by re-computing the necessary views on the fly, it is rarely necessary to change the native projection of a drawing or an image. We would normally do so only to improve the speed of map windows.

Maps can work faster if the drawings and images they contain as layers use the same projection that is requested of the map. If we always use a particular projection within a map, it will be worth it to re-project the constituent drawings and images of that map into that particular projection as well. To permanently re-project a drawing or image, use the Edit - Change Projection dialog. In order for maps to run faster when the constituent drawings or images are in the same projection, they must use that same projection in all parameters. It does not help if both the map and its constituent drawings use Lambert Conformal Conic projection but with different center latitudes and longitudes.

Projection Toolbar Buttons

We may want to re-use the same projection information with different components. For example, suppose we have many shapefiles covering the same region of interest that contain projected information requiring the use of the Edit - Assign Projection dialog after import. Since all of the files will require the same projection information, after importing one file and manually specifying the projection settings in the Edit - Assign Projection dialog we can save the projection information using the Save to File toolbar button. With subsequent files we can then use the Load from File button to load the settings and thus avoid manual re-entry of repetitive information.

Another time saver is to load projection information from an existing component using the Load from Component button. For example, we may want to re-project all files into a certain standard projection used by a given component and would like to be sure that all settings are identical. In that case, we open each component to be re-projected, launch the Edit - Change Projection dialog and use Load from Component to load the desired settings from the component we wish to use as the standard.

Sizing Images and Surfaces

When choosing Edit - Change Projection to re-project an image or surface the image size will often change slightly in size. The actual size of the resulting image or surface in pixels will be determined by the Local Scale parameters, which set by implication the size of each pixel. Choosing inappropriate scale parameters can result in absurdly large images or surfaces. Attempting to create a very large image or surface in this way will cause Manifold to raise a confirmation dialog.

Discussion

To change the native projection of a drawing, image, surface or labels component use the Edit - Change Projection dialog.

Very Important: Do not use the Edit - Assign Projection dialog in an attempt to change the native projection of a component. This dialog is used to complete the import of a projected component from a format that does not correctly save projection information. Instead, use the Edit - Change Projection dialog to re-project a component.

Edit - Change Projection is virtually identical to the Edit - Assign Projection dialog because the two dialogs deal with similar information. However, the two are very different in function. The Edit - Assign Projection dialog the system how to interpret existing data without modifying the data. The Edit - Change Projection dialog changes the data to fit a required interpretation.
The **Edit - Assign Projection** dialog is used to make changes on a "one time" basis only when an import from a legacy format requires manual entry of the correct projection parameters. Changing parameters in the **Edit - Assign Projection** dialog changes only the interpretation of the existing data and not the coordinate data.

The **Edit Projection** dialog, in contrast, changes both the actual coordinate numbers as well as their interpretation. It is used every time one desires to re-project a drawing or image into a new projection.

Maps are a special case because they are viewports that show their contents in whatever temporary projection is desired. They don't change their contents, they simply show them in a different form. The projection used by a map to display its contents is set in the **Edit - Assign Projection** dialog.

### Local and External Coordinate Systems

The offset, scale, scale correction and easting/northing factors are intended for expert use. These parameters are scale and offset values for use with either the local coordinate system or the external, projection coordinate system.

In a nutshell, the external coordinate system is a coordinate system specified by the projection and projection parameters as described in the usual treatises on projection systems. The internal or **local** coordinate system is the coordinate system peculiar to the component, which may be a scaled and shifted version of the external coordinate system. Local systems occur when working with images imported from certain formats and possibly with drawings as well.

The **Local scale** and **Local offset** values expose the internal values used by a component to control the scale and shift of the internal coordinate system. These are given in the projection's units of measure displayed in the units box.

The **Scale correction** and **False easting/northing** parameters control the scale and shift of the external coordinate system. "False easting/northing" is used instead of "offset" for historical reasons. These factors are commonly met in projection systems like UTM. **Scale correction** values are given in dimensionless units (such as 0.9996 for UTM) and **False easting/northing** values are given in degrees or meters depending on type of the coordinate system (such as 500,000 meters for UTM).

**Example:** When importing a Manifold System Release 4.50 map that uses a **Unit2Degree** factor of 10,000 (the default), the **Local scale** will be 0.0001 for both X and Y. This means that one native unit within the imported drawing equals 0.0001 degree. Release 5.00 still uses full 1:250-millionth of a meter precision, but it imports the unit numbers from a 4.50 map knowing that the units used in that drawing had a scale factor of 0.0001.

**Example:** Increasing the **Local scale** in X of an image or drawing used as a layer in a map will make it look wider. Increasing the **Scale correction** in X will make it look narrower.

**Example:** Increasing the **Local offset** in both X and Y of an image or drawing used as a layer in a map will move the component towards the upper-right. Increasing the **False easting/northing** in both X and Y of an image or drawing used as a layer in a map will move the component towards the bottom-left (hence, the word "false").

**Local scale** and **Local offset** are applied to internal coordinates in a mirror image, inverse way as compared to how **Scale correction** and **False easting/northing** are applied to external coordinates within a projection system. In general, one can achieve exactly the
same scale or offset effect by applying inverse values to either the local or the external scale/offset pairs.

The choice of which to use depends on the context of the activity. **Local scale** and **Local offset** values are better suited for manual georegistration while **Scale correction** and **False easting/northing** values are better for the professional use of projections.

**Native Coordinates**

Manual edits of coordinates, scripting and use of intrinsic fields in tables may involve use of **native coordinates**. Native coordinates or native units are numbers stored within the drawing that Manifold uses internally as positional coordinates. These numbers are shown in the Object Coordinates dialog that pops up if you right-click an object and choose **Coordinates**. They are also used in the X (I) and Y (I) intrinsic field columns.

Projected coordinates are native coordinates adjusted with the local scale and local offset parameters of the coordinate system (projection) in use. In many cases, projected coordinates are the same as native coordinates (because of the local scale and offset values) but sometimes they are different.

The relationship between projected coordinates, native coordinates and the local scale and local offset parameters may be expressed in pseudo-code as:

\[
\text{ProjectedX} = \text{NativeX} \times \text{LocalScaleX} + \text{LocalOffsetX} \\
\text{ProjectedY} = \text{NativeY} \times \text{LocalScaleY} + \text{LocalOffsetY}
\]

**Adjust for units Option**

When manually changing units of measure the false easting and northing values will not be changed correspondingly. Checking the **Adjust for units** box will force a recomputation of the easting and northing values into the corresponding values for the new units of measure. For example, to change from Feet to Meters as units of measure and to change easting / northing accordingly:

- Verify the **Adjust for units** option is off,
- Set the units box to **Foot**,
- Turn on the **Adjust for units** option,
- Set the units box to **Meter**.

**Differences between Assign Projection and Change Projection**

- **Assign Projection** appears both with map windows and with individual component windows. When used with map windows it changes the projection used in the map view without actually changing the data in the components. Map windows have dynamic projections that can show their contents in whatever projection is desired regardless of the native projections of what is inside them. When used with component windows, this dialog changes the projection assigned to be used to interpret the coordinate data within the component.

- **Change Projection** appears only with individual component windows such as drawing windows or image windows. This command changes the actual coordinate data in the component into a new coordinate system. It can only work correctly if the starting projection assigned to that component was correctly assigned, so before we can use **Change Projection** to change a projection we must use
Assign Projection to verify that the projection originally assigned was correctly assigned.

Additional Reading

Experts may jump directly to the Projections Quick Reference topic.

If you are new to coordinate systems in GIS or would like a refresher on coordinate systems and projections, consult the Coordinates Tutorial, the Projections Tutorial, and the Coordinates in Projected Maps topics followed by a quick review of the Projections Quick Reference topic for a summary.

See also the Projections and Images topic.
Segmentization

*Segmentization* is the use of redundant, extra coordinates to define very large straight-line shapes so that they may be projected correctly. This is an advanced topic required only when creating very large geographic objects that have straight-line features. This topic assumes the reader understands how coordinates are used to define objects and how coordinate systems are used in projections. Let's begin with a refresher on how objects are drawn within projected coordinated systems.

Recall that all objects in Manifold ultimately consist of straight-line segments between the coordinates that define those objects. Even smoothly curved lines will be seen at high magnification to consist of straight-line segments between coordinates that define changes in direction. When re-projecting a drawing the coordinate numbers are changed to the new locations for each coordinate pair and then objects are drawn in the usual way in a "connect-the-dots" fashion as straight-line segments between the coordinates.

Consider a map of the United States shown in *Latitude / Longitude* projection. Suppose we use the *Shapes toolbar* to create a sequence of straight lines between points as shown. The two coordinate pairs at its beginning and its end define each straight line. A single coordinate pair defines each point.

If we change the map's projection to *Lambert Conformal Conic* the position of all coordinates will change slightly as required by the new coordinate system. Because the straight lines are defined by only two coordinate pairs they appear in the projected map as straight lines as well. This is fine as an abstract idea but it is not an accurate rendition of how a straight line in a Latitude / Longitude projection should appear in a Lambert Conformal Conic projection. If a feature is straight within a Latitude / Longitude projection unless it is a Meridian it should be gently curved in a Conic projection.
Let us consider an even more blatant example: Suppose we use the Shapes toolbar to create a rectangular box as illustrated within a Latitude / Longitude projection. The box is created as a single line that runs from a corner that is the beginning of the line through three additional corners and then back to an end position that is at the same corner as the beginning. Within the drawing that contains this line it is defined by a list of five coordinate pairs. Each pair defines the beginning or the end of the line (two pairs) plus one coordinate pair for each of the three other corners.

If we change the map’s projection to Lambert Conformal Conic the box (in black) will appear as a rhomboid with straight lines at the top and bottom; however, this is not a correct visual representation. A correct projection of the shape shown in the first illustration would appear as the magenta figure with curved top and bottom line. The box is wrongly portrayed with a straight top and bottom because those parts of the line run in a straight-line segment between only two coordinate pairs.

If we would like the box to have a gently curved top and bottom as is called for by the projection we need to provide extra coordinate pairs that can be moved as part of the re-projection.

If we look at the upper left-hand corner of the box in a close up zoom we can imagine a red dot showing the location of the coordinate pair defining that corner. (The coordinate pair defining the upper right-hand corner of the box is out of view off to the right.)
There's no reason we could not define the upper part of the line as a series of coordinate pairs. For CAD purposes, these are redundant. For geographic purposes, each coordinate pair is another location in the connect-the-dots list defining the line that can be moved slightly to achieve a curve in a projected map.

In fact, that's how the magenta figure was created in the illustration, by taking a copy of the black box and applying the Segments command in the Transform Toolbar for drawings. This command replaces straight-line segments of lines with additional segments using redundant coordinate pairs. The projection transformation then moved each of these coordinate pairs slightly to achieve a smooth curve instead of one straight line. The zoomed-in screen shot above shows alternate segments colored in red. Approximately 100 segments were used to achieve smooth top and bottom curves.

**Note:** The Segmentize command does not create new line objects. It starts with one line object and ends up with one line object. However, the line object it creates uses many more coordinates than needed by the original object to define the same line. The illustration above was created by taking a single line, breaking it into multiple lines and then coloring alternate lines red and black to show where the original segments were located. Even though the illustration uses multiple lines to convey the idea of segmentation, the reader should not be misled by it into thinking that the segmentize operator creates multiple lines from a single line object.

**Use in Geographic Maps**

Most features in geographic maps that are big enough to suffer visible distortion in projected maps will consist of hundreds or thousands of coordinate pairs. When projected, there are so many coordinate pairs available to move slightly in the re-projection that the map will appear smoothly projected. The risk of unwarranted straight lines appearing from the use of too few coordinate pairs happens only in the case of straight-line features that stretch over entire countries or very large states and provinces. Such features are rare and occur only in places such as the American West.

Geographic maps prepared by professional organizations such as USGS already use numerous redundant coordinates to define the straight-line sequences stretching over great distances. For example, the straight line defining the border between the US and Canada and borders of large, rectangular Western states is coded within USGS maps using many redundant coordinates. That is why the straight-line state borders in the US background map in the illustrations above appear smoothly curved in Lambert Conformal Conic projection.
Lack of enough coordinate pairs becomes an issue only when we create our own drawings on a continental scale or when we add objects in a simple way to existing drawings. In such cases, after creating the drawing or objects we should apply the Segmentize command to split the objects up into numerous redundant segments. This will provide many coordinate pairs to use as "handles" when re-projecting the drawing.

There is no need to use Segmentize within CAD drawings since all such drawings (factory plans, local site blueprints, etc.) are normally so small in geographic extent they are unaffected by projection distortion as are large states or other geographic shapes on a continental scale.

**Available Commands**

Segmentization can be accomplished either by using the Segments operator in the Transform Toolbar or by using the Segmentize command in the Drawing menu. The Segments transform operator adds the specified number of segments, whereas the Segmentize command adds segments so that each segment is no greater than a given Distance parameter.

Segments

**Georegistration**

Georegistration is the process of adjusting one drawing or image to the geographic location of a "known good" reference drawing, image, surface or map. For brevity, this topic and other georegistration topics use images as examples. However, the same procedures apply when georegistering drawings or surfaces.

- The drawing, image, surface or map being used as a reference is called the reference component.
- The drawing, image or surface being adjusted is called the target component.

Control points are used georegister images, surfaces, drawings and labels components. During georegistration the target image will be re-projected to match the reference drawing.
using the control points as a guide. The image above shows conceptually how control points in a reference drawing are matched up with equivalent control points in a target image.

Control points are matched by their name. For example, the spot marked by a control point named "ControlPoint2" in the drawing will be matched to the location in the image marked by a control point that is also named "ControlPoint2." Control points may be called by any names so long as the names used for control points within the reference component or target component correspond to the same location. For example, we could use the name "San Mateo Bridge East" for control points in both the reference component and the target component. These two points with the same name will be matched during the georegistration process. The choice of names is up to you. Some users prefer long, descriptive names while others prefer short names.

Any extra control points within either the reference component or the target component will be ignored. If there is a "ControlPoint18" in the target component but no control point of that name in the reference component it will be ignored.

We use the Control Points pane to add new control points to a drawing, image or map. Control points may be added to maps so that they may be used as a reference component, but maps are not georegisterable as a target component since they are made up of images or drawings in layers.

To Georegister a Target Component to a Reference Component

1. Place as many control points as is possible in the target image or drawing to be registered. Control points should be as evenly distributed as possible.
2. Place control points in the reference component with names matching the equivalent control points in the target.
3. Click on the image or drawing to be registered to make it the active window and choose Register in the Control Points pane. Manifold will present a dialog asking which component to use as the reference component. Only components with matching control point names will be listed.
4. Chose the reference component desired. Manifold will match those control points in the reference component to the target component by name and will re-project the target component so that its control points are in the same locations as the reference component.

