Welcome to Manifold® System. Manifold System has exploded onto the GIS scene with unprecedented quality, performance, and value. Release 8 is a major upgrade to the previous release. It introduces many new capabilities while retaining key methods that will be immediately familiar to users of previous versions of Manifold System.

If you are new to Manifold System please do not be misled by the low price. Manifold System is by far the largest and most sophisticated GIS program ever created. Manifold includes many advanced capabilities beyond those found in ordinary GIS or mapping systems. It includes features similar to those in professional graphics editors such as Adobe Photoshop, CAD systems like AutoCAD, database systems like Access or SQL Server, a full forms-based scripting environment, statistics and mathematics, data mining and charting, a sophisticated Internet Map Server, an optional US street address geocoder and one of the richest mapping packages around. There is so much functionality in Manifold that you should plan on spending a day or two reading the documentation and trying out examples to become aware of the full range of the product.

Read at least the topics in the Introduction chapter and the topics in the Examples chapter and you'll see that everything falls into place pretty quickly. Reading the topics in the suggested order will reward you with rapid expertise. Conversely, failing to read the documentation as suggested will cause unnecessary frustration, as Manifold cannot be learned by trying out menus or by quick skimming of Help topics.

More users new to GIS have learned to do GIS with Manifold than with any other system, so no matter what your level of expertise if you can patiently read through the documentation you too will learn Manifold rapidly and effectively.

Please begin by reviewing the Read Me First topic. This is a very important topic that should be read by all users.

Users of previous Manifold editions should read the What's New topic.

Technical Support

Manifold System licenses do not include free technical support. If you have acquired any technical support incidents, either a free incident as part of a marketing promotion or by purchasing one or more incidents, please take care not to waste those incidents. Free incidents are always for tech support by email using the procedures published on the manifold.net web site.

Should you ever need technical support, please read the Technical Support topic before contacting manifold.net. This will help you make best use of any free support incidents you may have available without wasting incidents. Note that all emails of a technical support nature that are sent to any manifold.net email address will be forwarded to tech support and will use up a support incident.

See the Products page on the manifold.net website for current pricing and availability of technical support products.

Documentation for All Versions

By default, Manifold System uses the web-based version of Help. Your computer must have Internet connection to read Help. This documentation is available in a local version that may be downloaded and installed for use when there is no Internet connection available. Please see the How to Install this Documentation topic for details. That topic also describes how you can modify Help or create your own version of Help.

This documentation is written for all versions of Manifold System and options such as Business Tools, Geocoding Tools and Surface Tools. All editions and options share the same source code and user interface features so that any advance in quality, performance or ease-of-use advances will help users of any Manifold edition. All Manifold System editions are installed using the same installation file, either delivered by download or on a single disc. The serial number you provide when first launching Manifold determines which edition will be configured on startup and which options will be enabled.

Some features described in this Help file will apply only to a specific edition, such as Enterprise Edition. For a handy road-map of features in different Manifold editions, see the About manifold.net topic. If you are not familiar with the features packaged with different Manifold editions, take a moment to review that topic now.

Enterprise users should familiarize themselves with the basic operation of Manifold by reading the topics in the Introduction and Examples sections and then read all of the topics in the Enterprise Edition section.
Options

This documentation includes topics that discuss features installed by optional Manifold products. The Surface Tools and Business Tools optional extensions provide additional commands and capabilities. The Geocoding Tools extension turns on street address geocoding capability within Manifold System and also enables rapid and easy creation of county maps in the US.

From time to time, manifold.net may make available free downloads of add-ins or other extensions to Manifold System. At the present writing the Traditional Topology Tools add-in package and the Manifold Spatial Extender for SQL Server may be downloaded from the manifold.net web site.

If you have not purchased these options or downloaded and installed the Traditional Topology Tools add-in or the Manifold Spatial Extender, you will not be able to use the capabilities described. All topics that depend upon an option will make it clear the option is required.

Users are also strongly advised to take advantage of free downloadable Image Server and (for users who have licensed the Geocoding Tools extension) Geocoding Server modules from the product downloads page. In particular, the use of Image Server modules is a revolution in ease of use and convenience when creating background images or background maps.

Important Configuration Notices

**Very Important:** Before starting Manifold, go to the Windows Control Panel Display dialog Effects tab and make sure that the Show window contents while dragging check box is not checked.

- In Windows XP this option is found in the Control Panel's Appearances and Themes - Display choice under the Appearance tab by pressing the Effects button.
- In Windows XP or Windows 2003, from the Start button open the Control panel and then open the Display dialog. Click on the Appearance tab and then press the Effects button. Uncheck the Show window contents while dragging check box.
- In Windows 2000, Windows ME and Windows 98 open the Control panel and then open the Display dialog. Click on the Effects tab, and uncheck the Show window contents while dragging check box.
- In Windows Vista, open the Control Panel and click Appearance and Personalization. Click Customize colors, then click Open classic appearance properties for more color options and click the Effects button. Uncheck the Show window contents while dragging check box.

Checking this box will greatly slow down the system when displaying complex maps and images because it forces a refresh of the window contents with each minor change in mouse position while dragging the window. Make sure the box is unchecked.

**Very Important:** When working with large projects make sure to set your Windows use of virtual memory appropriately. Some editions of Windows, such as Windows XP x64, will set a maximum pagefile size that is too small by default. Drill down through the Control Panel - System applet's Advanced settings to change the maximum pagefile size to four or five times the largest project you will need to use. For example, if you will be working with 10 GB projects set the pagefile size to 50 GB. See the discussion in the Memory Requirements topic.

More from manifold.net

Manifold® System is another fine product from your friends at manifold.net. See the About manifold.net topic for information on other Manifold family products.

We appreciate your business and your vote of confidence in our products. If you have suggestions for improvement write us at sales@manifold.net. Each new release benefits from thousands of user suggestions to make a better Manifold for you.

If you like Manifold and the value that it provides please tell your friends about Manifold and post your views online. Because manifold.net invests into software development instead of into advertising the company depends upon the satisfaction of the Manifold user community for continued success. Enjoy!
How to Install this Documentation

This Help documentation is available in two forms: a web-based version and a Microsoft compiled help (.chm) version. Other forms may also become available over time as users and others keep growing this documentation.

By default, Manifold System uses the web-based version and has no local documentation built installed. When we click the Help menu the web version will be launched. This helps keep product installation packages smaller for faster downloads, it allows more frequent updating of documentation on the web without having to re-issue new product builds and it allows users, resellers, VARs, software developers and others to create their own versions of documentation, including translations into other languages.

To display the web-based version your computer must be connected to Internet. The web-based version is hosted at a variety of sites worldwide, by default in the georeference.org user community at http://www.georeference.org/doc/manifold.htm.

If we would like a local version of the documentation we can download the manifold.chm file from documentation repositories such as the georeference.org user community, and install the manifold.chm file using these instructions. If a manifold.chm file has been installed, when we click the Help menu the .chm version will be launched instead of the web version.

If you want to create your own version of the documentation, for example, a simplified overview or a translation into a language other than English, you can create your documentation, compile it into a Microsoft compiled help file using any one of the help compilation tools that are widely available, name it manifold.chm and install it using the instructions in this topic. In that case your documentation will be launched by Manifold via the Help menu commands. Your computer does not need to be connected to Internet to read Help if the manifold.chm file has been installed.

Downloading and Installing Manifold.chm

By default, Manifold System installation packages do not contain the manifold.chm compiled help package. This file must be downloaded and installed on your system.

Download the manifold.chm file from the georeference.org user community or other web site and place it into your Manifold installation folder, typically C:\Program Files\Manifold System. In some Windows systems, after downloading the manifold.chm file you may have to allow navigation to the internal web pages to see topics: in Windows Explorer right click on manifold.chm, choose Properties and then click the Unblock button.

If you have installed a 64-bit Manifold version and you would like to have Help available when launching Manifold in 32-bit form, you can also place a copy of the manifold.chm in the 32-bit Program Files installation folder, typically C:\Program Files (x86)\Manifold System. That completes the installation.