Control Points

<table>
<thead>
<tr>
<th>Name</th>
<th>X / Longitude</th>
<th>Y / Latitude</th>
</tr>
</thead>
<tbody>
<tr>
<td>Control1</td>
<td>-122.480997</td>
<td>37.811238</td>
</tr>
<tr>
<td>Control2</td>
<td>-122.048519</td>
<td>37.467911</td>
</tr>
</tbody>
</table>

The Control Points pane always shows a list of control points defined for the current image or drawing together with their coordinates. When we click on a different window the Control Points pane will switch context to show any control points defined for the active window.

Control points may be added by clicking with the mouse into drawings, images or maps or they may be added by manual entry of X / Latitude and Y / Longitude coordinates. See the Control Points pane topic for details.

The Control Points pane is also used to rename control points or to change their location by changing their coordinates. We can click into the Name field to change the name from
the defaults, if desired. To change the coordinates of a control point we click into their X / Longitude or Y / Latitude fields.

**Tech Tip**

Uncheck the **Autoscroll window on edit or selection operations** option in Tools - Options when working with control points. Because using the **New Control Point** tool activates the mouse as soon as it leaves the Control Points pane, if this option is not deactivated the target window will begin to autoscroll as the mouse enters it.

**Georegistering Images**

The most frequent use of georegistration is to georegister images. Images, such as scanned paper maps, are often imported with the intent of tracing them to create new, custom drawings and maps. The first step in the tracing process is to georegister the image into the correct geographic location.

If the image includes features that also exist in a known good drawing we can use the drawing as a reference to georegister the image. For example, we may have scanned a paper map that shows property lines within a city boundary. We might already have a drawing that shows the city boundary but not the property lines. We can use the common feature of the city boundary to locate control points in both the reference drawing and the scanned image target. This procedure is discussed in the Georegistering an Image to a Drawing topic.

At times we need to georegister an image where we have no pre-existing drawing that has features in common with the image. To georegister such an image we need to identify features within the image for which we know the precise latitude and longitude coordinates. We can then use these features as control points based on the latitude and longitude coordinates they are supposed to have. For example, perhaps we have a small-scale paper map showing trails through a park where the park does not appear in any existing GIS drawing that we have. We would like to scan the map and georegister it so we can trace it. We can physically go out to different locations shown in the map and measure their precise coordinates with a handheld GPS device and then use these locations as control points. This technique is discussed in the Georegistering an Image to Known Coordinates topic.

Georegistering an image re-projects that image. Re-projecting an image invariably involves re-sampling the image by interpolating the image to a greater or lesser number of pixels. Images that are imported into Manifold from geographically-mute formats such as .jpeg or .gif do not have any scale associated with them. Georegistering such images into a geographic context will be the first time that the “size” of a pixel matters. By default, Manifold will attempt to preserve approximately the same number of pixels in height and width in the image. This can be adjusted if desired by changing the **Size** parameters in the georegistration dialog.

**Georegistering Drawings**

Drawings may also be georegistered. When we insert a new, blank drawing into a project it appears as a drawing in orthographic projection centered on the 0,0 origin of the Prime Meridian with the Equator. We can work with such drawings as if Manifold were a CAD editor to create blueprints, factory plans and other drawings where we do not care if they have or do not have a geographic context. We can also import pure CAD drawings from editors such as AutoCAD where the drawing has no geographic context.
We may wish to use such "CAD" drawings within geographic maps. For example, we may wish to place a CAD drawing of a real estate development within a geographic map of a town. To do this we can georegister the drawing to the desired location as is shown in the Coordinates Tutorial topic.

**Georegistering Surfaces**

Surfaces representing terrain elevation rarely need to be georegistered since most formats used in GIS to convey digital elevation can be imported as georegistered images. On occasion one encounters a format from which surfaces are imported that must be georegistered.

**Georegistration Dialog**

To georegister the active image or drawing, click on the **Register** button in the Control Points pane.

**Note:** Some options will be enabled only for certain methods or when sufficient control points have been defined.

- **Reference** The name of the drawing or image to be used as a source of control points to be used as reference points.
- **Method** One of the following algorithmic methods:
  - **Affine (triangulation)** - Also called geometric transforms, affine methods can georegister a target component to a reference component using fewer control points than required by the **Numeric** method. However, affine registration requires care in placement of control points.
  - **Affine (scale, shift, rotate)** - A fast method that is algorithmically equivalent to using **Numeric** with an **Order** of 1. This is the default method since it works with any number of control points.
  - **Simple (scale, shift)** - Match components using XY translation and re-scaling only. Works with any number of control points.
  - **Numeric (polynomial)** - Numeric matching uses numerical computation methods to transform one component to match another. A large number of control points are required for good matching but the method is algorithmically simple and fast. Available only when eight or more control points have been defined, thus allowing an order of 2 or greater.

  **Note:** Only those methods usable with the number of control points you have defined will be displayed. If you don’t see a method, add more control points.

- **Order** The level of mathematical sophistication applied. Higher orders result in better matches but take more time and more control
points. In numeric methods the highest order exponent used in the polynomial equations generated to transform the coordinate system of the target component. Enabled only for the **Numeric method**.

**Modify Coordinate System**

Enabled when the **Simple** method is selected. If checked (default) the coordinate system (projection) of the component being georegistered is converted to the coordinate system of the guiding component. If not checked, the coordinate system is not changed.

**Interpolate pixels**

Enabled when georegistering non-palette images or surfaces using the **Numeric method**. Creates a much smoother image when transforming the image into the new projection. Very computationally expensive: requires approximately twice the processing time to georegister an image if enabled. **Note**: Methods other than **Numeric** always interpolate pixels for non-palette images and surfaces and never interpolate pixels for palette images.

**Scale pixels equally in X and Y direction**

When this option is off, the user can specify both the width and the height of the resulting image or surface component. When the option is turned on, the user can only specify the width of the resulting component and the system will automatically compute the height. By default the option is turned on.

**Save error surface using**

Create a surface containing the root mean square error value for each location in the georegistered component. Choose the data type for the error number saved in the surface at each location. If checked, this option doubles the time required for georegistration. Enabled for the **Numeric method**. See the Error Surfaces topic.

**Size**

The transformed size of the image or surface in pixels. By default this will be set to some value that attempts to approximately preserve the size of the image or surface before georegistration. Enabled for images or surfaces.

The **Order** chosen will have a great impact on the number of control points required, especially when using the **numeric method**. For numeric georegistration, there usually must be at least four times the order number in control points, give or take a few. Thus, for numeric registration of order 4, there should be about 16 control points. This guideline is a minimum value. The **Order** value used can greatly effect the quality of the outcome. If the image is not georegistered well, try a different value of **Order**.

Certain arrangements of control points may require an even greater number of control points. Exception for the **Simple method**, the more control points the better. Images of scanned paper maps will often be registered with 35 to 70 control points in a production map environment when using **numeric** or somewhat fewer points for **affine registration**.
Affine registration works with fewer control points, as few as two or three in the case of **Affine (scale, shift, rotate)**. However, greater care must be taken when assigning affine control points. In general, control points should be placed for affine registration so that control points are drawn along the outer border of an imaginary shape without control points in the middle of the shape. For example, placing control points in a rectangular or rhomboidal arrangement is OK. Placing control points in a circle with several additional control points in the center of the circle is not OK.

**Affine** registration is a good choice when registering scanned images of maps that have a graticule grid of latitude and longitude lines shown. One can choose four intersections of latitude and longitude graticule lines that are near the four corners of the image to use as control points. Because fewer control points are required affine registration is often a better choice if we can place control points in a rectangular or rhomboidal arrangement.

**Numeric** registration may be a better choice when registering images to control points that are scattered throughout the image. When using numeric registration, evenly distributed control points will yield better results. This will, however, usually require many more control points than affine registration.

Either affine or numeric registration is a good choice when registering scanned images of maps that have a graticule grid of latitude and longitude lines shown if we are able to place many control points. One can choose a number of intersections of latitude and longitude graticule lines to rapidly mark many control points.

In either case, if control points are restricted to only part of the image it is quite likely that other parts of the image will not be georegistered well. When used in maps they will appear to be out of alignment with overlying drawing objects. It is critically important to use control points that are dispersed throughout the entire image. With the **numeric** method, the more control points that are used, the better the ultimate georegistration.

Given the labor of marking many control points the appeal of **Simple** registration is obvious. If an image is already in a North up overhead view and need only be resized and moved to be registered to a given target drawing this is a good choice. If the image is in Orthographic (the default when importing from geographically-unaware formats like .jpg), re-project the drawing into Orthographic and note the central latitude and longitude. Use **Edit - Assign Projection** with the image to specify the same central latitude and longitude. Then use **Simple** registration to georegister the image to the drawing.

**Example**

We begin with our **SanFran** sample Landsat image, which has been cropped to a smaller image centered upon San Francisco Bay.
The image has had six control points added that are reasonably dispersed near the edges of the image. This is a good pattern when the image is a near-overhead view and numeric registration is to be used. However, in "real life" we would use many more control points, probably over 30 scattered throughout the image. The image will be registered to control points in a drawing of hydrographic lines imported from a 1:100K-scale DLG downloaded from USGS.

After numeric registration, we can show the image in a map with the drawing lines show in yellow. Even though a small number of control points has been used registration is still very good.

**Using Maps as Reference Components**

If an image is being georegistered for display within a map it makes sense to use the map itself as a reference component, or to use a component that has the same projection as the map as the reference component. This will assure that the projection assigned to the image when it is georegistered will be exactly the same as that used by the map. The image will thus display faster within the map.
Maps are often a good choice for a reference component because they can show several layers such as roads and hydrography. Quite often a feature that is visible in an image may be identified with greater precision in a map when several layers are available to ascertain location.

For example, suppose we have an image like the one above where a bridge is visible. The example shows our SanFran sample image with the San Mateo Bridge crossing the South Bay.

The bridge provides a useful feature for use with control points, but if we work only with a hydro layer we will not see where the ends of the bridge could be marked.

Viewing both a roads layer and a hydro layer at the same time makes it easy to mark the ends of the bridge with control points. Note that the roads layer alone would not be any more useful than the hydro layer alone.
The resultant georegistration allows a reasonable match. The hydro outlines in the lower right of the image follow what USGS considers to be the shoreline in a region of tidal flats where a one foot (about a third of a meter) variation in water level changes the water’s edge by hundreds or thousands of feet.

**A Fast Arrangement**

Many users will set up their consoles so that the reference drawing and the target image appear side-by-side with the control points pane in the middle.

One can then zoom into approximately the same region in both map and image windows to add control points.

Workflow with this arrangement is a simple cycle: zoom into particular region in both the map and the image. Click on the image and add three or four control points. Click on the
map and add the analogous three or four control points. Click on the map and click the Back arrow to get back to the original view. Click on the image and click the Back arrow to get back to the original view. Repeat the cycle zooming into a different region to add control points.

Note that one can Zoom Box into a region, assign control points, and then click the Back arrow without losing the Zoom Box command. This sequence therefore is quick and easy to do. We can continue the zoom in / assign control points cycle until lots of control points have been assigned, and then georegister. With lots of control points the fastest method is usually Numeric.

Zooming into a particular region to place control points provides two main benefits:

- It allows us to place several control points in that region with zoomed-in accuracy.
- If the same region is zoomed in within the map window and the image window we are less likely to make a mistake when placing a control point because fewer points are involved.

The above advice, of course, assumes you have a reasonably high-resolution display with a reasonably large monitor so that there is enough room to have two reasonably useful windows open at once. 1024 x 768 is the absolute minimum, and really too small for serious georegistration work. Invest in a quality monitor or flat panel that's big enough to allow you to run at 1280 x 1024 resolution or greater.

Notes

Because control points can be imported from points that are in the drawing, a fast way of adding many control points is to add points into the drawing using Instant Data to specify the name of each point as it is clicked. We can then use these points as control points. See the Managing Control Points topic for essential methods that will save time and hassles.

Manifold will refuse to use control points that are placed on top of each other in the same image or drawing. The nature of control points is that they must refer to separate locations.

Most images that are overhead views of a subject can be georegistered to drawings in Orthographic projection using the Simple method with only two control points. This is a very fast match that is adequate for many GIS purposes.

The Save error surface as box option is not enabled for simple and affine methods.

Performance

Georegistering larger images can take substantial amounts of time. Depending on the size of image and the speed of the processor, large images can take hours to georegister. A very slow processor with an exceptionally large image might take days. The size of image, the speed of the processor and the method or other options selected can result in extensive variations in computation time required for georegistration. Checking the save error surface box will double the amount of time required.

For example, the Affine (triangulation) process is the most computationally intensive. Georegistering a 6500 x 7500 pixel grayscale image using the affine method on a slow machine with limited RAM, such as a 600Mhz PIII with 384MB of RAM, will take well over an hour. Georegistering the same image using the simple method (if it is a suitable
overhead image that can be treated as Orthographic) to an Orthographic drawing will require a few seconds on the same machine. Georegistering the same image using the numeric method (less computationally intensive) on a faster machine (1.1 Ghz Athlon with 512MB of RAM) will require 10 to 15 minutes. Depending on the hardware and method chosen the time required to georegister the very same image can range from seconds to over an hour.

Try smaller images, or try georegistering the image using a greatly reduced number of pixels from the defaults initially appearing in the Register box. Begin with very small images until you have some experience in realistic time required for your system. Use a lower Order with the Numeric method to speed it up. See the Performance Tips topic for suggestions on getting maximum performance out of your system.

Consider also the true size of an image. An image that is imported from a compressed file format, such as a .tif file, that uses only 50MB on disk may actually represent over nearly a gigabyte of pixels. Compute the size of the image by multiplying the X and Y dimensions in pixels times four for RGB images and times five for RGBA images. Grayscale images require much less space.

Finally, check to see if the image has invisible pixels. It is almost always best to crop the image to the desired area of interest right after importing it into Manifold, to make sure that it is not bordered with a swath of invisible pixels. Doing so avoids wasting computational time on georegistering or otherwise manipulating large numbers of invisible pixels that have no real role in the image.

**Technical Notes**

The Numeric method computes a set of coefficients for X and Y polynomials of the specified order minimizing the error at control point locations. The computed polynomials are then applied to transform the source data.

The Affine (triangulation) method utilizes a proprietary manifold.net algorithm that deploys not one, but many affine transforms.

Large images or surfaces can take a very long time to georegister when using Affine (triangulation) method or the Numeric method with higher Order. If desired, the georegistration process can be cancelled and then re-launched using a different method or lower Order.

Occasionally we might make a mistake in the placement or naming of control points that results in a bizarre and obviously wrong georegistration. In such cases, it is nice to know that Undo will work.

Images must be resized during some types of georegistration. Palette images will always be resized using the nearest neighbor method (no interpolation of colors) to guarantee that the georegistration process does not introduce any new colors.

- See the Error Surfaces topic for examples of usage, including visual examples of the effect of higher Order and control point location.
- For fine adjustment of registration, use the layer repositioning commands.
• The File - Print dialog used to print a component includes a **Control Points** option that may be used to print the control points in a component.