If you have installed the manifold.chm file, in addition to launching Help from within Manifold via the Help menu, you can also launch Help directly from Windows by double-clicking on the manifold.chm file. Create a shortcut to that file if you use it frequently. You can then drag and drop the shortcut onto your desktop or drag and drop it into the Windows taskbar Start button to pin it to the Start menu for easy access.

Using Help to Create your Own Help

Many users worldwide have contributed to the creation of Help. Help is unbundled from the Manifold System product so it can be an open, user-generated document with few license restrictions. Help is not part of the licensed Manifold System product but is an independent document that users are encouraged to utilize to create their own versions if they want.

You may make as many copies as you like of Help and give it to as many people as you like. Manifold Help documentation may be freely copied and exchanged, adapted, edited, translated, enhanced, slimmed down otherwise altered and used at no charge consistent with the grant of license for use of Help given on the original websites (such as the repository at georeference.org) that either serve the web-based version or provide downloads of the manifold.chm file. For example, college instructors may want to make workbooks using Help or a manager in charge of an application based on Manifold may want to create a simplified overview for new employees who only need to perform a specific task. Translations into other languages are also popular.
There are a few restrictions on the free use of what is intended to be as open usage as possible: Content from Help may not be used for the documentation of or promotion of products other than Manifold products. If you use content from Help you agree to indemnify prior authors and organizations involved in creating or in providing you the content against any claim or costs that may arise from your use of the content, and you must require anyone to whom you provide any derivative work to also agree to that indemnity. See the grant of license for details.
Read Me First

Follow these three steps to master Manifold:

**Step 1: Finish the Installation**

Make sure you have all files and recommended downloads for using Manifold:

- Manifold is downloaded from the manifold.net website's Product Downloads page. That page always has the most recent version available for download. If you have obtained your Manifold installation files from some other source, please follow the instructions below to make sure you have the latest version.
- Download the help examples files from the Product Downloads page. You’ll need these to learn Manifold.
- Download the image servers and geocoding servers from the Product Downloads page and install them. Most Manifold users make heavy use of image servers.
- If you have licensed the Geocoding Tools extension and you will be working in the United States, download the free geocoding database from the Product Downloads page and install it. This is a very large download but well worth it.

**About Updates:** Service packs and updates for Manifold System fix bugs and provide upgrades until the next major release. If you installed Manifold from some other source other than a fresh download from the Product Downloads page, your installation may not be up to date. Your Manifold System installation is not complete if the latest Service pack or update has not been installed.

If your computer is connected to Internet, Manifold will automatically inform you upon startup if a new update has been issued. Please note that this automatic update checking service cannot work if your network installation prevents Manifold from connecting to the update servers. See the discussion in the Tools - Options topic.

To manually determine if a new update has been issued, use the Help - Check for Updates command. It is not a good idea to turn off automatic update checking.

If Manifold informs you that an update is available, download and install it. Updates play an important role in fixing bugs, improving performance and adding new features.

**Very important:** Before starting Manifold, make sure that your Windows **Show window contents while dragging** check box is not checked. This option is located in the Windows Control Panel Display dialog as follows:

- In Windows XP or Windows 2003, from the Start button open the Control panel and then open the Display dialog. Click on the Appearance tab and then press the Effects button. Uncheck the Show window contents while dragging check box.
- In Windows 2000, Windows ME and Windows 98 open the Control panel and then open the Display dialog. Click on the Effects tab, and uncheck the Show window contents while dragging check box.
- In Windows Vista, open the Control Panel and click Appearance and Personalization. Click Customize colors, then click Open classic appearance properties for more color options and click the Effects button. Uncheck the Show window contents while dragging check box.

Checking this option box will unnecessarily slow down the system when displaying complex maps and images, so make sure this option box is unchecked.

**Very Important:** When working with large projects make sure to set your Windows use of virtual memory appropriately. Some editions of Windows, such as Windows XP x64, will set a maximum pagefile size that is too small by default. Drill down through the Control Panel - System applet's Advanced settings to change the maximum pagefile size to four or five times the largest project you will need to use. For example, if you will be working with 10 GB projects set the pagefile size to 50 GB. See the discussion in the Memory Requirements topic.
Very important: When linking images into a project from certain image servers (such as OGC WMS image servers or from Microsoft TerraServer) Manifold will automatically cache files using the settings in the Tools - Options - File Locations dialog. Read the Managing Cache Files topic and make sure you have chosen your cache file locations and have taken measures to assure you won't run out of disk space by allowing your cached files to grow unreasonably large.

Important: If you are upgrading from an earlier Manifold release, read the What's New topic. Take special note of changes made and transition issues.

Step 2: Invest a Few Days to Assure Success

Manifold is a sophisticated system that rewards users with great power once they master a handful of key techniques. It takes a day or two of reading Help topics and experimenting with Examples to understand enough about Manifold to work at an elementary level.

No matter how smart or experienced you are, the minimum amount of reading required to operate Manifold is to read all the topics in the Introduction chapter followed by reading all of the topics in the Examples chapter.

Even if you have a very simple job to do there is no way to shorten this time or to skip necessary topics. It's like learning to drive a car: you must learn to operate the steering wheel, the brake, the gas pedal and the transmission or you don't go anywhere. Just because you want to drive a short distance or because you are under time pressure doesn't mean you can skip learning about the steering wheel or the brakes.

If you have never used a GIS product before, we suggest not skipping over the Key Ideas in GIS and the Key Ideas topics in the beginning of the Introduction chapter. If you are a GIS expert, Manifold is very different from anything you have used before. Experts can avoid wasting time by also reading the topics suggested below. Programmers should not begin design or coding until they learn Manifold as an interactive package - that will provide the conceptual and practical foundation to use the API effectively.

All readers should read the Introduction and then dive right into Windows and the other topics in the Introduction chapter. All users should also read the topics in the Drawings, Images, Maps, Labels, Tables, Surfaces and Queries chapters. Take a break from straight reading from time to time to work through various Examples topics. Don't skip over Examples topics, since later examples assume you have read previous topics. If you are unsure how to use a particular menu item, topics for all menus and dialogs are organized by menu in the Menus, Dialogs and Controls Reference. Enterprise Edition users should also read the topics in the Enterprise Edition chapter.

Advice from Technical Support: Some topics are so detailed you will be tempted to jump directly into them if they look like what you need to do today under deadline pressure. Resist the temptation. All topics assume you've read and understood the foundation material presented in the Introduction and Examples chapters, so other topics do not repeat necessary, but elementary, steps. Jumping into a topic without reading the introductory material in the Introduction and Examples chapters will most likely waste time and cause needless frustration.

Step 3: Follow Through with Continuing Education

Expand your mastery of Manifold with advanced reading in this Help file. Some very serious users will read the entire documentation. Reading the entire Help file will encounter some repetition. Essential information is often repeated in several topics so that it is available when one parachutes into a topic via a hyperlink. That's OK; the repeated information is so essential it will help to read it more than once.

The fastest, lowest cost way to eliminate difficulties is to use the resources that are immediately available to you. See the Troubleshooting topic for tips for fast resolution of problems.

Other questions? Check the Support page for Manifold System at the main www.manifold.net web site. Resources such as Frequently Asked Questions, Updates, guides to specific procedures, supplemental data or software and more are available online. If you have Manifold running, in the main menu clicking on Help - Manifold on the Web will call up a menu of useful web pages.

If you would like to contact manifold.net with questions of a technical nature regarding Manifold System, please read the Technical Support topic first to avoid wasting any free support incidents you may have available. Please note that any questions of a technical support nature, even what may appear to be simple questions, which are sent to any manifold.net email address are processed in accordance with
the procedures set forth in the Technical Support topic. Don't waste your incidents by sending simple tech support questions to sales. Take a moment to search Help or the free resources and save your incidents for really difficult questions the answers to which cannot be found otherwise.

Manifold users meet online in forums such as the forum which may be accessed via the Community page on the manifold.net home page. Postings in the forum are a good way of meeting other Manifold users online. Please keep in mind that the forum is a user community and is not a communications channel to manifold.net; however, news of a technical nature (such as a new update) will be posted to the forum.

See the Help - Manifold on the Web topic for fast access to the Manifold online community in the forum as well as other resources.

There are several online forums operated by Manifold System user groups in different parts of the world in languages other than English. Reading the discussion in online forums and searching their archives is a great way to get more out of Manifold and to avoid expending technical support incidents on matters that are easily answered by colleagues or have already been discussed in a forum.

Third parties provide training for Manifold System. Many users report that self-paced training products are an easier path to learning than relying exclusively upon reading documentation. See the manifold.net web site for links to third parties offering training, or consult the forum for postings about educational opportunities such as classes offered by private companies or by universities.

A Note for Experienced GIS Users

Manifold is a completely new package that introduces many new methods, user interfaces, terms and concepts not available in traditional GIS software. No matter how much you know about GIS and mapping in general it is critically important to read this documentation in the recommended order to avoid wasted effort.

GIS experts can leverage their expertise by beginning with the For Experienced GIS Users topic and then also reading the topics suggested for GIS newbies, beginning with the Introduction. Please do not skip the introductory topics. Although some material will cover ground already known to experts, the introductory topics will also introduce many important details that are essential to successful Manifold operations. Experts may also enjoy reading User Interface Design and other essays in the Appendix.

GIS experts have often honed their expertise in non-Windows operating systems. Because Manifold heavily utilizes numerous Windows ideas, methods and shortcuts it is essential that you become a fluent Windows power user to be successful with Manifold. The Windows topic will teach you what you need to know.

Users of previous Manifold Releases should check out the What's New topic and then jump back into the flow of introductory topics, beginning with the Introduction.

A Note for Users New to GIS

If you are familiar with Microsoft Windows applications and you have the ability to read documentation carefully in the recommended order you'll do just fine with Manifold.

During the first day or so of learning you'll probably think the learning curve is nearly vertical. It is, initially, but then you'll find that things drop into place very rapidly.

Stick with it. Read the documentation carefully without just skimming it and you will be rewarded with the ability to use an entirely new type of software tool that will let you do amazing things.

Serial Numbers and Activation Keys

Manifold System requires a serial number and an Activation key for permanent installation. This copy protection mechanism allows a much lower cost for Manifold System. To get the most out of your license and to not waste activations it is important that you read the Activation Keys and Serial Numbers topic.
Very Important: Manifold is not licensed for endless usage no matter how many times you need to re-install it. Each serial number can be used for only a limited number of activations. Through sensible use and by taking advantage of low-cost upgrades that may be offered from time to time it is fairly easy for virtually all users to continue using Manifold without running out of activations at a very low cost per year even if they encounter computer failures or upgrade computer hardware. See the Activation Keys and Serial Numbers topic for details.

32-bit and 64-bit Editions

Manifold System is published in 32-bit editions and 64-bit editions. Please read the 32-bit and 64-bit Manifold Editions topic when installing, activating or working with 64-bit editions.

Legal Notes

Throughout this documentation the word "Manifold" by itself is an abbreviation for "Manifold® System" which is the full name of the product and includes a ® registered trademark symbol. Because this documentation is licensed material provided to you under the terms and conditions of the End User License Agreement (EULA), you have already agreed as part of your acceptance of the EULA that "Manifold" is a registered trademark. We use the abbreviation to avoid disrupting the easy reading of the text.

Likewise, the terms "buying" or "purchase" may be used in this documentation as casual language referring to the acquisition of Manifold brand products when in fact any such acquisition is a matter of licensing the products. As set forth in the EULA Manifold brand products are always licensed, and never sold. To provide easy reading for average GIS users more relaxed words such as "purchase" are often used in this documentation instead of more technical terms such as license which, as understandable as they are, may disrupt the easy flow of text for people who are not lawyers. Readers should understand that any relaxed language, slang or colloquialisms used in this documentation do not in any way modify the nature of the EULA nor do they convert the licensing of Manifold into a "purchase."

Let's Go!

… Enough preliminaries - it's time to check out the 32-bit and 64-bit Manifold Editions topic for 64-bit software users and then we can dive straight into the Introduction.
32-bit and 64-bit Manifold Editions

Manifold System products are available in native, 64-bit editions for use in x64 Windows operating systems. 64-bit editions of Manifold System can execute in x64 Windows systems running as 100% 64-bit code, making it possible for Manifold installations to take full advantage of modern 64-bit processors and 64-bit Windows systems.

All Manifold 64-bit capabilities are limited to x64 processor architecture as implemented in AMD and Intel x64 processors, including single core and multi core x64 processors. There is no support for Intel Itanium. All topics in this Help file use terms "64-bit" and "x64" interchangeably.

Many Manifold users have adopted 64-bit hardware and 64-bit Windows while other Manifold users have continued to run 32-bit processors and 32-bit Windows. To support both types of users Manifold System is available both in 32-bit products and 64-bit products. 64-bit versions of Manifold have "x64" in their product name. For example, Enterprise Edition may be licensed as either Manifold Enterprise or, for a slightly higher fee, Manifold Enterprise x64.

- A 32-bit Manifold download can be installed into either a 32-bit or a 64-bit Windows system but it can run only in 32-bit mode in either case. A 32-bit Manifold product can run in 32-bit Windows systems in 32-bit mode, or it can run in 64-bit Windows systems in 32-bit mode using the ability of 64-bit Windows to execute legacy 32-bit products in 32-bit mode.

- A 64-bit Manifold download can be installed only into a 64-bit Windows system. When installed in 64-bit Windows systems it can run either in 32-bit mode or in 64-bit mode.

- Licensing a Manifold product provides a serial number that authorizes the associated product. Licensing a 64-bit product provides a 64-bit serial number. Licensing a 32-bit product provides a 32-bit serial number. A 64-bit serial number can authorize either a 64-bit download or a 32-bit download. A 32-bit serial number can authorize only a 32-bit download.

Although most Manifold System editions may be licensed either as 32-bit products or as 64-bit products, some products are provided only as 64-bit products. 64-bit products can be used in either 32-bit or 64-bit Windows.

- Personal, Professional, Enterprise, Universal, Database Administrator and Ultimate editions are published in both 32-bit and 64-bit x64 versions. The x64 versions require a slightly higher licensing fee.
- License Server edition is available only in an x64 version and supports use of both 32-bit and 64-bit Manifold versions as floating licenses. This allows the greatest possible flexibility for use of floating licenses, with usage enabled regardless of whether the target machines happen to be 32-bit or 64-bit Windows installations.

- Professional Runtime and Universal Runtime editions are published only as 64-bit editions at the same low price. 32-bit programs using the Manifold object model will use 32-bit Manifold modules and 64-bit programs will use 64-bit Manifold modules, automatically. Installing a Manifold runtime license on a 64-bit operating system will automatically allow the use of Manifold from both 32-bit and 64-bit programs or web sites, automatically. Of course, the x64 Manifold runtime editions may be installed and used on 32-bit Windows using the 32-bit Manifold installation.

- The Business Tools, Geocoding Tools and Surface Tools extensions (as well as the combined Option Pack bundle) are published only as 64-bit editions and will run either in 32-bit or in 64-bit mode depending on whether the host Manifold System license is running in 32-bit or 64-bit mode. For example, if Surface Tools has been installed on a 64-bit Windows system together with Manifold Enterprise x64 and Manifold is launched in 32-bit mode, then the Surface Tools functionality within that package will also run in 32-bit mode. If Manifold is launched in 64-bit mode, the Surface Tools functionality will also run in 64-bit mode. If a 32-bit version of Manifold has been installed then the extensions will always run in 32-bit mode with that system. If that 32-bit version of Manifold System is upgraded to a 64-bit version, there is no need to upgrade the extensions, as they will simply switch automatically to running in 64-bits when the new 64-bit Manifold package is installed.