• The Georegister a Scanned Paper Map example topic shows a common georegistration task in step-by-step detail.
Georegistering an Image to a Drawing

Georegistering an image to a drawing is one of the most frequent tasks in GIS involving images. It's easy in Manifold:

1. Open the image to be georegistered. Place as many control points as possible in the image at locations that may be readily identified in the reference drawing.
2. Click open the reference drawing to which the image is to be registered.
3. Place control points in the drawing at locations corresponding to those used for control points in the image.
4. Click on the image to make it the active window and choose Register in the Control Points pane. Manifold will present a dialog asking which component to use as the reference component. The reference drawing used in steps 2 and 3 above will be listed in the list box of available reference components.
5. Chose the new drawing for use as the reference. Manifold will re-project the image to match the control points placed in the drawing.

See the Georegistration topic for additional details on how to use control points to georegister images and drawings.

For brevity, this topic and other georegistration topics use images as examples. However, the same procedures apply when georegistering drawings or surfaces.

**Tech Tip**

Before georegistering an image to a drawing, if the image is in Orthographic projection (the default for non-georegistered images), take a moment to re-project the drawing into Orthographic projection centered on the approximate central latitude and longitude of the drawing.

Images that are imported from non-geographic formats will import using the default Orthographic projection. In most cases, such images are overhead views photographed from aircraft or satellites. Their natural appearance, therefore, is already effectively the same as their appearance in Orthographic projection.

Drawings, on the other hand, are quite often imported from geographically aware formats and so will usually appear within some projected form. Due to the difficult of saving projection information in simple GIS formats like .shp, many drawings that are published on Internet are provided in unprojected Latitude / Longitude form. Such drawings may appear distorted as compared to a direct, Orthographic, overhead view, especially in higher latitudes.

If the distortion is great enough, the visual difference between the image and the drawing may make it more difficult to pick out features in common. By re-projecting the drawing into Orthographic projection we can given the drawing a visual appearance similar to the image. This will make it easier to pick out features that are common to both the drawing and the image.

Georegister a Scanned Paper Map
Georegistering an Image to Known Coordinates

At times we have an image that we would like to georegister where we do not have any known good components available for use as a reference component to which the image may be registered. If we have locations within the image for which we know the coordinates (say, as recorded using a GPS device taken to that location) we can nonetheless georegister that image.

Georegistering an Image to Coordinates

1. Open the image to be georegistered. From the Control Points pane use the **New Control Point** button to place at least three (and preferably many more) control points in the image at locations for which the coordinates are known.
2. Click on the project pane and insert a new drawing. This will be our target drawing.
3. Open the drawing. It will be blank. Re-project this drawing into Latitude / Longitude projection if it is not already in Latitude / Longitude projection.
4. In the Control Points pane use the **New Blank Control Point** button to add blank control points to the drawing that correspond to the control points placed in the image. For each control point, double click into the X / Longitude and Y / Latitude boxes to enter the known coordinates for the location of that control point.
5. After all of the control points are entered, re-project the drawing into whatever projection is desired as the end projection for the image.
6. Click on the image to make it the active window and choose **Register** in the Control Points pane. Manifold will present a dialog asking which component to use as the reference component. The new drawing created in step 3 above will be listed in the list box of available reference components.
7. Chose the new drawing for use as the reference. Manifold will georegister and re-project the image to match the control points placed in the drawing. After the georegistration process, the image will be in the same projection as the target drawing.

The above process is often made faster if we have used a GPS device to measure locations in the image and have stored each location as a waypoint in the GPS device. We can then download the waypoints into a drawing and use those points as our control points without the need to manually enter coordinates for each.

Another use of this process is to georegister a scanned image of a paper map. Paper maps often have graticules printed on them so we know the exact latitude and longitude coordinates at the intersection of the graticule lines. We can place control points at the intersections of the latitude and longitude lines in the image and then use these coordinates for the corresponding control points in the target drawing.

**Example**

Suppose we have a Landsat 7 image of the San Francisco Bay area. We would like to use this image to create new digital maps; however, we do not have any current digital maps to use as reference components. We do have latitude / longitude coordinates for two locations provided by friends with GPS devices who live in the Bay area. The first location is at the southern foot of the Golden Gate Bridge. The second location is at the south end of the Oakland International Airport.
We begin by using the Control Points pane’s **New Control Point** command to mark the known locations on the image with the mouse.

![Control Points](image)

We then insert a new drawing into the project. Make sure this new drawing is in **Latitude/Longitude** projection so that we can enter control points into it using latitude and longitude coordinates. To do this, first create a new drawing in the project pane, open the drawing and then use Edit - Change Projection to change the projection to **Latitude / Longitude**. It opens as a blank drawing.

<table>
<thead>
<tr>
<th>Name</th>
<th>X / Longitude</th>
<th>Y / Latitude</th>
</tr>
</thead>
<tbody>
<tr>
<td>ControlPoint</td>
<td>0.000000</td>
<td>0.000000</td>
</tr>
</tbody>
</table>

In the Control Points pane we click **New Blank Control Point** to add a blank control point to the pane.

![Blank Drawing](image)

The new control point will appear in the blank drawing.

<table>
<thead>
<tr>
<th>Name</th>
<th>X / Longitude</th>
<th>Y / Latitude</th>
</tr>
</thead>
<tbody>
<tr>
<td>ControlPoint</td>
<td>0.000000</td>
<td>0.000000</td>
</tr>
</tbody>
</table>

We double click into the X / Longitude field to change it.
We now type in the coordinate to use for Longitude.

When we push Enter the new coordinate is entered.

We can repeat this procedure with the Latitude coordinate.

Clicking New Blank Control Point we add another line to the Control Points pane.

We can manually add the coordinates for this new control point.

We can click Zoom to Fit in the drawing to show both control points in the drawing.

We can now click on the image to make it the active window and then press Register in the Control Points pane to register it in the usual way, using the new drawing in which we have created two control points. This example uses only two control points to save space. In "real life" we must use three or more control points. See the Georegistration topic and the Control Points pane topics for details in using these dialogs.

See the Georegister a Scanned Paper Map example for a detailed, step-by-step process to georegister an image to known coordinates.

Notes

As we edit the coordinates for control points manually by double clicking into the X / Longitude and Y / Latitude fields the control points being edited will jump about in the
drawing as their specified position moves about. Use **Zoom to Fit** to see the control points that have been added once manual editing has been completed.

Manifold maintains all coordinates to full precision. The default format for how many positions after the decimal point are shown in dialogs such as the Control Points pane is set in **Tools - Options**.

This topic is written showing the registration of an image as the target component. We can apply exactly the same procedure when registering a drawing (such as a CAD drawing of a factory plan) to known coordinates.

We can use tables to make lists of control points for use in georegistering images. When editing fields in tables, Manifold will automatically make sense of many different ways of entering latitude and longitude data into latitude and longitude type fields. This is extremely useful when entering coordinates for control points read off from paper maps that are marked using degrees, minutes and seconds notation. See the Create a Table and Add Records example for a step by step example of how one could add control points to a table using degrees, minutes and seconds format.

Suppose we have the GPS device in hand that was used to measure the known locations. We could have saved these in the GPS device as waypoints and then used the Manifold GPS Console to download the waypoints as points into a drawing. We could then use the **Load Points** command in the Control Points pane to load these points as control points. This would eliminate the need to enter coordinates by hand and thus also eliminate any possibility of typographic error when entering the coordinates.

For brevity, this topic and other georegistration topics use images as examples. However, the same procedures apply when georegistering drawings or surfaces.

See the Georegistration topic for additional details on how to use control points to georegister images and drawings.

Keep in mind that scanned images can be immense. An RGB image that is 12000 x 14000 pixels is over 800 megabytes in size. If you work with such large images you should have Windows 2000 or XP to avoid Windows bugs in 16 bit Windows versions such as Windows '95 or Windows '98. You should also have a **fast** processor and at least a gigabyte of RAM. Do not work with higher resolution images than is necessary.

Georegister a Scanned Paper Map
Error Surfaces

Georegistration is usually a tradeoff between a desire for high accuracy and the operator's patience or willingness to enter many control points or to tolerate long georegistration processing times required by using higher orders. When fewer control points are used the accuracy of georegistration declines. If desired, Manifold can compute a measure of accuracy of transformation when using the numeric method. The accuracy report is presented in the form of a surface where the value at each location in the surface provides a measure of georegistration accuracy at that location.

Checking the Save error surface as dialog box will create a surface in the same coordinate system and the same size as the component being registered. The value of the surface at each location reports the georegistration accuracy by reporting the RMS (root mean square) error at that location. The RMS values are computed by applying an inverse georegistration to the registered surface and then comparing the inverse result to the original component.

Beginning with an original component and then georegistering the component introduces some errors and then reversing the georegistration through an inverse transformation introduces additional errors. The component resulting from georegistration and then an inverse georegistration is therefore different from the original. It can be compared to the original using a root mean square comparison of original and transformed / re-transformed values for X and Y coordinates at each location.

The root mean square computation is reported in units of the source coordinate system. Values range from zero in regions where the transformation results in exact matches to some non-zero value in regions where the transformation and inverse transformation results in imperfect matches. The RMS error values are assembled into a surface called an error surface for convenient display of error values. The RMS error value in each pixel of the error surface is treated as the "height" of the surface at that pixel.

Error surfaces have their View - Display Options set to no shading and no palette. When opened in a surface window the error surface will have black tones in regions of low error transformations and lighter tones in regions of higher error transformations. High accuracy regions will be near control points and lower accuracy regions will be further away from control points.

If greater accuracy is desired we can then add more control points in regions of lighter tones and repeat the georegistration (save a copy of the original component so that the georegistration may be repeated using the original). Error surfaces created during georegistration will inherit control points.

Important: Computing an error surface requires not only the original georegistration transformation but also calculation of an inverse transformation. This requires additional computation and results in a longer georegistration process, approximately doubling the time required to georegister images and surfaces. Do not check the Save error surface as box unless you are willing to wait twice as long for the georegistration process.

Examples

Caution: This example uses some options that are not available in production Manifold releases. It is an artificial example cobbled up using a special version of Manifold created by manifold.net engineering. The special version was used to create illustrations of the effects of the Order parameter that will fit within the very small screen space available for Help illustrations.
The difference between this example and production Manifold releases is that this example uses the **Numeric** method with an **Order** of 1. That's not possible in production releases, where the minimum **Order** usable with the **Numeric** method is 2. However, using an **Order** of 1 provides a dramatic, obvious example when compared to an **Order** of 2 even though a relatively small number of control points (seven) has been used.

These examples use a portion of the **SanFran.jpg** sample image. The image was cropped and resized to a smaller number of pixels.

We have placed seven control points in the image that match seven control points in the **Bay_hydro** example drawing.

![Control Points](Sanfren.png)

Clicking the **Register** button in the control points pane launches the georegistration dialog. We choose the **Numeric** method, check **Save error surface as** and press OK. The **Order** is left at 1. [**Note**: Remember, this is possible only in the special version of Manifold used for this illustration. Production Manifold releases require a minimum **Order** of 2].
The image is georegistered to the **bay_hydro** drawing...

...and a new surface reporting errors is created.

If we open the error surface we see that by default it is seen in grayscale with no shading applied. Dark regions show lower errors and lighter regions show higher errors.

We can choose **View - Display Options** and assign a palette to the error surface. This also has the side effect of showing the minimum and maximum error values in the surface within the **Display Options** dialog.
Seen using the Spectrum palette the error surface shows finer visual detail of the distribution of errors. The surface is shown next to the georegistered image.

The error pattern seen in the above example is a very simple pattern that results from our use of a low order, 1, for the numeric georegistration. It’s fairly obvious why the Numeric method in production versions of Manifold requires an order of 2 or higher in order to avoid error surfaces like the above. If we were to repeat the georegistration using a higher order a more sophisticated georegistration would occur showing a more detailed error pattern.

To see this effect we can begin with a copy of the original image and use an Order of 2 in the Register dialog, as seen above.
The result is a slightly different appearance in the georegistered image as it is warped into registration with the latitude / longitude projection of the Bay_hydro drawing.

Opening the created error surface we see that it has a different pattern of grayscale tones.
Applying the **Spectrum** palette we can see that there is a region of high accuracy that correlates well to the placement of control points. The least accuracy occurs in the upper right corner of the image which is farthest from any control points.

Error surfaces are created using the same projection as the georegistered component. This allows us to overlay the error surface in a map with the georegistered component.

![Error Surface Image](image)

The illustration above shows the error surface in a map overlaid upon the georegistered **SanFran** image together with the **Bay_hydro** drawing. The opacity of the error surface has been reduced using Layer Opacity so the **SanFran** image may be partially seen through the error surface. This allows direct comparison between the accuracy implied by the error surface and the georegistered image.

**Technical Discussion**

As mentioned earlier, the above illustrations were created using a specially engineered version of Manifold that allows use of an **Order** of 1. Production versions do not allow this. Why was a special version created? There are two reasons why:

First, although production Manifold versions could use the **Affine** (scale, shift, rotate) method that is algorithmically equivalent to using **Numeric** with an **Order** of 1, only the **Numeric** method allows creation of an error surface since the **Affine** method is not exactly the same as the **Numeric** method.

Second, although it would have been possible to show a comparison between using an **Order** of 2 with an **Order** of 3. However, in order to use an **Order** of 3 there would have had to be many more control points in the image, so many that the relatively small sizes of images used for illustrations would have appeared very cluttered. By using a small number of control points any relationships between the pattern of control points and any resulting pattern in the error surface is more easily visible.

Georegister a Scanned Paper Map
Managing Control Points

Use the Control Points pane to add new control points to a drawing, image or map. Control points are used to georegister an image or drawing to the same geographic location and projection used by a "known good" image or drawing.

<table>
<thead>
<tr>
<th>Name</th>
<th>X / Longitude</th>
<th>Y / Latitude</th>
</tr>
</thead>
<tbody>
<tr>
<td>Control1</td>
<td>-122.480997</td>
<td>37.811238</td>
</tr>
<tr>
<td>Control2</td>
<td>-122.046519</td>
<td>37.467911</td>
</tr>
</tbody>
</table>

The Control Points pane always shows a list of control points defined for the active image or drawing together with their coordinates. When we click on a different window the Control Points pane will switch context to show any control points defined for the active window. See the Georegistration topic for basic use of control points.

For more sophisticated use and management of control points we can use four controls in the Control Points pane:

- **Load Points** - Load control points from points that exist in the drawing (enabled for drawings only).
- **Save Points** - Save control points as points in the drawing (enabled for drawings only).

**Load Points**

Drawings often contain named points that can be used as control points. This saves us the extra work of adding control points for those locations.

Suppose we have a scanned image of a paper map that we would like to georegister using control points.
Suppose we also have a drawing of the same geographic region that contains points. In this example we will assume that the points represent waypoints we have acquired with a GPS device.

<table>
<thead>
<tr>
<th>Name</th>
<th>Street</th>
</tr>
</thead>
<tbody>
<tr>
<td>WP 001</td>
<td>University</td>
</tr>
<tr>
<td>WP 002</td>
<td>University</td>
</tr>
<tr>
<td>WP 003</td>
<td>University</td>
</tr>
<tr>
<td>WP 004</td>
<td>University</td>
</tr>
<tr>
<td>WP 005</td>
<td>University</td>
</tr>
<tr>
<td>WP 006</td>
<td>University</td>
</tr>
</tbody>
</table>

If we look at the table for the points we can see that each has a **Name** plus additional fields, such as the name of the street on which each waypoint is located.