In a nutshell, all non-interactive Manifold editions such as License Server or runtime editions and all Manifold extensions always support running in both 32-bit and 64-bit modes, while regular Manifold editions may or may not support running in 64-bit mode depending on the license that has been acquired. A 64-bit license must be acquired to enable operation of regular Manifold editions in 64-bit mode.

Checking Status of Serial Numbers

To check the status of any particular serial number, visit the Support page on the www.manifold.net web site to find a link to the Serial Number Status page. The status page may be used to find out if a particular serial number is a 32-bit or 64-bit serial number, whether it is still active or has been revoked (as might occur if it has
been traded in for an upgrade), what product it authorizes and how many Activation keys are available. This same page may also be used to check the status of a technical support token.

**A reminder:** Any use of a serial number, such as checking status via the Serial Number Status page, should be done using Copy and Paste from the original serial number email sent out by manifold.net. Do not use the "masked" version of the serial number that may be displayed in the Help - About dialog which ends in a series of X characters. The masked version displayed in Help - About has had the final characters altered with a series of X characters so that someone who has physical access to your computer cannot steal your Manifold serial number. The masked version displays enough of the serial number so you can determine for your internal record keeping which serial number you used on a particular machine, but not enough of the serial number for someone to be able to steal it and use it to obtain Activation keys or other wise use it.

**64-bit Requirements**

Only a 64-bit Manifold edition can run in 64-bit mode on 64-bit x64 processors running 64-bit Windows editions. Manifold x64 is not supported for Itanium or other non-x64 bit architectures. To run Manifold in 64-bit mode you must do the following:

- Use an x64 processor, such as AMD Athlon64x2 or Intel EM64T.
- Use an x64 edition of Windows, such as Windows XP x64 or Windows Server 2003 x64.
- Install the x64 edition of .NET Framework 2.0.
- Install an x64 edition of Manifold.
- Activate the x64 edition of Manifold using a 64-bit Manifold serial number.

Manifold download pages provide both 32-bit and 64-bit versions of the Manifold installation package. A Manifold System serial number issued for a 64-bit edition of Manifold can activate either a 32-bit installation or a 64-bit installation. A Manifold System serial number issued for a 32-bit edition of Manifold can activate only a 32-bit installation.

A 64-bit edition of Manifold can only be installed if you have x64 Windows running on an x64 processor. If you attempt to install a 64-bit edition of Manifold on a 32-bit Windows edition you will get an error message. That error message is a sure sign your computer system is not set up to run 64-bit software.

**Is My Computer a 64-bit Computer?**

Users sometimes are not sure if their computer system has a 64-bit processor or is running 64-bit Windows. This can be confusing because some manufacturers don't make it clear whether the processor in use is a 32-bit or a 64-bit processor. A further point of confusion is that some people have installed 32-bit Windows even though their processor is 64-bit. It doesn't matter if you have a 64-bit processor if you are running 32-bit Windows: when you do that, as far as Windows is concerned you are running a 32-bit processor and cannot run 64-bit applications.

If you are not sure whether your system meets the requirements for running 64-bit Manifold, the easiest way to find out is to check what version of Windows you are running. Because x64 versions of Windows will install and run only on x64 processors, if you are running x64 Windows you know you can run 64-bit Manifold x64 as well.

Note that because x64 processors can run 32-bit programs, it is possible to install 32-bit Windows on a 64-bit x64 processor. In that case, it doesn't matter that your processor is 64-bits, because Windows will insist on treating it as a 32-bit processor and you will be unable to install or run 64-bit software like Manifold x64.

To determine what version of Windows you have installed, launch the Windows Control Panel - System applet. The version of Windows in use will be cited in the General tab of that applet. The processor in use will also be cited. If an x64 version of Windows is installed that will be clearly marked with an "x64" designation. If the version of Windows is not clearly marked with an "x64" designation then it is 32-bit Windows.

If you have an x64 version of Windows running you can proceed with x64 Manifold installation. If you have 32-bit Windows running you cannot install or run 64-bit Manifold.

It is possible, although unlikely, that if you have 32-bit Windows it has been installed on a 64-bit processor. You can tell if this is the case by noting the processor reported by the System applet. This might not be so easy to determine, as some manufacturers do not use clear processor names.
AMD uses a refreshingly clear and straightforward naming scheme that usually includes "64" in the names of 64-bit AMD processors. Intel in contrast uses a bizarre naming scheme that features confusingly similar names for radically different processors. For example, as of this writing the Intel "Core Duo" processor is a 32-bit processor while the Intel "Core 2 Duo" processor is a 64-bit processor.

If you can't tell from the name of the processor reported by the System applet whether or not it is a 64-bit processor, contact your hardware vendor and ask them or use any good Internet search engine to research the matter on websites providing information on computer hardware and processors.

If you are running a 64-bit processor but someone nonetheless has installed 32-bit Windows you might be able to install 64-bit Windows on that computer to enable you to use your processor as a 64-bit processor. For information on such upgrades contact your system vendor and/or Microsoft.

Important: These instructions for using the Windows Control Panel - System applet are basic Windows instructions that apply to typical Windows installations. Your installation may be slightly different. If so, please review your Microsoft documentation to determine how to tell what version of Windows you are running.

Manifold.net is not a hardware manufacturer and cannot assist you in determining what hardware you have installed. Manifold.net cannot advise you on your hardware configuration or help you determine whether or not the computer hardware you have is running Windows x64 or be upgraded to Windows x64. Please contact your system vendor and/or Microsoft for such assistance.

32-bit and 64-bit Manifold Installation Packages

There are two separate installation packages for Manifold:

- **32-bit Manifold installation** - This installation package installs 32-bit Manifold. The 32-bit Manifold installation package may be installed on either 32-bit or 64-bit Windows systems. One program shortcut will be created named **Manifold System**. When installed on a 64-bit Windows system a 32-bit Manifold installation will run in 32-bit mode using the capability of 64-bit Windows editions to run legacy 32-bit programs.

- **64-bit Manifold installation** - This installation package installs a Manifold package that can run either in 32-bit mode or in 64-bit mode. The 64-bit Manifold installation package may be installed only on 64-bit Windows systems. Two program shortcuts will be created named **Manifold System (32-bit)** and **Manifold System (64-bit)**. Launching Manifold using the **Manifold System (32-bit)** shortcut will launch Manifold in 32-bit mode. Launching Manifold using the **Manifold System (64-bit)** shortcut will launch Manifold in 64-bit mode. Both the 32-bit and 64-bit shortcuts use the same registry entries so that options set by users will be the same when switching back and forth between launching Manifold in either 32-bit or 64-bit mode.

The 64-bit Manifold installation is a mixed package that installs both 32-bit and 64-bit Manifold modules. For the sake of brevity, it is referred to as "64-bit" Manifold. Installing a 64-bit version of Manifold will allow using Manifold in both 32-bit and 64-bit modes on the same system, simultaneously. When running in 64-bit mode Manifold is executing entirely as 64-bit code.

Activation

Manifold serial numbers can authorize either 32-bit or 64-bit licenses. For the sake of brevity, a serial number that authorizes a 32-bit Manifold license is called a **32-bit serial number**, while a serial number that authorizes a 64-bit Manifold license is called **64-bit serial number**.

A 32-bit serial number will only allow Manifold to function in 32-bit mode. A 64-bit serial number will allow Manifold to function in 32-bit as well as 64-bit mode. Any serial number can be used with any installation package on any operating system. It is perfectly OK to use a 64-bit serial number to activate Manifold on a 32-bit operating system.

A 32-bit serial number will only allow Manifold to function in 32-bit mode. A 64-bit serial number will allow Manifold to function in 32-bit as well as 64-bit mode. Any serial number can be used with any installation package on any operating system, but the results will be guided both by the capabilities of the operating system (it must be a 64-bit operating system to allow Manifold to function in 64-bit mode) and by the nature of the serial number used (a 64-bit serial number must be used to enable 64-bit Manifold operation). For example, it is perfectly OK to use a 64-bit serial number to activate Manifold on a 32-bit operating system, but in that case because the operating system is a 32-bit operating system Manifold will run in 32-bit mode even though the serial number used is a 64-bit serial number.
To consider another example, suppose we jumped the gun a bit on computer procurement and bought an Athlon 64 hardware system but we have been running it using 32-bit Windows. We expect to upgrade to 64-bit Windows but we would like to wait for an Intel Core 2 Duo system to become available before upgrading to 64-bit Windows. However, we would like to license 64-bit Manifold right now so that we have a 64-bit license when we are ready to install 64-bit Windows.

In that case we can immediately license 64-bit Manifold and we can install and activate a 32-bit Manifold installation on our 32-bit Windows systems. When we upgrade to our new 64-bit hardware and new 64-bit Windows system we can use the same 64-bit Manifold serial number with the 64-bit Manifold installation package.

**Note:** Extensions are always issued with 64-bit serial numbers

### Advantages of 64-bit Editions

The main advantages of 64-bit Manifold is that 64-bit processors will always work in 64-bit mode. This is often faster than using a 64-bit processor in 32-bit mode and it allows the processor to use 64-bit wide memory fetches for higher bandwidth to memory as well as a larger, 64-bit memory addressing space. This means that the processor can use far more memory and use that memory more efficiently.

When running in 32-bit Windows, a Manifold process can use no more than 2 GB of memory, the 32-bit Windows process space limit. Because of system and application overhead, in actual practice individual tasks within Manifold (such as running a particular transform operator) could have no more than 1 GB of memory to work with in 32-bit Windows. 64-bit Manifold editions running in x64 Windows can use up to 16 Terabytes of process space, the maximum allowed by x64 Windows.

The ability to use more memory and to more efficiently use memory in 64-bit systems ripples throughout the internal architecture of Manifold System and also provides opportunities for Manifold to leverage enhanced capabilities in 64-bit Windows. For example, many data structures are used throughout the system for stacks, buffers and other needs, and these data structures can be made both larger and implemented more efficiently in 64 bits. Windows itself in 64-bit editions has immensely greater capabilities for the capacity of important architectural components such as virtual memory, paging file size, hyperspace, paged and non-paged pools, system cache and system Page Table Entries (PTEs).

The best way to take advantage of such 64-bit capabilities is to install as much RAM as possible in your computer, ideally at least 4 gigabytes. RAM is cheaper than ever, so load your machine up with as much RAM as you can install, and consider motherboards with larger RAM capacities when procuring new systems. RAM has become so inexpensive that thinking in terms of 8 or 12 gigabytes of RAM for a 64-bit system is not unusual. It is also important to increase the size of the Windows pagefile to give Manifold as well as other applications more virtual memory. If a machine is hobbled by insufficient RAM, such as having only a gigabyte of RAM, then the potential advantages of 64-bit operation will not be realized. It makes little sense to go to 64-bit processors and software and not install plenty of RAM.

The most popular 64-bit processors from AMD and Intel are also multi-core, having two or four processor cores in each chip. Because Manifold can take advantage of multiple cores in many key functions and because having extra cores can offload background Windows and other applications processes, it is wise when procuring 64-bit computer systems to also take choose multi-core processors. Prices are so inexpensive for such processors that it makes sense to use them.

The advantages of 64-bit operation are normally seen in applications large enough for the differences between 64-bit and 32-bit operation to be noticeable. For example, clicking open the Help - About dialog will appear just as fast in 32-bit systems as it is in 64-bit systems, and opening a small drawing that takes up only a few megabytes of storage space will likewise seem fast in either environment. In contrast, many larger jobs or computationally intensive analytic tasks (which end up using lots of memory for intermediate algorithmic operations) can operate dramatically faster in 64-bit systems.

However, even in smaller applications or in computers with only 2 GB of memory a 64-bit Manifold system will be faster than a 32-bit system due to the many application and system efficiencies available when working with a 64-bit application in a 64-bit Windows edition. Redisplay of larger drawings, for example, is usually twice as fast on a 64-bit system than on a 32-bit system.

Small, but significant effects add up in hundreds of places to make 64-bit operation more responsive and pleasant than 32-bit operation. For example, 32-bit systems are limited to 16 megabytes of "last rendered" cache (allowing the Back and Forward display buttons to redisplay the contents of a window faster) to store approximately 16 views in cache while 64-bit systems use a full 64 megabytes of applications cache to save
approximately 64 views. This means that when very actively combining use of various pan, zoom-to-fit, Back and Forward commands a 64-bit system will need to re-render large drawings less frequently than the 32-bit system, because the 64-bit system will have a better chance of finding a previously rendered display in the cache.

Limitations of 64-bit Editions

64-bit Windows editions do not include all features included within 32-bit Windows editions, so those Manifold features that depend upon such missing features will not be available when running in 64-bit mode. In general, such Windows features are older Windows features that have been replaced by more modern, more efficient capabilities. Limitations when running Manifold in 64-bit mode include:

- No common ActiveX controls for forms. The Manifold ActiveX control works OK and may be used by programmers.
- No debugger for scripts written in VBScript or JScript.
- No Microsoft Jet DBMS engine, thus no export, import or linking of DB, HTML, MDB, XLS or WKx format files. This includes no access to the MDB parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System (64-bit) shortcut. Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

Programmers working in 64-bit environments should move to .NET and .NET languages. Lack of immediate access to "Office" file formats like MDB and XLS is highly annoying but can be worked around by temporarily switching to 32-bit mode. The main hit will be to people who are storing data in Excel XLS spreadsheets or Access DBMS MDB files. But that's a very backward thing to do in 64-bit environments: far better to use a real DBMS engine like SQL Server Express, which provides twice the storage capacity and far, far greater reliability.

What about the Microsoft Access Database Engine 2010 Redistributable?

In 2010 Microsoft issued the Microsoft Access Database Engine 2010 Redistributable package intended to help 64-bit applications connect to Access and Excel in 64-bit Windows. The package is great, a reasonable 64-bit version of much of what is in Jet, but it is limited in that it does not work well in mixed environments typical of people who have been living with 32-bit Office versions in a 64-bit Windows system.

For example, suppose you have been using 64-bit Windows systems for the many years (seven or more) they have been available. Because Microsoft did not make 64-bit versions of Office applications until very recently you probably have 32-bit Office versions installed in your 64-bit Windows system. Try to install the 2010 redistributable package and it won't install: it tells you that first you must remove your 32-bit installation of Office Products. Sure.

If you uninstall your existing Office applications, acquire 64-bit versions of those Office applications and then install the 2010 redistributable package, a 64-bit Manifold edition will be able to use it to import from .mdb files and .xls files and it will be able to link to these Access and Excel files. But it still won't be the same as real Jet. In fairness to Microsoft, the download page for the 2010 redistributable makes it clear it is not intended as a general replacement for Jet and within the published limitations the package works flawlessly.

However, most users are unwilling to uninstall their existing Office applications and to buy new 64-bit versions just to open an .mdb or .xls file. If you need to do this in a Manifold context we think a much simpler situation is to just launch Manifold as a 32-bit application and connect directly. No muss, no fuss.

For those users who are using 64-bit Excel and need to dynamically link to Excel .xls in scenarios like that in the A Flashy Demo - Web Queries and KML topic, the new redistributable is great. Search the Microsoft downloads website for "Microsoft Access Database Engine 2010 Redistributable" to find the download page.

Launching Help

When an x64 Manifold license is installed on x64 Windows, both 64-bit and 32-bit Manifold applications are installed. The 64-bit application will be launched by default, but the 32-bit application is available for special purposes as noted above. Manifold Help is connected to the Manifold 64-bit application, so Help is not available from the Help menu when the 32-bit Manifold application is running.
Manifold Help can always be launched directly from Windows. Press the Windows Start button in the Windows taskbar, and then choose All Programs, Manifold System and then Manifold System Help. It is often convenient to launch Help directly from Windows. Some Manifold users will launch Help in this way and keep that Help session available on their Windows taskbar for easy reference.