We will pick out four of the waypoints to use as control points. We could use all of the points in the drawing, but for the purposes of this example we will choose only four so the screen shots do not get too cluttered with labels.

<table>
<thead>
<tr>
<th>Name</th>
<th>Street</th>
</tr>
</thead>
<tbody>
<tr>
<td>WP 043</td>
<td>Embarcadero</td>
</tr>
<tr>
<td>WP 017</td>
<td>Embarcadero</td>
</tr>
<tr>
<td>WP 006</td>
<td>University</td>
</tr>
<tr>
<td>WP 001</td>
<td>University</td>
</tr>
</tbody>
</table>
We've picked out the points named **WP 043**, **WP 017**, **WP 006**, and **WP 001**, as can be seen by looking at the table.

The Control Points pane so far is empty for this drawing.

We click on the **Load Points** button to load points from the drawing. This opens the **Load Control Points** dialog.

The **Load Control Points** dialog asks us which field to use as the name field for the control points. The list box will be loaded with all text fields available in tables associated with that drawing. We choose the field called **Name** since that is where the names of our waypoints are stored. We click **OK** to load the drawing's points as control points.

The drawing's points will be imported into the Control Points pane as control points, using the designated name field value for their **Name**.
The control points will appear in the drawing in the usual way, with labels using the imported names for each point.

To use these control points, we click on the image to be georegistered and add control points in the image at the same locations and with the same names as the control points that were added to the drawing with the **Load Points** button. The image is shown slightly desaturated and lightened so that the control point labels stand out better.

**Save Points**

After adding control points to a drawing using the Control Points pane we may wish to add them to the drawing as point objects as well.
Suppose we have added many control points to a drawing of the United Kingdom.

We can add these locations to the drawing as point objects by pressing the **Save Points** button in the Control Points pane.

The result is the creation of a new point object at every location of a control point. We can see the new points by turning off display of control points by unclicking the **Preview** button in the Control Points pane. We have formatted points in the drawing to be largish, green squares so they are more easily visible.
By opening the table associated with this drawing we can see that the **Save Points** command created new point objects and also saved the name of each control point into a text field that we specified (in this example, a field that is called "Name").

The **Save Control Points** dialog allows us to save the names of the control points into any text field in the database table associated with the drawing. The **Name** list box will display a list of all available text fields in the table that we can use for saving the name. There is also a choice available to not save the name text, in which case the control points will be created as point objects without their names being saved to any text field.

**Notes**

It does no harm to load lots of control points if there are many points in a drawing. If desired, we could have loaded dozens of control points into the drawing's Control Points pane and then specified only four control points in the image. All of the extra control points in the drawings whose names didn't match those in the image would have been ignored. Why then, did we use only four control points in the drawing in this example?

There are two main reasons: first, in real life usage it is easier to see where to place control points in an image if there are only a few control points in the drawing that need to be matched. Second, since Help file illustrations must be small in size there would have been too much visual clutter in the screen shots if we had loaded dozens of control points.

One of the illustrations above shows only four points being used in a drawing out of many original points. To create this illustration, we selected the four points desired, used a **Select Box** with **Invert** selection mode to select all the other points except these four and then deleted all the other points. In real life we would probably have copied the four selected points to a new layer instead of deleting all the unnecessary points.

The **Ignore blank values** and **Ignore duplicate values** checkboxes are disabled in the Load Control Points dialog screen shot because no point records in the example table had blank values or duplicate values.

Why is there an **Ignore duplicate values** checkbox in the Load Control Points dialog? Why would we ever want to load more than one control point with the same name? If more than one point in the drawing has the same name, we might wish to see all of the duplicates as control points. We can then easily decide which duplicates should be deleted from the control points list.

The **Native Coordinates** button was not used to toggle to regular latitude / longitude values in the screenshot of the Control Points dialog, so the **X / Latitude** and **Y / Longitude** fields were shown in the control points list using the "native" internal coordinates of the projected map.

**Very important:** Points in drawings that we might wish to use as control points will often have data fields associated with each point in which latitude or longitude values occur. When acquiring points from a GPS, for example, we will often ask the GPS console to save the latitude and longitude for each point in a data field in addition to creating a point at that location. It is very important to understand that the location of the control point is taken directly from the actual geometric location of the point within the drawing and is not taken from any fields with latitude or longitude values that happen to exist within the data table. See the **Editing Data in Tables** topic for a discussion of this issue.
For brevity, this topic and other georegistration topics use images as examples. However, the same procedures apply when georegistering drawings or surfaces.

The font used for control point labels may be changed in Tools - Options.

**Tech Tips**

When we have lists of control points measured from a paper map or taken from a GPS device it is often convenient to enter many control points by creating a table with latitude, longitude (type latitude and longitude, of course) and name (type text) fields. Each control point can then be entered into the table.

When editing fields in tables, Manifold will automatically make sense of many different ways of entering latitude and longitude data into latitude and longitude type fields. This is extremely useful when entering coordinates for control points read off from paper maps that are marked using degrees, minutes and seconds notation. See the Create a Table and Add Records example for a step by step example of how one could add control points to a table using degrees, minutes and seconds format.

Uncheck the **Autoscroll window on edit or selection operations** option in Tools - Options when working with control points. Because using the **New Control Point** tool activates the mouse as soon as it leaves the Control Points pane, if this option is not deactivated the target window will begin to autoscroll as the mouse enters it.

**See Also**

- The File - Print dialog used to print a component includes a **Control Points** option that may be used to print the control points in a component.
- See the **Control Points pane** topic for a reference guide to the pane used to assign and manage control points.
- The Georegister a Scanned Paper Map example topic shows a common georegistration task in step-by-step detail.
Manual Georegistration

Manual georegistration of a component involves moving and re-scaling the component using manual techniques by manually editing the scale and positioning of the component. This is rarely done since the automated georegistration process is far easier to use. In some rare cases, manual georegistration as set forth herein may be used to "nudge" an image slightly that has already been positioned using the automated process.

For georegistration using manual methods an image must already be arranged in a pattern equivalent to some geographic projection. The two most frequently seen such arrangements are:

- Images showing the whole world or large sections thereof with pixels arranged in Latitude / Longitude projection.
- Images showing local, overhead views that may be taken to be in Orthographic projection.

Because Manifold imports all images from non-geographic formats into Orthographic projection, manually georegistering images showing local, overhead views in North-up orientation may be done by people willing to endure the tedium involved.

Manual Georegistration using Orthographic Projection

1. Import the target image into the project.
2. Import a reference drawing that has features in common with the target image.
3. Insert a map that includes the reference drawing.
4. Click open the map and note the approximate geographic center of the drawing.
5. Drag and drop the target image into the map. Position it in a layer beneath the drawing.

Option 1

6. Click open the image in its own image window.
7. Open the Edit - Assign Projection dialog for the image. Change the Center Latitude and Center Longitude values to those measured as the center of the drawing. Press OK.
8. In the map window, the image will appear as a microscopic dot at the exact center latitude/longitude give above. Change the Local scale values for X and Y to rescale the image. Usually, the X and Y unit values should be the same and will be some fractional amount, such as one X or Y unit is .004 meters. Adjusting these values up and down in a trial and error fashion will quickly show which is the right direction to go.
9. Some images may also require a shift in Local offset in X and Y to move them sideways or up and down to match the drawing.

Option 2

6. Right click on the image's layer tab and choose Register from the context menu.
7. Using directions like those given in the Maps - Register topic, change the X unit and Y unit values to rescale the image and also change the Easting and Northing properties to move the center of the image to the center of the map. This will prove incredibly tedious and frustrating. With larger images and Preview checked it will also be annoyingly slow to boot.
There are two options to the above procedure because there are two alternative methods after step 5. The net effect of the Register dialog is to change the coordinate properties of the image. These properties may also be edited directly in the Edit - Assign Projection dialog.

See the Manually Georegister an Image topic for an example. See the Edit - Change Projection dialog topic for more on advanced projection options such as Local scale.

Notes

For fine adjustment of registration, use the layer repositioning commands.

For certain expert uses it makes sense to use manual georegistration. For almost all other purposes, the automated georegistration process employing control points is far easier to use.

For brevity, this topic and other georegistration topics use images as examples. However, the same procedures apply when georegistering drawings or surfaces.

Projections Readings

The three topics in the Projections Readings section are based on the writings of John Parr Snyder as published by the U.S. Geological Survey. They have been liberally supplemented with writings contributed by the manifold.net team. The intent is to provide access to a classical view of projections and their usage as expressed by Snyder.

Much of this material is taken word-for-word from Map Projections Used by the U.S. Geological Survey, Geological Survey Bulletin 1532, Second Edition, John P. Snyder, 1982. However, it has been liberally revised by the current author so any errors that have been introduced should not be attributed to Snyder.

General Projections Concepts
The Earth as an Ellipsoid
Guide to Selecting Map Projections
General Projections Concepts
For almost 500 years, it has been conclusively established that the Earth is essentially a sphere, although there were a number of intellectuals nearly 2,000 years earlier who were convinced of this. Even to the scholars who considered the Earth flat, the skies appeared hemispherical, however. It was established at an early date that attempts to prepare a flat map of a surface curving in all directions leads to distortion of one form or another.

A map projection is a device for reproducing all or part of a round body on a flat sheet. Since this cannot be done without distortion, the cartographer must choose the characteristic that is to be shown accurately at the expense of others, or a compromise of several characteristics. There is literally an infinite number of ways in which this can be done, and several hundred projections have been published, most of which are rarely used novelties. Most projections may be infinitely varied by choosing different points on the Earth as the center or as a starting point. Manifold, for example, allows the setting of the projection’s center point for most projections.

It cannot be said that there is one "best" projection for mapping. It is even risky to claim that one has found the "best" projection for a given application, unless the parameters chosen are artificially constricting. Even a carefully constructed globe is not the best map for most applications because its scale is by necessity too small, a straightedge cannot be satisfactorily used on it for measurement of distance, and it is awkward to use in general.

The characteristics normally considered in choosing a map projection are as follows:

Area - Many map projections are designed to be equal-area, so that a coin, for example, on one part of the map covers exactly the same area of the actual Earth as the same coin on any other part of the map. Shapes, angles, and scale must be distorted on most parts of such a map, but there are usually some parts of an equal-area map which are designed to retain these characteristics correctly, or very nearly so. Less common terms used for equal-area projections are equivalent, homolographic, authalic, and equiareal.

Shape - Many of the most common and most important projections are conformal or orthomorphic, in that normally the shape of every small feature of the map is shown correctly. On a conformal map of the entire Earth there are usually one or more "singular" points at which shape is still distorted. A large landmass must still be shown distorted in shape, even though its small features are shaped correctly. An important result of conformality is that relative angles at each point are correct, and the local scale in every direction around any one point is constant. Consequently, meridians intersect parallels at right (90 degree) angles on a conformal projection, just as they do on the Earth. Areas are generally enlarged or reduced throughout the map, but they are relatively correct along certain lines, depending on the projection. Nearly all large-scale maps of the Geological Survey and other mapping agencies throughout the world are now prepared on a conformal projection.

Scale - No map projection shows scale correctly throughout the map, but there are usually one or more lines on the map along which the scale remains true. By choosing the locations of these lines properly, the scale errors elsewhere may be minimized, although some errors may still be large, depending on the size of the area being mapped and the projection. Some projections show true scale between one or two points and every other point on the map, or along every meridian. They are called equidistant projections.

Direction - While conformal maps give the relative local directions correctly at any given point, there is one frequently used group of map projections, called azimuthal or zenithal, on which the directions or azimuths of all points on the map are shown correctly with respect to the center. One of these projections is also equal-area, another is conformal, and another is equidistant. There are also projections on which directions from two points are correct, or on which directions from all points to one or two selected points are correct,
but these are rarely used.

**Special Characteristics** - Several map projections provide special characteristics that no other projection provides. On the Mercator projection, all rhumb lines, or lines of constant direction, are shown as straight lines. On the Gnomonic projection, all great circle paths - the shortest routes between points on a sphere - are shown as straight lines. On the Stereographic, all small circles, as well as great circles, are shown as circles on the map. Some newer projections are specially designed for satellite mapping. Less useful but mathematically intriguing projections have been designed to fit the sphere conformally into a square, an ellipse, a triangle, or some other geometric figure.

**Method of Construction** - In the days before ready access to computers, ease of construction was of greater importance. Some projections have become popular simply because they are easy to compute. With the advent of computers, very complicated formulas can be handled as routinely as simple projections in the past.

While the above features should ordinarily be considered in choosing a map projection, they are not so obvious in recognizing a projection. In fact, if the region shown on a map is no much larger than the United States, for example, even a trained eye cannot often distinguish whether the map is equal-area or conformal. It is necessary to make measurements to detect small differences in spacing or location of meridians and parallels, or to make other tests. The type of construction of the map projection is more easily recognized with experience, if the projection falls into one of the common categories.

**Categories of Projections**

A **developable** surface is one that can be transformed to a plane without distortion. There are three types of developable surfaces onto which most of the map projections used by USGS and other agencies are at least partially geometrically projected. They are the **cylinder**, the **cone**, and the **plane**. Actually all three are variations of the cone. A cylinder is a limiting form of a cone with an increasingly sharp point or apex (i.e., drawn out to infinity). As the cone becomes flatter, its limit is a plane.

If a cylinder is wrapped around the globe representing the Earth, so that its surface touches the Equator throughout its circumference, the meridians of longitude may be projected onto the cylinder as equidistant straight lines perpendicular to the Equator, and the parallels of latitude marked as lines parallels to the Equator, around the circumference of the cylinder and mathematically spaced for certain characteristics. When the cylinder is cut along some meridian and unrolled, a cylindrical projection with straight meridians and straight parallels results. The Mercator projection is the best-known example.

Regular Cylindrical Projection

If a cone is placed over the globe, with its peak or apex along the polar axis of the Earth and with the surface of the cone touching the globe along some particular parallel of
latitude, a conic (or conical) projection can be produced. This time the meridians are projected onto the cone as equidistant straight lines radiating from the apex, and the parallels are marked as lines around the circumference of the cone in planes perpendicular to the Earth's axis, spaced for the desired characteristics.

![Regular Conic Projection](image)

When the cone is cut along a meridian, unrolled, and laid flat, the meridians remain straight radiating lines, but the parallels are now circular arcs centered on the apex. The angles between meridians are shown smaller than the true angles.

A plane tangent to one of the Earth's poles is the basis for polar azimuthal projections. In this case, the group of projections is named for the function, not the plane, since all common tangent-plane projections of the sphere are azimuthal. The meridians are projected as straight lines radiating from a point, but they are spaced at their true angles instead of the smaller angles of the conic projections. The parallels of latitude are complete circles, centered on the pole.