**Advice to Users**

Running 64-bit software is such a huge performance and reliability gain over 32-bit operation that users who have 64-bit hardware should make it a point to run 64-bit Windows and 64-bit Manifold. Don't hesitate - go 64 bits. It is almost certain that any reasonably newer system will already consist of 64-bit hardware, even if the processor name is some confusing name that does not make it clear the processor is indeed a 64-bit processor.

Pushing against this common sense approach to using the most reliable, most cost-effective and fastest systems are computer system vendors who sell 64-bit processors in systems loaded with 32-bit Windows. For example, most notebook computers use 64-bit processors but very few are available (as of this writing) with 64-bit Windows. Users are often shocked to discover that they have purchased a 64-bit processor but that the computer delivered to them is running that processor only in 32-bit mode because 32-bit Windows has been installed. Users are often especially shocked when they learn there is no possibility of installing 64-bit Windows on the computer because the manufacturer will not provide 64-bit drivers for their proprietary hardware.

Computer systems manufacturers will often use 64-bit chips because that is where the volume deals are available from the microprocessor vendors and that is the direction in which all modern microprocessor manufacturing is headed. But to save a bit of time and rush out a new model a systems vendor might be tempted to skip the small amount of effort to provide 64-bit drivers for their proprietary hardware so that 64-bit Windows can be used on the 64-bit hardware they sell. Perhaps they think their customers will neither notice nor care, which could well be true for many consumers.

This can be frustrating because major systems vendors who are most guilty of such practices do create very beautiful and desirable hardware. Some modern notebook computers are indeed exquisite machines as hardware even if their manufacturers are completely careless about software. That means one must often choose from second tier vendors and buy a heavier notebook than desired to get 64-bit Windows support on a portable computer.

In the case of desktop machines, it can be very frustrating to try to procure machines loaded with 64-bit Windows as well. Some vendors may be unaware that 64-bit Windows is for everyone, and may seem to want to sell it only through their "enterprise" sales divisions to server customers, as if the individual customer to whom they would sell a 64-bit processor-based machine would not also want to use all 64-bits of their processor!

One way to avoid such problems is to buy hardware from vendors who cater to gamers, since they tend to know all about the need to provide 64-bit Windows for performance, even on a desktop machine and even for just an individual user.

Ultimately, the widespread practice of selling computers based upon 64-bit processors but limiting them to 32-bit Windows usage is more than a little dishonest. It is somewhat like a car company selling cars that are advertised with 8-cylinder engines but not making it clear to consumers that the car will be delivered with a fuel injection system and ignition that allows only four of the cylinders to function. Don't let that happen to you. When buying a computer with a 64-bit processor, buy it from a vendor who can deliver it to you with 64-bit Windows. Don't settle for anything less.

**FAQ**

Why do you have separate 32-bit and 64-bit product offerings? Why not simply sell a 64-bit product at one low price? - The nature of 64-bit Windows technology and 64-bit processor technology is such that the creation and maintenance of true 64-bit code requires a significant amount of engineering in addition to what goes into creating the standard 32-bit product. At the present time there are many users of 64-bit Windows, enough to justify the expense of creating a 64-bit product, but there are still many users who continue to operate 32-bit Windows. That means Manifold must be made available for both 32-bit and 64-bit Windows versions. If there were just a single Manifold product that could run either 64-bit or 32-bit then 32-bit users would end up having to pay a higher fee to subsidize the creation of a 64-bit product they do not use. By offering two product versions, a 32-bit and a 64-bit version, we can retain the lowest possible price for 32-bit users while charging a slightly higher fee for 64-bits only to those users who desire the 64-bit version.

Does that mean I have to buy a separate Manifold product to run in 64-bits? Yes. Low cost upgrades to 64-bits are available if you already have a corresponding 32-bit Manifold product.
I'm not ready to jump to 64-bits quite yet but want to buy an x64 Manifold version now. Can I use it in a 32-bit Windows system? Yes. An x64 Manifold edition can also run in a 32-bit Windows system: simply install from the 32-bit installation package and use your x64 Manifold System serial number (which can activate either a 32-bit or a 64-bit installation). When you upgrade your computer to a 64-bit system, install Manifold from the 64-bit installation package and use your x64 Manifold System serial number again.

I have a 64-bit processor but I am running 32-bit Windows XP on it. If I install x64 Manifold will it run using all 64 bits of the processor? No. Manifold can only run in whatever mode the host Windows system allows. If you are running 32-bit Windows you are using your 64-bit processor to emulate a 32-bit processor as far as Windows and any other applications are concerned. Like all applications in that case, Manifold will also run in 32-bit mode. To run Manifold in 64-bit mode on a 64-bit processor you must also be running 64-bit Windows.

Are there real benefits to running x64 Manifold in x64 Windows? Yes, if you have a reasonable amount of memory (2 GB or more recommended). 64-bit Windows is far more reliable than 32-bit Windows, and far faster as well. 64-bit Manifold is visibly faster in most cases than 32-bit Manifold. Don't hesitate about this.

Isn't it a hassle to get device drivers for 64-bit Windows? Not if you are using a well-established 64-bit operating system like Windows XP x64 and you are running reasonably standard hardware purchased from a vendor who is looking out for the interests of their customers. Because of the popularity of 64-bit Windows for gaming, virtually all motherboard vendors catering to gamers (the market driving the best deals for the highest performance) make it a point to package 64-bit Windows drivers by default for their products. Using newer operating systems, like 64-bit versions of Vista, or making the mistake of buying products from vendors who sell 64-bit processors but don't intend to allow customers to use them in 64-bit mode (just about every laptop vendor around) may require some detective work to locate 64-bit drivers.

Isn't Windows Vista always 64-bit? No. Windows Vista is available both in 32-bit and in 64-bit x64 editions. If you want to run 64-bits you must have Windows Vista x64.

Should I use Windows XP x64 or should I use Windows Vista x64? That's up to you, as 64-bit Manifold will run in either XP x64 or Vista x64. If you are planning to use Windows Vista x64 it makes sense to procure it pre-installed on the computer system you are buying, since as of the present writing there is less driver support for Vista x64 than for XP x64. By purchasing Vista x64 pre-installed on a computer you assure that the manufacturer does indeed have full driver support for Vista x64 for their particular configuration of devices. Because XP x64 has been around longer than Vista x64, XP x64 is very widely supported with drivers by many different device vendors. For example, NVIDIA CUDA drivers for XP x64 will quite likely appear before Vista x64 drivers. XP x64 is faster than Vista x64, but Vista x64 is prettier.

If I provide a Manifold x64 product serial number to an existing 32-bit Manifold installation, will it re-launch in 64-bit mode? No. You must uninstall your old Manifold and install the new 64-bit installation package. The 64-bit installation package may be downloaded. If you have not installed a 64-bit installation package the 64-bit serial number provided for x64 Manifold products will not work.

If I provide a Manifold x64 product serial number to a 32-bit Manifold installation, can it continue running in 32-bit mode? Yes, if the serial number is for the correct Manifold release level. For example, you can't provide a 7x 64-bit serial number to a 8.00 installation and expect it to work. Assuming you are using serial numbers that match the release, 64-bit serial numbers will work with either 32-bit or 64-bit Manifold installations.

How can I tell what kind of serial number is currently in use? Launch Manifold and look in the Help - About dialog. That will identify the serial number and the mode of operation for Manifold. If you have shortcuts for both Manifold System (32-bit) and Manifold System (64-bit) then you have installed a 64-bit product. You can always check the status of a particular serial number by visiting the Support page on the manifolds.net web site and visiting the link on that page to the Serial Number Status page.

To switch between 32-bit and 64-bit operation on a 64-bit Windows system, must I re-install Manifold? No. Install the 64-bit version, which then installs two short cuts, one which launches Manifold in 32-bit mode and one that launches Manifold in 64-bit mode. You can go back and forth between 32-bit mode and 64-bit mode simply by choosing which shortcut you use to launch Manifold. This is exactly similar to how Windows x64 editions provide Internet Explorer in both 32-bit and 64-bit versions, either of which may be used at will.

Can I launch two Manifold sessions, one of which is 32-bit and one of which is 64-bit at the same time? Yes, if you have installed a 64-bit Manifold installation package on a 64-bit Windows system.

Are .map project files for 32-bit and 64-bit Manifold editions compatible? Yes. The same .map format is used both for 32-bit and 64-bit Manifold editions.
I have a dual core 64-bit processor. Will x64 Manifold work with that? Yes. If you have a dual core or other multiple core processor Manifold will run fine and those parts of Manifold that are designed to take advantage of multiple processors or multiple cores (such as, for example, the multithreaded rendering architecture used by Manifold to render image libraries) will take advantage of all processors or cores available. For example, if you have a motherboard that has two processor sockets and each socket has a quad core processor in it, Manifold will be able to take advantage of all eight processor cores.

Will Manifold x64 run with Itanium processors? No. manifold.net has no plans to support Itanium. We believe x64 is the way to go, using processors like AMD's x64 processors or Intel's x64 processors.

My runtime application requires access to MDB files. How do I arrange that in a 64-bit Windows system? That can be accomplished by writing your application as a 32-bit application. Installing an x64 edition of Manifold, such as Manifold Professional Runtime x64, on an x64 operating system installs both 32-bit modules and 64-bit modules. 32-bit programs using the Manifold object model will use 32-bit Manifold modules and 64-bit programs will use 64-bit Manifold modules, automatically. Your 32-bit application will use the 32-bit Manifold modules and thus have access to MDB.
Introduction

Manifold is a Geographic Information System (GIS) software package. A GIS package is different than an "atlas" package, such as Microsoft's Streets and Trips or the various DeLorme products that can display only one, built-in, read-only map. A GIS can work with many different maps and can be used to create new maps, to edit maps and to combine maps with database information. See the Key Ideas in GIS topic for how a GIS differs from consumer-oriented atlas products.

Manifold is a "word processor for maps" that will let you create new maps or edit existing maps. It is also a "database system for maps" that will allow you to embed database information into a map so that the map can be used as a visual interface into the data. Anyone can use Manifold interactively to create new maps or to use Manifold to explore database information displayed within a map. In the hands of experienced users with programming skills, Manifold may be used to create new applications to work with maps, images, surfaces and databases.

Manifold includes a huge number of capabilities to work with different types of data at the same time. The summary below sets forth highlights. These are provided as a reality check to help the reader realize the resources he or she has on hand in Manifold, and thus to motivate the reader to invest a day or two into reading this documentation before beginning work. The more of Manifold you learn to use, the better Manifold can serve you.

- **Drawings** - Most digital maps are "vector" drawings like those used to create blueprints in Computer Aided Design (CAD) programs such as AutoCAD. To deal with these, Manifold includes a vast array of CAD-style editing features. These are so extensive that people will use Manifold as a general purpose CAD editor. Specialized features such as tracing ("vectorization") of images provide special CAD capabilities that are required in a mapping environment.

- **Linked Drawings** - Manifold can create linked drawings "on the fly" from data within databases and can show those linked drawings within Manifold projects just like regular drawings. There are many applications where data that has a fundamentally geographic character is stored within centralized databases. An example might be a list of a bank's ATM locations that are maintained in a geocoded database in one of the bank's DBMS servers. It's convenient for the bank to keep that data in some centralized database where other applications, such as archival storage of ATM machine maintenance records, can work with it, but it is also very convenient that Manifold can dynamically create drawings from that data for purposes such as displaying a map of the nearest ATM locations in a Manifold IMS web site. It's also very convenient that any changes made to that centralized ATM database will automatically be incorporated into linked drawings created from that database. Linked drawings can also be used as a visual user interface to edit data by multiple users within centralized databases. For example, a town might maintain tax parcel information in a database and use Manifold via linked drawings as the user interface to that data to display parcels, to allow people to find parcel information, edit the shapes of parcels, add or delete parcels or edit the database information associated with each parcel.

- **Database Management** - Modern maps will link the objects in drawings with records from database management systems. One can then use the map as a visual interface to the data. Manifold includes a full-power database management system complete with SQL and numerous other capabilities to make it easy to work with databases and maps simultaneously. The system includes sophisticated data exploration tools and decision support using variable views, fuzzy logic and Manifold's patent-pending "more like this" technology. Manifold's database facilities are so strong that people will often use Manifold to explore and manage databases having nothing to do with maps. Manifold includes the most powerful and sophisticated spatial SQL engine ever introduced in GIS.

- **Direct Connect to Spatial DBMS** - All Manifold releases can connect to almost any DBMS for attribute storage while Enterprise Edition and above can connect directly to spatial DBMS products like Oracle, Oracle Spatial, SQL Server 2008, IBM DB2 with Spatial Extender and PostgreSQL / PostGIS. No middleware is required to achieve simultaneous access by potentially thousands of users to potentially terabytes of data stored on enterprise class spatial DBMS. In fact, Manifold even provides a spatial extender to convert SQL Server 2005 into a true spatial DBMS and Manifold provides generic spatial DBMS capability that can confer spatial DBMS capability onto virtually any DBMS product, including MySQL and even Access. See the Spatial DBMS topic for an introduction to this amazing capability.

- **Images** - Images in various formats are used throughout mapping. We use images as backgrounds, as semitransparent layers within maps, as sources for creating new digital maps, as graphics arts embellishments for a better presentation and for many other purposes. Manifold includes full capabilities for importing, editing and manipulating images, including alpha transparency capability on a per pixel basis, georegistration for use in geographic contexts and transformation to any geographic projection. The roster of image editing effects is rivaled only by professional graphics editors such as Adobe Photoshop.
Compressed images allow very rapid display of even multi-gigabyte images when used as backgrounds in maps.

- **Linked Images** - Just as with linked drawings, Manifold can create linked images that are created "on the fly" from data stored in external databases or fetched on demand from image servers of various kinds. For example, Manifold can automatically fetch and mosaic images from TerraServer or other types of image servers, such as Google Earth, to automatically provide photographic images that cover a particular region of interest.

- **Surfaces and Terrains** - Manifold can import terrain elevation data from almost any format known and incorporate surfaces into maps as shaded 2D images showing relief, slope, aspect or visualized as realistic 3D terrain views. Terrains may be overlaid with any combination of vector drawings or raster images. Surfaces are also used to provide continuous gradient displays of data such as population, temperature or other variables. Manifold can automatically create surfaces from scattered data points and compute contours, aspect, slope and other features.

- **Raster Data and Images** - Many data sets such as satellite sensor scans of the Earth's surface are published as raster data. These can be used as Manifold "images" for analysis and presentation. There are many names for such data used in GIS, such as "Grid" data, depending on the context of usage. In Manifold, such data sets are either raster images or surfaces. Manifold provides numerous analytic and image processing capabilities to get the most out of raster data.

- **Statistics and Analysis** - Manifold’s solvers and analytic subsystems include hundreds of analytic capabilities in statistics, general purpose mathematics, network analysis, graph theory, database logic, topology and computational geometry. Active Columns™ and ViewBots™ provide a new style of interactive analysis that's easy to use.

- **Charting and Data Mining** - Manifold’s chart windows provide 2D charts for data exploration of information in maps and databases as well as minicharts that appear in drawings and maps for each object. Manifold Charts are a straightforward visual interface for exploring and understanding data. Other data exploration tools include ViewBots™ and the Manifold Decision Support System.

- **Spatial Analytics** - Manifold provides a wealth of spatial analytic capabilities embedded throughout the entire system. Relief effects in 2D images are automatically computed based on terrain elevations from their associated 3D terrains, for example. Manifold SQL includes dozens of spatial extensions, which apply throughout raster images as well as within vector maps. Buffer zones, spatial statistics and numerous other functions provide sophisticated spatial analytics within every system.