![Polar Azimuthal Projection](image)

On some important azimuthal projections, such as the Stereographic (for the sphere) the parallels are geometrically projected from a common point of perspective; on others, such as the Azimuthal Equidistant, they are non-perspective.

The concepts outlined above may be modified in two ways, which still provide cylindrical, conic, or azimuthal projections (although the azimuthals retain this property precisely only for the sphere, not for ellipsoidal Earth models):

- The cylinder or cone may be secant to or cut the globe at two parallels instead of being tangent to just one. This conceptually provides two standard parallels (as settable in some Manifold projections); but for most conic projections this construction is not geometrically correct. The plane may likewise cut through the globe at any parallel instead of touching a pole. Those Manifold projections which allow secant projection surfaces will allow the setting of additional standard parallels beyond what is required for the simple tangent form of the projection.
- The axis of the cylinder or cone can have a direction different from that of the Earth's axis, while the plane may be tangent to a point other than a pole. This type of modification leads to important oblique, transverse and Equatorial projections, in which most meridians and parallels are no longer straight lines or arcs of circles. What were standard parallels in the normal orientation now become standard lines not following parallels of latitude.
Some other projections in common use resemble one or another of these categories only in some respects. The Sinusoidal projection is called pseudocylindrical because its latitude lines are parallel and straight, but its meridians are curved. The Polyconic projection is projected onto cones tangent to each parallel of latitude, so the meridians are curved, not straight. Still others are more remotely related to cylindrical, conic, or azimuthal projections, if at all.

**Projection Names**

Manifold System includes a vast array of different projections that are named mostly in accordance as described in US Geological Survey bulletins which tend to follow international cartographic practise for the names of the most common projections.

Many of the "standard" projections allow the use of various projection parameters as described above. Some countries have standardized on the use of a particular projection for mapping their countries that has acquired a local name when used with the locally-preferred set of parameters. Manifold includes these "projections" as choices for many of the more well known national projections.

Datum names used within Manifold originate with the U.S. National Imagery and Mapping Agency the official keeper of such data for the U.S. government.
The Earth as an Ellipsoid

For many maps, including nearly all maps in commercial atlases, it may be assumed that the Earth is a sphere. Actually, it is more nearly a slightly flattened sphere - an oblate ellipsoid of revolution, also called an oblate spheroid. This is an ellipse rotated about its shorter axis. The flattening of the ellipse for the Earth is only about one part in three hundred; but it is sufficient to become a necessary part of calculations in plotting accurate maps at a scale of 1:100,000 or larger, and is significant even for 1:5,000,000-scale maps of the United States, affecting plotted shapes by up to 2/3 percent. On small-scale maps, including single-sheet world maps, the oblateness is negligible.

The bad news is that the Earth is not an exact ellipsoid. In fact, because the Earth is such a "lumpy" ellipsoid no single smooth ellipsoid will provide a perfect reference surface for the entire Earth. The practical solution to this is to measure the Earth's shape in different areas and to then create different reference ellipsoids used for mapping different regions on Earth.

For example, the ellipsoid shown in yellow above is a fair match to the Earth's surface (shown in blue) in some areas but not in others. In some areas the Earth's surface protrudes above the even ellipsoid shape and in other areas the Earth's surface is lower than the ellipsoid's surface. We can use the yellow ellipsoid for precision mapping in areas where the Earth's surface is a close match.
We can use a different ellipsoid (shown in magenta) to map other areas where the magenta ellipsoid is a better match to the Earth's surface. We can specify many different standard ellipsoids to map different areas of the Earth.

**Offset Ellipsoids**

One more refinement lets us use a standard collection of ellipsoids without having to create hundreds of different reference ellipsoids to fit all the different lumpy regions of the Earth. The refinement is to use the same ellipsoid in different areas, but to offset the ellipsoid slightly to make it a better match. For example, in the illustration above we could use the magenta ellipsoid as is for mapping northern regions and we could also use it in southern regions if we moved it up slightly.

To see how this works, consider a translucent Earth in blue color with the center of the Earth marked by the intersection of three green axes.
For any ellipsoid we choose to use we can mark the center of the ellipsoid as well. The ellipsoid is shown in dotted outline with yellow axes marking the center.

To achieve a better fit between a given ellipsoid and a particular region of the Earth we can offset the standard ellipsoid from the center of the Earth.
If we illustrate the situation with a wireframe ellipsoid and solid Earth we can see the ellipsoid is above the Earth's surface in some areas and below it in others. In those regions where the ellipsoid closely follows the surface of the Earth we can use it for high-accuracy mapping.

To get it to fit better in other areas we can move the ellipsoid relative to the Earth.

A datum is a reference ellipsoid together with an offset from the center of the Earth. By specifying different offsets, we can use the same standard ellipsoids in many different regions of the Earth. Different countries will often use the same ellipsoid but with different offsets for standard government maps in those countries. In Manifold, each such unique combination is listed as a different datum in the Datum choice box in Manifold projection dialogs. There are literally hundreds of choices.

There are over a dozen principal ellipsoids that are frequently used by one or more countries. The Datum choice box in Manifold projections dialogs will call up a table of hundreds of datums that each use some standard ellipsoid. The different dimensions for various standard ellipsoids result from varying accuracy in geodetic measurements (the
measurements of locations on the Earth). Differences also arise because the curvature of the Earth’s surface is not uniform due to irregularities in the gravity field. Therefore the ellipsoid one calculates to be a best fit for the surface of the Earth depends not only on how the measurements are made but also where they are made.

Until recently, ellipsoids were only fitted to the Earth’s shape over a particular country or continent so that in effect every datum used in various countries employed an offset ellipsoid as illustrated above. The discrepancy between centers is usually a few hundred meters at most. In more recent years satellite-determined coordinate systems, such as the WGS series, have resulted in geocentric ellipsoids. The center of a geocentric ellipsoid is the same as the center of the Earth. Satellite-computed geocentric ellipsoids represent the entire Earth more accurately on an overall, average basis than ellipsoids determined from ground measurements but they do not generally give the "best fit" for a particular region.

The hundreds of choices for the datum in Manifold projection dialogs arise because many different countries over the years have used hundreds of different combinations of "standard" ellipsoids with different offsets. When creating new maps, pick the datum that is the one most used by other maps with which you will work. For general-purpose mapping, the safest choice is the Manifold default, the WGS 84 World Geodetic datum used for almost all GPS work.

**Historical Notes**

A frequently-used official Earth ellipsoid was defined in 1924, when the International Union of Geodesy and Geophysics (IUGG) adopted a flattening of exactly 1 part in 297 and a semi-major axis (or Equatorial radius) of exactly 6,378,388 m. The radius of the Earth along the polar axis is then 1/297 less than 6,378,388 or approximately 6,356,911.9 m. This is called the International ellipsoid and is based on John Fillmore Hayford’s calculations in 1909 from U.S. Coast and Geodetic Survey measurements made entirely within the United States. Although this datum is most accurate in the US it is amusing to note that this ellipsoid was adopted for international use and not adopted for use in North America. The datums still used in many countries employ the International ellipsoid together with a particular offset that best aligns the International ellipsoid with the Earth’s surface in the region of that particular country.

**The North American Datum of 1927 / NAD 27**

The first official geodetic datum in the United States was the New England Datum, adopted in 1879. It was based on surveys in the Eastern and Northeastern states and referenced to the Clarke ellipsoid of 1866, with triangulation station Principio, in Maryland, as the origin. The first transcontinental arc of triangulation was completed in 1899, connecting independent surveys along the Pacific Coast of the U.S. In the intervening years, other surveys were extended to the Gulf of Mexico. The New England Datum was thus extended to the south and west without major readjustment of the surveys in the east. In 1901, this expanded network was officially designated the United States Standard Datum, and triangulation station Meades Ranch, in Kansas, was the origin. In 1913, after the geodetic organizations of Canada and Mexico formally agreed to base their triangulation networks on the United States network, the datum was renamed the North American Datum.

By the mid-1920’s, the problems of adjusting new surveys to fit into the existing network were acute. Therefore, during the 5-year period 1927-1932 all available primary data were adjusted into a system now known as the North American 1927 Datum. The coordinates of station Meades Ranch were not changed but the revised coordinates of the network comprised the North American 1927 Datum.
Recent Ellipsoids

The ellipsoid adopted for use in North America is the result of the 1866 evaluation by the British geodesist Alexander Ross Clarke using measurements made by others of meridian arcs in western Europe, Russia, India, South Africa, and Peru. This resulted in an adopted Equatorial radius of 6,378,206.4 m and a polar radius of 6,356,583.8 m, or an approximate flattening of 1/294.9787. Since Clarke is also known for an 1880 revision used in Africa, the Clarke 1866 ellipsoid is named with the year. Once again it is amusing to note that the ellipsoid used for the North American Datum is based on data compiled outside of North America and thus is a less accurate choice than the International ellipsoid.

Satellite tracking data have provided geodesists with new measurements to define the best Earth-fitting ellipsoid and for relating existing coordinate systems to the Earth’s center of mass. The Defense Mapping Agency’s efforts produce the World Geodetic System 1966 (WGS 66) followed by more recent evaluations (WGS 72, WGS 84).

The North American 1927 Datum has been replaced with a new datum, the North American Datum 1983 (NAD 83) that is Earth-centered based on satellite tracking data, using the Geodetic Reference System 1980 (GRS 80) ellipsoid, an ellipsoid very similar to that for the WGS 72.

Eccentricity

In most map projection formulas, some form of the eccentricity $e$ is used rather than the flattening $f$ ratio. Manifold can accept the specification of a custom ellipsoid using the Major axis together with either the Minor axis or eccentricity.

Other Planets and Satellites

For the mapping of other planets and natural satellites, only Mars and Earth among the inner planets is treated as an ellipsoid. The Moon, Mercury, Venus, and the satellites of Jupiter and Saturn are taken as spheres. Manifold provides parameters for all the planets except Pluto.

Numbers for radius (Major axis and minor axis are the same for a sphere) for many planets and satellites may be found from a variety of Internet sites. Recent planetary missions have greatly improved accuracy.

Notes

The illustrations for this topic were created in Manifold 3D View Studio. They are greatly exaggerated to illustrate the concepts. The actual differences between ellipsoids and the Earth’s surface are rarely more than a few hundred meters.

It is difficult for humans to realize just how smooth the surface of the Earth really is on a large scale. Although we are impressed by the dramatic rise of mountains on a human scale, if the Earth were reduced to the size of a billiard ball the Earth would be much smoother than the billiard ball. The difference in height between the median surface and even the Himalayan Mountains is much less than the variations in smoothness of billiard balls.

[About half of this topic is taken word-for-word from Map Projections Used by the U.S. Geological Survey, Geological Survey Bulletin 1532, Second Edition, John P. Snyder, 1982. However, it has been liberally revised by the current author so any errors that have been introduced should not be attributed to Snyder.]
Guide to Selecting Map Projections
(This topic is based almost verbatim on the text in An Album of Map Projections, U.S. Geological Survey Professional Paper 1453, by John P. Snyder. It is included so Manifold users can benefit from the words of the master himself.)

The advent of computer-assisted cartography has now made it much easier to prepare maps. A map can now be centered anywhere on the globe, can be drawn according to any one of many projection formulas, and can use cartographic data files having a level of detail appropriate to the scale of the map.

Properties of Map Projections

An equal-area map projection correctly represents areas of the sphere on the map. If a coin is placed on any area of such a map, it will cover as much of the area of the surface of the sphere as it would if it were placed elsewhere on the map. When this type of projection is used for small-scale maps showing larger regions, the distortion of angles and shapes increases as the distance of an area from the projection origin increases.

An equidistant map projection is possible only in a limited sense. That is, distances can be shown at the nominal map scale along a line from only one or two points to any other point on the map. The focal points usually are at the map center or some central location. The term is also often used to describe maps on which the scale is shown correctly along all meridians.

An azimuthal map likewise is limited in the sense that it can correctly show directions or angles to all other points on the map only with respect to one (or rarely two) central point(s).

A conformal map is technically defined as a map on which all angles at infinitely small locations are correctly depicted. A conformal projection increasingly distorts areas away from the map’s center point or lines of true scale and it increasingly distorts shapes as the region becomes larger but distorts the shapes of moderately small areas only slightly.

Consistent with these definitions, maps simultaneously exhibiting several of these properties can be devised:

<table>
<thead>
<tr>
<th></th>
<th>Conformal</th>
<th>Equal Area</th>
<th>Equidistant</th>
<th>Azimuthal</th>
</tr>
</thead>
<tbody>
<tr>
<td>Conformal</td>
<td>-</td>
<td>No</td>
<td>No</td>
<td>Yes</td>
</tr>
<tr>
<td>Equal Area</td>
<td>No</td>
<td>-</td>
<td>No</td>
<td>Yes</td>
</tr>
<tr>
<td>Equidistant</td>
<td>No</td>
<td>No</td>
<td>-</td>
<td>Yes</td>
</tr>
<tr>
<td>Azimuthal</td>
<td>Yes</td>
<td>Yes</td>
<td>Yes</td>
<td>-</td>
</tr>
</tbody>
</table>

A map projection may have none of these general properties and still be satisfactory. For example, the Robinson projection is well suited for thematic presentations involving the entire Earth, but it has none of the above properties.

A map projection possessing one of these properties may nevertheless be a poor choice. As an example, the Mercator projection continues to be used inappropriately for world-wide thematic data. The Mercator map projection is conformal and has a valid use in navigation but very seriously distorts areas near the poles, which it cannot even show. It should not be used (although it frequently is) for depicting general information or any area-related subjects.
Some Nomenclature

From the perspective of design as well as distortion reduction, a projection may be selected because of the characteristic curves formed by the meridians and parallels. Using nomenclature suggested by L.P. Lee, we use the following terms to describe projections:

**Cylindric:** Projections in which the meridians are represented by a system of equidistant parallel straight lines, and the parallels by a system of parallel straight lines at right angles to the meridians.

**Pseudocylindric:** Projections in which the parallels are represented by a system of parallel straight lines and the meridians by concurrent curves.

**Conic:** Projections in which the meridians are represented by concentric circular arcs and the meridians by concurrent curves.

**Pseudoconic:** Projections in which the parallels are represented by concentric circular arcs, and the meridians by concurrent curves.

**Polyconic:** Projections in which the parallels are represented by a system of nonconcentric circular arcs with their centers lying on the straight line representing the central meridian.

**Azimuthal:** Projections in which the meridians are represented by a system of concurrent straight lines inclined to each other at their true difference of longitude, and the parallels by a system of concentric circles with their common center at the point of concurrency of the meridians.

Map Projection Illustrations

**Note:** In a few cases, projection is geometric, but in most cases the projection is mathematical to achieve certain features.

Regular Cylindrical - Specifying latitude and longitude origin centers the projection about a given location. Various cylindrical projections allow the specification of standard parallels that are used to govern the mathematical mapping from sphere to cylinder.
Transverse Cylindrical - Specifying latitude and longitude origin (or in some cases, the standard meridian) centers the projection about a given location. Various transverse cylindrical projections allow the specification of standard parallels that are used to govern the mathematical mapping from sphere to cylinder.

Oblique Cylindrical - Specifying latitude and longitude origin (or in some cases, the standard meridian) centers the projection about a given location.

Regular Conic - Illustrated with the latitude and longitude origin at the pole. Specifying a lat/lon origin other than the pole results in an oblique projection. Standard parallels, if specified, define the mathematical mapping from ellipsoid to the cone.

Polar Azimuthal (plane) - The projection’s latitude and longitude origin is at the pole.

Oblique Azimuthal (plane) - The projection is centered at a latitude and longitude origin other than the pole.

Philosophy of Map Projection Selection
Three traditional rules for choosing a map projection were at one time recommended as follows:

- For low-latitude areas: cylindrical.
- For middle-latitude areas: conical.
- For Polar Regions: azimuthal.

Inherent in these guidelines was the idea that it would be difficult to re-center a map so that the area of main interest was near the area of the map that has the least areal or angular distortion. On the other hand, with Manifold it is easy to recenter the projection to any location.

As a result, a projection no longer needs to be rejected merely because previous uses were traditionally centered inappropriately for the desired application.

In fact, the mathematical form of many projections (as implemented in Manifold) permit the user to alter the form of the map to reduce the distortions within a certain area. Most commonly, such alteration is accomplished by establishing standard lines along which distortion is absent; often, these lines are parallels of latitude. The Albers Equal-Area Conic projection, for example, will often be used with two standard parallels to “customize” the projection to a particular region. However, most properties of the map projection are affected when a standard line is changed. One should therefore keep track of what parameters were used in a particular projection.

Another way of altering the relationships on a map is by using different aspects, which involves moving the center of the projection from the normal position at a pole or along the Equator to some other position. As with the case of custom standard lines, one should keep track of any re-centering done with a given projection.

When a map requires a general property, the choice of a projection becomes limited. For example, because conformal projections correctly show angles at every location, they are advisable for maps displaying the flow of oceanic or atmospheric currents. The risk of using a conformal projection for a world-wide map is that the distortion of areas greatly enlarges the outer boundaries, and a phenomenon may seem to take on an importance that the mapmaker did not intend. Equal-area maps should be considered for displaying area-related subjects or themes, such as crop-growing regions.

Once the purpose of a map has been decided, the geographical area to be included on the map must be determined. This may be a region, or the entire world. The larger the area covered, the greater is the Earth’s curvature involved in the map. If the map area is a region, then its shape, size and location are important determinants in making decisions concerning projections.

Bearing in mind these determinants, mapmakers can apply traditional rules of choice, such as those mentioned above, or they can study the patterns of distortion associated with particular projections. For example, azimuthal projections have a circular pattern for lines of constant distortion characteristics, centered on the map origin or projection center. Thus, if an area is approximately circular and if its center is made the origin of the projection, it is possible to create a map that minimizes distortion for that map area. Ideally, the general shape of a geographic region should be matched with the distortion pattern of a specific projection.

An appropriate map projection can be selected on the basis of these principles and classifications. Although there may be no absolutely correct choice, it is clearly possible to make a bad judgement.
Addendum: Suggestions from the Manifold Team

Mapping experts will choose from a wide array of projections to meet specific objectives as discussed above. For general use, most people will usually develop a favorite projection for a particular situation and then use that projection over and over. For most situations either Orthographic or Lambert Conformal Conic are good choices.

The Manifold team recommends the following:

<table>
<thead>
<tr>
<th>Region to be Mapped</th>
<th>Suggested Projections</th>
</tr>
</thead>
<tbody>
<tr>
<td>Whole Earth</td>
<td>Robinson (pseudocylindrical) or Miller Cylindrical. Robinson seems to be fashionable for thematic maps. Any of the pseudocylindrical projections will be fine if you like their appearance better.</td>
</tr>
<tr>
<td>Hemispheres</td>
<td>Orthographic (azimuthal) for a &quot;view from space&quot; look, and Lambert Azimuthal Equal Area for thematic maps where the relative size of countries near the edge of the projection is to be preserved.</td>
</tr>
<tr>
<td>Continents</td>
<td>Use Lambert Conformal Conic for North America and Eurasia. Use Lambert Azimuthal Equal Area or Orthographic for South America and Africa. Use Orthographic for Australia, and Antarctica.</td>
</tr>
<tr>
<td>E-W Countries or Regions</td>
<td>Use Lambert Conformal Conic for US, Canada, Russia, and China. Use either Lambert Conformal Conic or Orthographic for Europe. Use Orthographic or Lambert Azimuthal Equal Area otherwise.</td>
</tr>
<tr>
<td>Polar Regions</td>
<td>Orthographic or Lambert Azimuthal Equal Area.</td>
</tr>
<tr>
<td>Oceans</td>
<td>Orthographic or Lambert Azimuthal Equal Area.</td>
</tr>
<tr>
<td>Smaller Countries or Regions</td>
<td>Orthographic.</td>
</tr>
<tr>
<td>N-S Countries, Oblique Regions</td>
<td>Long, thin countries aligned North-South such as Chile are one of the few times we would use Transverse Mercator. Oblique regions like the Alaska panhandle are mercifully rare: Use the Oblique Mercator in such cases.</td>
</tr>
</tbody>
</table>

Other than personal taste in visual appearance there are only two reasons not to use one of the above projections:

- A specific projection is required to match other data available or to exchange data with other users.
- The technical characteristics of a particular projection such as preservation of scale or relative area are required for creating a paper map or other presentation.

Manifold provides a very wide array of projections in addition to the standard projections.
mentioned above.

Frequently Asked Question

If Orthographic or Lambert Conformal Conic work well for almost all mapping that does not involve the entire world, why are systems like Universal Transverse Mercator (UTM) so frequently encountered? These systems came into use in a day when any mapping or projection computation had to be painfully prepared by hand. They were developed to solve problems within the technological limits of their day. They live on in modern times as living fossils simply because so many maps have been prepared using them that their usage has gained momentum. In some cases, the use of projections like UTM is required by law.

Modern desktop computers make it possible to compute a precise, perfectly centered projection for any location on Earth so in modern times we can use whatever projection works best for all the factors we wish to consider. We can completely ignore the cost of projection since there isn't any cost. We can therefore choose projections that minimize distortion such as the Lambert Conformal Conic or provide a very natural look like the Orthographic, and compute each projection to fit perfectly the view desired.

Manifold Projections

Manifold Projections

Because there is no perfect way of representing a three-dimensional Earth on two-dimensional paper maps or computer screens, many different projections have been invented that trade off various advantages and disadvantages. It is important to remember that every projection has some disadvantage and inaccuracy to it. When using projections, the key to choosing the right projection is to choose so that the disadvantages of that particular projection are irrelevant to the proposed usage of our map while the advantages serve our purposes.

Manifold includes numerous standard types of projections that with optional parameters may be used to specify hundreds of standard projections. For example, choosing a UTM zone in the Universal Transverse Mercator (UTM) projection series will specify any one of 60 specific projections in the UTM series.

Within most projection types, optional parameters may be used to create an effectively infinite number of different projections. Even standard projection types can exist in thousands of different variations when optional parameters such as datum are changed.

The individual projection topics introduce each main type of projection with a summary of the main characteristics, usage and origin of the projection. The projection descriptions are taken (almost verbatim, in some cases) from the writings of John Parr Snyder (1926 - 1997) of the USGS, most notably "An Album of Map Projections" by Snyder and Voxland (USGS Professional Paper 1453). Additional descriptions have been taken from the wonderful summary poster by Tau Rho Alpha and John P. Snyder "The Properties and Uses of Selected Map Projections", 1982, USGS Map I-1402.

All projection formulas used within Manifold have been programmed by the manifold.net team using the full ellipsoidal formulae that define the projection, wherever applicable. The main source of projection formulae is J.P. Snyder's definitive work, "Map Projections - A Working Manual" (USGS Professional Paper 1395).

Manifold forces the results of a coordinate system (projection) transformation to stay finite. This allows working with maps containing layers with locations which can not be represented in the coordinate system of the map. For example we can work with a
Mercator map that contains a drawing in latitude / longitude of the Antarctic region with objects touching a latitude of -90, which otherwise would have to be projected to infinity.

**Automatic use of Custom Datum Transformations**

Manifold uses high accuracy coordinate transformation mathematics when re-projecting data from one coordinate system to another. In certain parts of the world, custom transformation formulae are routinely used (and, at times mandated by law for certain uses) to convert datums during re-projection. If the **Use custom datum transformations** option is checked in the Tools - Options - Miscellaneous pane (checked by default) Manifold will use such custom datum transformations when available.

Currently, **NADCON** formulae are used to convert between **NAD27** and **NAD83** in North America and **NTv2** formulae are used to convert Canadian, Australian and New Zealand datums supported by **NTv2**.

If a converted location is outside of the conversion domain supported by such custom methods, no datum conversion is done and Manifold will display a message box to that effect after the attempted re-projection. If desired, such a re-projection can be undone, the data set edited to fall entirely within the region supported by the custom method and re-projection attempted once more.

**Note:** the message box mentioned above appears only when a component is re-projected using **Edit-Projection**. It does not appear when a component is re-projected on-the-fly for display as part of a map view.

In general, if we attempt to make a datum conversion between any of the datum pairs shown below and the datum is not converted, that tells us part of the data set we are attempting to convert falls outside the service area of the custom transformation formulae.

**Datum Pairs supported by Custom Transformations**

| North American 1927 (mean for CONUS) | **< NADCON >** | North American 1983 (mean for CONUS) |
| North American 1927 (mean for Canada) | **< NTv2 >** | North American 1983 (mean for CONUS) |
| Australian Geodetic 1966 (Australia, Tasmania) | **< NTv2 >** | Australian Geocentric 1994 (GDA94) |
| New Zealand Geodetic 1949 (New Zealand) | **< NTv2 >** | New Zealand Geodetic 2000 |

Custom datum transformations will be invoked **only** when converting between the above pairs in either direction. For example, they will be used when converting NAD27 to NAD83, or when converting from NAD83 to NAD27. Pairs shown above are listed using their full names as they appear in the datum box in Manifold projection dialogs, not using the abbreviated form commonly used. For example, **North American 1983 (mean for CONUS)** is referred to as **NAD83** in abbreviated form.

The **names** of the above datums are significant, not the parameters used. For example, if we convert **GRS80** (the parameters of which are identical to NAD83 so it is the same datum) to **NAD27** (mean for Canada), Manifold will **not** use the custom NADCON conversion formulae. This is done on purpose, so we can use NAD83 as the name of the datum for conversion-sensitive North American data (so that the custom transformation will be used).
and GRS80 as the name of the datum for all other data where we would like to use the
general purpose routines.

Custom Datum Pairs for NTv2

Additional datum pairs may be added to those supported by Manifold for use in NTv2
transformations through customization. See the Custom Datum Grids for NTv2 topic for
details.

Organization

There are so many projections available within Manifold that they have been organized into
several classes in the Edit - Assign Projection tree diagram:

- **Gauss Kruger**: A Universal Transverse Mercator projection
defined in zones and used in Germany, South
America, the former USSR and various
Eastern European nations. The European
alternative to UTM.

- **National Grids**: Presets for various national grid systems,
including the US State Plane Coordinate
System using either NAD27 or NAD83.

- **Standard**: Selection of standard Azimuthal, Conic,
Cylindrical, Pseudocylindrical, Satellite
View and Latitude / Longitude projections.

- **Universal Transverse Mercator**: The Northern Hemisphere projections for the
infamous UTM system consisting of 120
zones (60 different zones with North and
South variants of each). Originally developed
for military use and now widely misused in
civil mapping.

- **Universal Transverse Mercator (South)**: The Southern Hemisphere projections for
UTM. These are mainly distinguished by
each having a Northing parameter of 10
million so that no coordinates need involve
negative numbers.

Datums

There are hundreds of datums available within Manifold. They are listed alphabetically by
their official names as classed by the United States government agency (NIMA) current in
charge of such things. Each datum incorporates a specific Earth ellipsoid together with a
specific datum offset.

For general mapping use the **World Geodetic 1984 (WGS84)** datum. It uses an "Earth
centered" ellipsoid that provides a good match when the entire Earth is considered and is
the standard for GPS work.

Clip Coordinates Option

Some projections, like the Orthographic have a **clip coordinates** check box that clips
invisible parts of objects, such as countries located on the other side of the Earth from the
point of view of the projection. Clipping is a destructive process in that objects being
clipped are permanently removed. If the component might at a future date be used in a
different projection, make a copy before projecting using **clip coordinates**.
**Customization**

Experts may specify custom units of measure, ellipsoids, datums and even customized coordinate systems (projections) by specifying customized projection presets. See the Customization topic.

**Note**

Take a moment to purchase "An Album of Map Projections" by John P. Snyder and Philip M. Voxland (USGS Professional Paper 1453) from USGS. At $20 it's a steal and worth every penny for the numerous, clear illustrations of various projections. This and the other USGS publications noted above should be in every serious Manifold user's library.

**Gauss Kruger**

A system using Transverse Mercator projections to map the world into numerous standard zones that are six degrees wide. The standard Manifold Gauss-Kruger projection is also known as the Pulkovo 1942 Gauss-Kruger projection. A similar Gauss-Kruger projection is implemented in the **National Grids** group of Manifold projections under Germany as the **DHDN** Gauss-Kruger projection presets.

Americans can best understand the Gauss Kruger system by thinking of it as a version of the **Universal Transverse Mercator (UTM)** system with zones defined for European and Asian coverage. (Europeans, of course, can think of the UTM system as a version of the Gauss Kruger system that has been implemented by Americans.)

See the Universal Transverse Mercator (UTM) topic for information on how systems such as UTM and Gauss Kruger operate.

**Comments**

Like UTM or the State Plane Coordinate System, the Gauss Kruger system of projections is a living fossil. It was created mostly as a reflection of the technological limitations of an earlier era. When used with skill as originally intended it still functions well in expert hands. The problem with the Gauss Kruger system (as with UTM or the State Plane) is that it is constantly misused in civil applications by inexpert users who do not realize the limitations built into the system.

**Graphics**

**Graphics Projections**
Manifold includes several coordinate system (projection) presets that are useful when working with images in graphics editing that does not involve any geographic context. The graphics projection presets configure the default Orthographic projection with **Local scale** and units so pixel sizes correspond to typical sizes used at various DPI (dots per inch) settings commonly used for monitor displays or scanning. The graphics projections are normally assigned using the **Edit - Assign Projection** dialog to images imported from non-geographic formats.
There are four resolutions (72 DPI, 96 DPI, 150 DPI and 300 DPI) and two variations for measurement units (inches and millimeters). Be sure to uncheck the **Preserve local values** box when switching to these presets.

**Assigning a graphics projection to an image:**

1. Import the image.
2. Open the image.
3. Launch the *Edit - Assign Projection* dialog.
4. In the *Assign Projection* dialog, uncheck the **Preserve local values** box.
5. Choose the desired DPI and units and press **OK**.

The main value of the graphics projections is that the size shown by the image when using View - Zoom To - Native will be the "true" size of the image given the DPI intended. In addition, the size reported by selection tools and the Tracker will be accurate for the intended size of the image.

**Tech Tip**

*Advanced users desiring resolutions other than those provided may create their own presets using settings similar to those provided. See the Custom Coordinate System (Projection) Presets topic.*

**National Grids**

*National Grids*

National grid systems are set up by countries to provide a standard scheme of map projections for their country. Such systems might use one standard projection type (such as UTM) with specific parameters for standard zones within the country.

Other national grid systems will use different projections for different parts of the country. The US State Plane Coordinate System, for example, uses UTM as well as Lambert Conformal Conic in different State Plane zones.

Manifold includes standardized projections for a vast number of national grids. All have been implemented using local standards for such grids. The detailed description of such grids and how to use them is beyond the scope of this documentation. When working with a particular country's national grid, consult the references published by the national cartographic authority.

Following is a partial list of national grid projection systems in Manifold:

**GS50 Projection**

A conformal projection designed to show the 50 states of the United States.

**Scale**

True along an irregular line approximately encompassing the regions of the 50 states of the United States. Varies less than 2 percent from true scale throughout the 50 states and adjacent bodies of water. This is less than one-fourth the variation in scale of the best standard projections.

**Distortion**

Shape and scale distortion very low for the 50 state region. Greater distortion for regions away from the 50 states so that the projection is unusable outside the 50 states and immediately adjacent regions.

**Usage**

Maps of the 50 states of the United States, especially maps for school children that show the true relative sizes and shapes of Alaska and the lower 48 states.

**Limitations**

Use only for US 50 state region.

**Origin**

Developed by J.P. Snyder of the U.S. Geological Survey in 1982. The **spherical** case uses a sphere for the Earth's ellipsoid.

The GS50 uses tenth-order complex-algebra polynomials to modify the Stereographic projection. Conformality is precise in these cases even though finite polynomial series are used.

**Options**

The coefficient choices are useful only for this design of a 50-State map.
State Plane Coordinate System
The State Plane Coordinate System is a set of many different projections organized by Zone. Transverse Mercator projections are the basis for the State Plane Coordinate System in U.S. States having predominately north-south extent. Lambert Conformal Conic projections are also used in many of the U.S. State Plane Coordinate System zones.

The State Plane Coordinate System projections are found under the National Grids heading in Manifold projections dialogs. There are three choices:

- **State Plane (NAD27, feet)**: State Plane Coordinate System used within the United States based on NAD27 datum. A mix of different projections and parameters, but mostly UTM-based. In feet.

- **State Plane (NAD83, feet)**: State Plane Coordinate System used within the United States based on NAD83 datum. A mix of different projections and parameters, but mostly UTM-based. In feet.

- **State Plane (NAD83, meters)**: State Plane Coordinate System used within the United States based on NAD83 datum. A mix of different projections and parameters, but mostly UTM-based. In meters.

Note that the NAD 27 version is provided in feet. Since some State Plane users of the NAD 83 version use either feet or meters the NAD 83 version is provided in both feet and meter based projections.

Limitations

The accuracy of Transverse Mercator projections quickly decreases from the central meridian. Therefore, it is strongly recommended to restrict the longitudinal extent of the projected region to +/- 10 degrees from the central meridian. [The US Army standard allows +/- 24 degrees from the central meridian].

This requirement is met within all State Plane zones that use Transverse Mercator projections. However, given modern computer technology these recommended limits result in ludicrously inaccurate maps. But then again, people seriously interested in exploiting the power of modern computers would not be using the State Plane system in the first place.

Because many state plane zones use Transverse Mercator projections they are subject to the same difficulties and limitations of the Universal Transverse Mercator (UTM) system, which also employs Transverse Mercator projections. It is very important for new users to realize that each State Plane Zone is a separate projection. Due to distortion effects induced by Transverse Mercator projections the State Plane system is highly unsuited for creating maps that combine more than more State Plane zone.

See the Universal Transverse Mercator (UTM) topic for a discussion of this and other problems with Transverse Mercator projections.

Comments

Like UTM or Gauss Kruger, the State Plane Coordinate System is a living fossil. It was created mostly as a reflection of the technological limitations of an earlier era. When used with skill as originally intended it still functions well in expert hands. The problem with the
State Plane system (as with UTM and Gauss Kruger) is that it is constantly misused in civil applications by inexpert users who do not realize the limitations built into the system.

**Standard**

**Latitude / Longitude Projection**

Not really a projection, but the graphical figure obtained by plotting latitude and longitude degree coordinates as if they were $Y$ and $X$ coordinates. The default "unprojection," it is also known as the geographical latitude / longitude projection.

Note that one latitude / longitude projection may be different from another because each such projection assumes that a particular datum is in use. While the WGS84 datum is almost universally assumed to the datum used, it is possible that some person assumed a different datum.

It is also possible to re-project latitude / longitude data into different datums, even including datums that include rotation factors. In such cases Manifold will faithfully reproject the data as direct taking into account datum rotation factors if applicable.

**Scale**

True in degrees along the Equator or vertically along any meridian.

**Distortion**

Considerable distortion away from the Equator due to horizontal increase in longitude degrees.

**Usage**

Used to save digital maps in unprojected form using some assumed datum.

**Azimuthal**

Azimuthal Equidistant
An azimuthal projection that is neither equal-area nor conformal. The main feature of this projection is that it shows distances and directions correctly from the central point.

**Scale**

All distances measured from the center are true. Distances not measured along radii from the center are not correct.

**Distortion**

The center of the projection is the only point without distortion. Directions from the center are true, except on some oblique and Equatorial ellipsoidal forms.

**Usage**

Used in the polar aspect for world maps and maps of polar hemispheres. Used in the oblique aspect for atlas maps of continents and world maps for aviation and radio use. The ellipsoidal oblique aspect is used for the plane coordinate projection system in approximate form for Guam and in nearly rigorous form for islands in Micronesia.

**Limitations**

Use only for a single hemisphere at a time

**Origin**

Known for many centuries in the polar aspect. It is believed the Egyptians used the polar aspect for star charts, but the oldest existing celestial map using this projection was prepared in 1426 by Conrad of Dyffenbach. The first known use for polar maps of the Earth was by Gerardus Mercator as insets on his 1569 world map, which introduced his famous cylindrical projection.
Donald
An azimuthal, two-point equidistant projection specially modified for the Earth ellipsoid and confined to the United States and southern Canada. Shows true distances, but not true azimuths, from either of two chosen points to any other point on the map.

Scale
True along a straight line from either of the two central points that define the projection. Distances are exact when measured from either one of two central points, at: 37 degrees 42 minutes 14.69 seconds North (37.7040806) latitude, 82 degrees 39 minutes 15.27 seconds West (-82.6542417) longitude in Floyd County, Kentucky and at 41 degrees 02 minutes 55.53 seconds North (41.0487583) latitude, 112 degrees 03 minutes 39.35 seconds West (-112.0609306) longitude in Webster County, Utah.

Distortion
No points free of distortion. Minimizes distance distortion in the lower 48 US states.

Usage
Used by telephone companies to establish long-distance rates in the United States and southern Canada.

Limitations
Use only for the lower 48 United States and Southern Canada.

Origin
Developed by Jay K. Donald of the American Telephone and Telegraph Company in 1956. Two-point equidistant projections were originally presented by Hans Maurer (1868-1945) of Germany in 1919 and by Charles F. Close (1865-1952) independently in 1921.
Double Stereographic

An azimuthal, conformal, polyconic (general) perspective projection that is visually similar to the ordinary Stereographic. Used most conveniently with a single hemisphere. This version of the Stereographic projection is called the "Double" Stereographic because it is really two projections: the surface of the utilized ellipsoid is first conformally projected to a sphere and then the sphere is stereographically projected to a plane. It therefore provides both a perspective view while also providing conformal mapping of the original ellipsoid onto a plane.

Scale

True only where the central latitude crosses the central meridian or, alternatively, along a circle concentric about the projection center (or a parallel on the polar aspect). Scale is constant along any circle having its center at the projection center, but scale increases rapidly with distance from the center within a hemisphere.

Distortion

Only the center or the circle of true scale (if not the center) is free from all distortion. Areas grow greater the farther from the center, albeit in a conformal manner.

Usage

Similar to that of the ordinary Stereographic. Commonly used in the polar aspect for topographic maps of polar regions. The Equatorial aspect was used regularly for maps of the Eastern and Western hemispheres in the 17th and 18th centuries. Oblique aspects are used to show paths of solar eclipses.

Recommended for conformal mapping of regions approximately circular in extent. For example, in 1997 it was used as the standard projection for the Fermilab Main Injector project, which involved injecting protons and antiprotons into a large, circular Tevatron ring. By centering the Double Stereographic projection at the center of the Tevatron, scale throughout the circular tunnels hosting the Tevatron could be kept accurate.

Limitations

The Double Stereographic projection must not be used to map the entire world’s surface at once: at least the point directly opposite to the projection origin must be excluded. This
limitation arises because the Double Stereographic projection maps the point opposite the projection origin to infinity, causing numeric overflows. For example, if the North Pole is used as the projection origin, the South Pole and region immediately about the South Pole should not be included in the map.

**Origin**

Apparently developed in polar aspect by Egyptians and Greeks by the 2nd Century BC

**Options**

Specify the latitude origin and longitude origin to center the map projection to the area to be mapped. Specifying a non-Equatorial or non-polar origin causes an oblique projection.
Gnomonic

An azimuthal projection that is a perspective projection and is neither conformal nor equal-area. Also called the Gnomic or Central projection and was known as the horologium (meaning "sundial" or "clock") in earlier times.

Scale

Scale true at the center only. Directions from the center are true.

Distortion

No distortion at the center only. Distortion and scale rapidly increase away from the center.

Usage

The only useful feature of the Gnomonic projection is that all great-circle arcs project as straight lines on this projection. The scale is badly distorted along such a plotted great circle, but the route is precise.

Except at the center, distortion of shape, area and scale on the Gnomonic projection is so great that it has seldom been used for atlas maps. Generally, the projection is used for plotting great-circle paths.

Several sets of star maps from the late 18th century and some terrestrial maps of 1803 used this projection with the sphere projected onto the six faces of a tangent cube. Also used from the mid-16th to the mid-20th centuries to project the terrestrial globe onto the faces of other polyhedra.

Limitations

Use only for a single hemisphere.

Origin

Used by Thales (636? - 546? BC) of Miletus for star maps.
Limiting Forms

Used in Spherical form only.
Lambert Azimuthal Equal Area

An azimuthal, equal area, nonperspective projection.

**Scale**

True only at the center in all directions. Decreases with distance from the center along radii. Increases with distance from the center in a direction perpendicular to radii.

**Distortion**

Only the center is free from distortion. Distortion is moderate for one hemisphere but becomes extreme for a map of the entire Earth.

**Usage**

Frequently used in the polar aspect in atlases for maps of polar regions and of Northern and Southern Hemispheres. The Equatorial aspect is commonly used for atlas maps of the Eastern and Western Hemispheres. The oblique aspect is used for atlas maps of continents and oceans. The Equatorial and oblique aspects are used by the U.S. Geological Survey in cooperation with others for maps of the Circum-Pacific Map Project.

Recommended for equal area maps of regions approximately circular in extent.

**Limitations**

Use only for a single hemisphere.

**Origin**

Presented by Johann Heinrich Lambert (1728-1777) of Alsace in 1772. Also known as Lorgna (for the polar aspect), Zenithal Equal-Area or Zenithal Equivalent.
Johann Heinrich Lambert

Lambert served at the Berlin Academy of Sciences, a contemporary of Euler and Lagrange. An extraordinary mathematician, he is best known as the first to prove rigorously that $\pi$ is irrational.

Options

Specify the **first standard parallel** and **longitude origin** to center the map projection to the area to be mapped. Specifying a non-Equatorial or non-polar origin causes an **oblique** projection.
Modified Stereographic
A modified azimuthal projection that is conformal. One of an endless possible series of
conformal projections using the Driencourt and Laborde algebraic transformations.

Scale

Scale is true along irregular lines, but the map is usually designed to minimize scale
variation throughout a selected region.

Distortion

Low, but continuous distortion within the target region. Profound distortion outside the
intended range of the map.

Usage

Used for maps of continents in the Easter Hemisphere, for the Pacific Ocean and for maps
of Alaska and the 50 United States. Provides extremely constant scale over regions as
large as the conterminous US. The GS-50 version of this projection minimizes scale errors
through all 50 United States including Alaska and Hawaii as well as island possessions.

Limitations

Use only for a single hemisphere.

Origin

Based on the Driencourt and Laborde complex algebraic series that satisfies the Cauchy-
Riemann equations that define the conformal transformation of one surface onto another
surface. Laborde applied this transformation to the mapping of Madagascar in 1928.

Options

Manifold provides a standard set of the most commonly used forms of projections based
on Driencourt and Laborde terms.
Orthographic

The "view from space" projection: An azimuthal, perspective projection that is neither conformal nor equal area. Range is no more than one hemisphere at a time. This is the default Manifold projection for new drawings, images and labels components.

Scale

True at the center and along any circle having its center at the projection center but only in the direction of the circumference of the circle. Scale decreases with distance from the center.

Distortion

Only the center is free from distortion, which increases rapidly away from the center. Distortion is extreme near the edge of the hemisphere.

Usage

Pictorial views of the Earth, resembling those seen from space. This is a perspective projection of the globe onto a tangent plane from an infinite distance (i.e., orthogonally); thus, the map has the look of a globe. The Orthographic projection is used by default within Manifold for images and drawings that are not otherwise georegistered.

Limitations

Use only for a single hemisphere. Defined only for a sphere, specifically a sphere that utilizes the same major axis as the WGS84 datum, 6378137. Note that although WGS84 appears as a datum for Orthographic projection, the flattening of the WGS84 ellipsoid is ignored and only the major axis is used to define the sphere. Note that this is different than the explicitly enumerated Sphere datum, which utilizes a major axis of 6370997. Use the Stereographic projection instead of Orthographic if non-spherical datums are to be utilized.

Origin

Apparently developed by Egyptians and Greeks by the 2nd Century BC
Options

Specify the center of the projection by setting **latitude origin** and **longitude origin**. Specifying a non-Equatorial or non-polar origin causes an **oblique** projection. The **Clip coordinates** check box clips invisible parts of objects, such as countries located on the other side of the Earth from the point of view of the projection. Note that **Clip coordinates** is a destructive change: parts of objects extending beyond the projection horizon will be permanently trimmed.

The Southern Hemisphere view above is created using a latitude origin of -90 and a longitude origin of 0.

The Eastern Hemisphere view above is created using a latitude origin of 0 and a longitude origin of 90.

The Western Hemisphere view above is created using a latitude origin of 0 and a longitude origin of -90.
If more than one hemisphere is displayed, countries will be "wrapped" from the invisible side of the world and displayed anyway in mirror image.

Above is an Orthographic projection centered on latitude 68 North longitude -70. The original map included areas and a graticule for just the Northern Hemisphere. If zoomed far into the latitude and longitude origin we would see essentially zero distortion.

**Using Clip Coordinates**

The *Clip coordinates* checkbox in the *Edit - Change Projection* dialog tells Manifold to cut objects so that they do not "wrap" around the Orthographic coordinate system.

If we import the *World_eg.mfd* sample drawing and use *Edit - Change Projection* to re-project it into Orthographic centered on the default 0, 0 origin we will see that some areas, such as Australia and New Zealand are "wrapped" around the edge of the Orthographic system. This effect arises because the Orthographic projection is not intended to deal with more than one hemisphere's worth of data at a time.

To avoid this effect we have two choices:

- Edit the drawing in advance so that only areas in the hemisphere of interest exist. This is the method used to create the screenshots in the previous section of this topic.
- Check the *Clip coordinates* box and let Manifold "trim" objects to only those parts that are visible in the centered hemisphere. This works well in many situations but can be very slow to compute with large drawings since it is an extremely
computationally expensive process (as will be seen from the operations reported in the progress dialogs it shows).

The illustration above shows the World_eg sample drawing after projection to Orthographic using Clip Coordinates. Note there is no overlap.

The Clip coordinates box is a convenience, not an exact cartographic instrument. It works by clipping objects using a clipping rectangle. If after using Clip coordinates in an Orthographic projection we re-project the World_eg drawing back into Latitude / Longitude we will see the areas have been clipped to fit inside a bounding box.

Using straight lines to clip objects at the Orthographic horizon is an imperfect approximation (it leads to a "lumpy" horizon sometimes at the edge of the Earth), but it is reasonably fast to compute.

**Technical Note: Why is Clip Coordinates so Slow?**

Users will soon learn that checking the Clip coordinates box changes the time required for a re-projection from nearly instantaneous to usually taking minutes or even hours although sometimes even with the Clip coordinates box checked the re-projection is still fast. Why is that?

Before Manifold System release 7.00 the Clip coordinates algorithms were relatively imprecise, trading accuracy away in order to gain speed. A side effect of that reduced accuracy was that in certain cases of very large data the error conditions accumulating from reduced accuracy would cause data to grow without end and result in a "no memory" error and a failed re-projection.

From release 7.00 the new Clip coordinates algorithms are much more accurate, using precision over 100 times greater than previously. In addition, the algorithms have been adjusted so that no matter how large the data set involved will Manifold run out of memory. The price of these changes for greatly improved accuracy and ability to handle very large data sets is that performance in all cases is really miserable. It is expected that future releases will introduce algorithmic improvements that will deliver performance gains.
In the meantime, users have two strategies to increase the performance when using the **Clip coordinates** box:

- Plan your work to schedule any re-projections requiring **Clip coordinates** for the end of your work day, so that the re-projection can be set cooking while you are away from the project and won't notice how long it takes. Plan big re-projections requiring **Clip coordinates** for the end of the day Friday when Manifold will have the entire weekend to crank away.
- Do re-projections only where the target center latitude is **zero**. A side effect of the algorithms used is that when the target center latitude is zero, the clipping areas used internally within the algorithms become much simpler and easier to compute and so the process goes much faster. As a result, if re-projecting to Orthographic where the target center latitude is zero, even with **Clip coordinates** checked the re-projection will still go reasonably fast.

**Notes on Default Use of Orthographic Projection**

Manifold uses Orthographic projection as a default projection when nothing is known about the geographic context of a component.

Geographic components imported into Manifold from geographically aware formats will automatically use whatever geographic context or projection is defined in the source file(s). Components (such as images and CAD drawings) imported from non-geographic formats will be imported as if they were in a meter-based Orthographic projection. Such components may acquire a geographic context at some point by georegistration but initially they are usually created in meter-based or pixel-based coordinate systems.

It makes sense to consider such components as being in Orthographic projection. Considering the small size of CAD drawings or images relative to the size of an entire Earth hemisphere, there is an essentially perfect correlation between the flat, Euclidean coordinates of the drawing or image space and the effectively flat, Euclidean coordinates of the very central portion of an Orthographic projection.

This convention of considering all abstract coordinate CAD drawings and pixel coordinate images to be emplaced within an Orthographic projection provides three main benefits:

- First, it allows standard dialogs for both geographic and non-geographic components because all components within Manifold are treated as geographic components.
- Second, it provides a simple way of dealing with geographic components imported from formats that do not store projection information: one imports the projection in a default way and then changes the component's projection properties to the required values.
- Third, many images used in GIS work are overhead images that may be assumed to be in Orthographic projection as a practical approximation for most purposes. This makes it relatively easy to georegister such images in a simple way.

See the Manually Georegister an Image topic for an example.
Often incorrectly spelled as the "Pierce" projection, this projection is a conformal projection also known as a quincuncial projection. It is a transverse case of the Guyou projection.

**Caution:** This is a "one-way" projection in terms of accuracy in that once data is projected into the Peirce coordinate system it cannot be re-projected to other systems without some loss of precision. The definition of the projection in common use does not include formulae for the inverse transformation, so projecting from Peirce to latitude/longitude uses iterative approximations and thus can lose precision.

**Scale**

Not true anywhere. Scale is especially false in the corners of the projection, where scale is elongated, and at the poles, where scale is compressed.

**Distortion**

The projection is conformal except at the four "corners" of the Equator. Conformality (and therefore local angle preservation) fails at the corners.

**Usage**

Useful for showing polar regions. In its complete form (the entire Earth), may be tiled infinitely to create a display that allows any point on Earth to be viewed in a direct line from any other point.

**Limiting Forms**

The Guyou and Peirce projections are transverse cases of each other. The Guyou is the equatorial aspect (hence the classification as a psuedocylindrical projection within Manifold) and the Peirce is the polar aspect (hence the classification as an azimuthal projection within Manifold).
The term "quinuncial" refers to a presentation using a whole-Earth form of this projection into a square consisting of a central diamond square and four corner one-fourth squares, thus having five regions (Latin for five is quinque).

Options

Specify the center of the projection by setting latitude origin and longitude origin.

Origin

Invented by Charles Sanders Peirce in 1879 while he was at the U.S. Coast and Geodetic Survey.

Charles Sanders Peirce (1839-1914)

A classic example of a very bright individual who dabbled in many areas but left virtually no enduring mark in history. Peirce was a troublesome employee at the U.S. Coast and Geodetic Survey until eventually resigning in 1891. He invented a philosophical approach called Pragmatism he hoped would provide a counterpoint to Kant, invented a method of obtaining acetylene, set forth a means for defining the meter by a wavelength of light, was fond of presenting logic using "semiotics" (a theory of signs), observed occultations, obtained a degree in Chemistry at Harvard in 1863 and died mired in poverty and illness in 1914 after being unable to find steady employment after leaving the Survey.

Peirce continues to have his fans, who create websites reprinting his philosophical gems such as: "Thought is what it is only by virtue of its addressing a future thought which is in its value as thought identical with it, though more developed. In this way, the existence of thought now depends on what is to be hereafter; so that it has only a potential existence, dependent on the future thought of the community." ...Thus speaks a pragmatist!

The Peirce quincuncial projection seems typically Peirce in that its use of elliptical integrals for computation achieves a result through fearsomely complex means when simpler methods would seem to serve as well.

When contemplating Peirce's life one wonders how it is that accidents of history have elevated some would-be philosophers to superstardom while others have been consigned to the dustbin of history. For example, but for an accident of utopian popularity, Marx, too, could have ended up as yet another unknown kook beavering away at writings that made sense only to him.
Stereographic

An azimuthal, conformal, polyconic (general) perspective projection. Used most conveniently with a single hemisphere. Illustrated centered on -90 degrees longitude and 0 degrees latitude.

The Polar Stereographic form of this projection (polar aspect) is provided as a separate projection within the azimuthal projections. It is illustrated above.

Scale

True only where the central latitude crosses the central meridian or, alternatively, along a circle concentric about the projection center (or a parallel on the polar aspect). Scale is constant along any circle having its center at the projection center, but scale increases moderately with distance from the center within a hemisphere.

Distortion

Only the center or the circle of true scale (if not the center) is free from all distortion. Areas grow greater the farther from the center, albeit in a conformal manner.

Usage
Commonly used in the polar aspect for topographic maps of polar regions. The Equatorial aspect was used regularly for maps of the Eastern and Western hemispheres in the 17th and 18th centuries. Oblique aspects are used to show paths of solar eclipses.

Recommended for conformal mapping of regions approximately circular in extent.

**Limitations**

The Stereographic projection must not be used to map the entire world's surface at once: at least the point directly opposite to the projection origin must be excluded. This limitation arises because the Stereographic projection maps the point opposite the projection origin to infinity, causing numeric overflows. For example, if the North Pole is used as the projection origin, the South Pole and region immediately about the South Pole should not be included in the map.

**Origin**

Apparently developed in polar aspect by Egyptians and Greeks by the 2nd Century BC

**Options**

Specify the latitude origin and longitude origin to center the map projection to the area to be mapped. Specifying a non-Equatorial or non-polar origin causes an oblique projection.

**Tech Tip**

The top illustration, showing a partially clipped Africa and Europe, was created using a trick to clip Europe and Africa. A graticule from 0 longitude to 90 longitude and from -80 latitude to 80 latitude was created as lines. Areas were then created within the graticule and unioned together to form one large area. This was used with the Clip with (Subtract) transform to clip those portions of Europe and Africa within the graticule area. Other areas in Europe, Africa and Asia were simply selected and deleted free hand. The remaining, unclipped portions of Europe and Africa fit neatly within the 0 to -90 longitude graticule seen in the illustration.
Tilted Perspective

A true "view from space" projection. Whenever the Earth is photographed from space, the camera records the view as a perspective projection. If the camera precisely faces the center of the Earth the projection is Vertical Perspective. If the camera does not precisely face the center of the Earth the projection is a Tilted Perspective.

Perspective projections are neither conformal nor equal area. They were known by Greeks and Egyptians in ancient times. Vertical Perspective projections are azimuthal; Tilted Perspective projections are not.

Scale

Scale is accurate only at the center for Vertical Perspective. Directions from the center are true for the Vertical Perspective for the sphere and for the polar ellipsoidal form.

Distortion

No distortion at the center for Vertical Perspective. Considerable distortion near the edges of the projection and throughout Tilted Perspective projections.

Usage

Used for pictorial views of the Earth as seen from space. Vertical Perspective is used for weather maps issued by the U.S. National Weather service as seen from geosynchronous satellites near the Equatorial plane. Tilted perspective in the ellipsoidal form is used for Space Shuttle Large Format Camera images and other photographs.

Limitations

Use only for a single hemisphere.

Origin

Known by Greeks and Egyptians in ancient times.

Limiting Forms
Orthographic, Stereographic and Gnomonic projections are special forms of the Vertical Perspective.
Vertical Perspective

A true "view from space" projection. Whenever the Earth is photographed from space, the camera records the view as a perspective projection. If the camera precisely faces the center of the Earth the projection is Vertical Perspective. If the camera does not precisely face the center of the Earth the projection is a Tilted Perspective.

Perspective projections are neither conformal nor equal area. They were known by Greeks and Egyptians in ancient times. Vertical Perspective projections are azimuthal; Tilted Perspective projections are not.

Scale

Scale is accurate only at the center for Vertical Perspective. Directions from the center are true for the Vertical Perspective for the sphere and for the polar ellipsoidal form.

Distortion

No distortion at the center for Vertical Perspective. Considerable distortion near the edges of the projection and throughout Tilted Perspective projections.

Usage

Used for pictorial views of the Earth as seen from space. Vertical Perspective is used for weather maps issued by the U.S. National Weather service as seen from geosynchronous satellites near the Equatorial! plane. Tilted perspective in the ellipsoidal form is used for Space Shuttle Large Format Camera images and other photographs.

Limitations

Use only for a single hemisphere.

Origin

Known by Greeks and Egyptians in ancient times.

Limiting Forms
Orthographic, Stereographic and Gnomonic projections are special forms of the Vertical Perspective.

Conic

Albers Conical Equal Area

A conic, equal area projection.

Scale

True along the one or two chosen standard parallels, which are usually but not necessarily specified on the same side of the Equator. As a rule of thumb, these parallels can be placed at one-sixth and five-sixths of the range of latitudes, but there are more refined means of selection.

Scale is constant along any given parallel. The scale factor at any given point along the meridian is the reciprocal of that along the parallel, to preserve area.

Distortion

Free of angular and scale distortion only along the one or two standard parallels. Distortion is constant along any given parallel.

Usage

Frequently used in the ellipsoidal form for maps of the United States in the National Atlas of the United States, for thematic maps, and for world atlases. Also used and recommended for equal-area maps of regions that are predominantly east-west in extent.

Limitations

Normally used only for a single hemisphere.

Origin

Presented by Heinrich Christain Albers (1773-1833) of Germany in 1805.

Limiting Forms
Polar Lambert Azimuthal Equal-Area projection: if a pole is made the single standard parallel. The cone of projection thereby becomes a plane.

Lambert Equal-Area Conic projection: if the pole and another parallel are made the two standard parallels.

Lambert Cylindrical Equal-Area projection: if the Equator is the single standard parallel. The cone of projection thereby becomes a cylinder.

Behrmann or other cylindrical equal-area projections: if the two standard parallels are symmetrically placed north and south of the Equator.

**Options**

Specify the **first standard parallel** and **second standard parallel** to tailor the projection to the area to be mapped.

Specify the **latitude origin** and **longitude origin** to center the map projection to the area to be mapped. Specifying a non-Equatorial origin causes an **oblique** projection.
Bipolar Oblique Conformal Conic

A conformal projection that consists of two oblique conic projections, side-by-side, but with poles 104 degrees apart.

**Scale**

Scale is true along two standard transformed parallels on each conic projection. Neither of these lines follows any geographical meridian or parallel.

**Distortion**

Very small deviation from conformality, where the two conic projections join. However, potentially very large distortion outside the intended region. When creating graticules for use with this distortion the graticule must be trimmed by selecting portions of the graticule and deleting those portions that otherwise are projected in unpleasant ways. Note how the graticule shown in the illustration above has been trimmed.

**Usage**

Used only in spherical form for maps of the Americas. Used by the AGS for maps of North and South America, by USGS for the North American portion of the Geologic Map of 1965, the Basement Map of 1967 and the USGS Geothermal Map and Metallogenic Map.

**Limitations**

Use only for maps of the Americas.

**Origin**

Developed by O.M. Miller and William A. Briesemeister and presented in 1941 and designed specifically for a map of North and South American constructed in several sheets by the American Geographical Society (AGS).
Bonne

A psuedoconical, equal-area projection. Central meridian is a straight line. All other meridians are complex curves.

Scale

Scale is true along the central meridian and along all parallels.

Distortion

No distortion along the central meridian and along the standard parallel.

Usage

Used for atlas maps of continents and for topographic mapping of some countries.

Limitations

Use only for a single hemisphere.

Origin

Used considerably by Rigobert Bonne (1727-1795) in the mid-18th century, but developed by others during the early 16th century.

Limiting Forms