- **Programming** - Manifold System includes a full programming environment using Microsoft languages at no additional cost. The power of Manifold System may be extended by writing scripts in Microsoft .NET scripting languages or Microsoft ActiveX scripting languages like Visual Basic Scripting (VBScript) or JavaScript. Free downloads from various sources allow ActiveX scripting in other languages as well, such as PERL and Python. Manifold’s programming environment includes full editing capabilities as well as "drag and drop" creation of programming forms using a wide variety of Windows controls. Manifold also may be programmed from external applications written in Microsoft standard languages such as Visual Basic or Visual C++ to create custom mapping applications based on Manifold. For casual customization, Manifold includes Active Columns and ViewBots for "ad hoc" programming. Manifold script windows automatically color script source code by syntax and support advanced editing "power moves."

- **Debugger** - The Manifold Debugger provides a sophisticated debugging environment. The Debugger allows stepping through multiple scripts with automatic stops at breakpoints, paused execution and stepping into, over and out of routines. The Call Stack, Variables and Watches panes provide dynamic, editable displays of variables, functions, computed values and contexts.

- **Internet Map Server** - All Manifold editions except Personal Edition include a built-in, enterprise-class, powerful Internet map server, Manifold IMS, which can publish your maps to Internet for people worldwide to view. The map server allows browsing, panning, and zooming within maps that you choose to publish as well as support for queries, geocoding, hyperlinks, information tools and layer selection if desired. Advanced users can customize the map server to create spectacular Internet pages. Manifold IMS is easy to use with no programming required. Use IMS to create web pages for your organization's internal network so that other people within your organization can see or themselves the value of what you do in GIS without the need to drag them one by one to your computer to see a demo. Manifold IMS works with any Windows HTTP server and provides pre-built templates for use in ASP and ASP.NET Windows IIS environments. Manifold IMS provides not only a classic HTTP style internet map server but also an OGC WMS server, an OGC WFS-T (WFS with transactions) server, and a Manifold Image Server for a complete range of GIS-enabled web technologies.
Sophisticated Image Linking and Serving - Manifold can create linked images from ECWP servers to provide high-speed, multi-resolution imaging, and Manifold can link images from OpenGIS Consortium (OGC) WMS servers, operating as a client. In addition to operating as a client, Manifold IMS can also function as an OGC WMS server, generating on-the-fly WMS images to be served to other clients that can operate using OGC WMS protocols.

Image Libraries - Manifold can automatically tile together collections of images from a wide variety of formats to form a single image mosaic. Image libraries make it easy to utilize collections of images covering broad regions as a single background image. Automated creating of index drawings provides the infrastructure for easy navigation and utilization of image libraries in applications such as IMS web sites.

Dynamic Geometry using Industry Standards - Manifold can read and write object geometry in connections to external database systems to create linked drawings from tables or queries. Manifold can use ESRI-style "geodatabase" geospatial geometry, OGC-style "well-known binary" WKB geometry as occurs within Oracle Spatial and other DBMS products Manifold's own high performance Geometry data type that can be stored in any leading DBMS product such as SQL Server, Oracle, IBM DB2 or MySQL. Manifold Enterprise Edition and above also supports the Oracle Call Interface for geometry storage using Oracle native technology in Oracle Spatial and Locator technologies as well as image storage using Oracle's GeoRaster technology.

Spatial SQL for Images and Surfaces - Manifold's Raster Extensions to spatial SQL enables use of "virtual tables" to create, analyze, modify and display raster data within images and surfaces. Images and surfaces can be linked from data stored in external DBMS providers using almost any leading DBMS product.

Import and Export - Manifold System can read data from over 80 different vector, raster, terrain elevation and database formats including specialty formats such as grids and the very latest government formats such as HDF EOS used with ASTER Earth observation satellite data. This allows users to access terabytes of free GIS data by Internet directly from the source, and to use data from every GIS system known as well as from numerous specialty software packages. The Professional Edition writes to standard interchange formats while the Enterprise and Universal Editions includes additional export capability for specialty formats of interest to larger organizations.

Enterprise Edition - If you have licensed Enterprise Edition, your edition of Manifold will also provide centralized storage of components within databases such as Oracle, IBM DB2 or Microsoft SQL Server or SQL Server Desktop Engine. In addition, Enterprise Edition provides a coordinated framework within which many users can share the same components, allowing editing of shared components without fear of simultaneous, incompatible edits by different users. Enterprise Edition also enables direct use of Oracle technologies such as Oracle Spatial, Locator and GeoRaster technologies.

Optional Business Tools - If the optional Business Tools extension has been installed, a variety of new commands will be added. Business tools provide advanced districts and visual districting commands, drive-time zone analysis, optimal routes and the ability to send email directly from Manifold for geo-targeted emailing.

Optional Geocoding Tools - When the optional Manifold Geocoding Tools product is installed, the geocoding engine built into Manifold System can find the geographic location for street addresses and ZIP codes in the United States. Use the geocoder to automatically plot the locations of addresses, to find distances and to execute spatial queries using the geocoding functions in Manifold SQL. The Manifold geocoding engine can be used from within IMS applications to address-enable web sites created with Manifold IMS. The Geocoding Tools package also adds the ability for fast and easy import of drawings from the Geocoding Database provided by download.

Optional Surface Tools - If the optional Surface Tools extension has been installed, Manifold will gain the ability to work with new Profiles and Elevations components as well as new commands and other capabilities. These include a sophisticated surface transform dialog, a transfer heights command and greatly extended surface interpolation capabilities for triangulation, Kriging, and Median-Polish Kriging. Surface Tools also adds sophisticated watersheds capability to enable computation of water sheds, streams, flow accumulation and other hydrological features.

Universal Edition - If you have licensed Universal Edition you have all Enterprise Edition features as well as all Business Tools, Geocoding Tools and Surface Tools features.

Database Administrator Edition - Manifold Database Administrator Edition is a version of Manifold System that includes additional capabilities for setting up and managing GIS data storage in DBMS systems such as Oracle Spatial. Database Administrator Edition includes tools such as Batch Export and Administrator Console that allow DBMS storage to be configured with capabilities like friendly names, support for
formatting and pre-configured import and link options that will thereafter make life easier for other Manifold users.

- **License Server Edition** - The Manifold System License Server product gives organizations the ability to maintain an inventory of floating Manifold licenses that may be used by any client computer that can connect to the License Server, all without needing to use serial numbers and Activation keys for individual client licenses. License Server provides the economy of floating licenses as well as greatly reduced administrative overhead for organizations that deploy many hundreds or thousands of Manifold licenses.

**Key Ideas**

Although the functional areas covered by Manifold capabilities are very broad, they have been implemented in Manifold System using a common set of user interfaces and a common set of key ideas, such as selection. The key to mastering Manifold is to understand those key ideas.

If you are new to GIS or wish a refresher in GIS from a manifold.net perspective, you must first get acquainted with a few basic GIS concepts. Please begin by reading the Key Ideas in GIS and Key Ideas topics in the Appendix.

After reading all of the topics in this Introduction section, please read the more detailed sections that are organized by component or activity. A general reference to nearly all menus, dialogs, panes, toolbars and context menus occurs in the Menus, Dialogs and Controls Reference section. The best way to begin working with Manifold System is to follow along with the many example topics in the Examples chapter.

**A Note on Illustrations**

Some illustrations in this manual use screen shots based on "classic" Windows appearance such as used in Windows 2000 and some use a more modern appearance such as used in Windows XP. When installed in Windows XP Manifold will automatically configure the user interface to use Windows XP style for controls, as seen below in a screen shot of the column formatting dialog for table windows.

![Column Format Dialog](image)

Depending on your Windows settings for Appearance choices in the Windows Display Properties dialogs, your desktop may be configured to use different colors, fonts or styles from those seen in screen shots used in this manual. Color and stylistic choices made for illustrations are not necessarily Windows defaults but have been chosen for maximum clarity and legibility.
Key Ideas in GIS

Read this topic if you have never worked with a GIS before or if you would like to see the manifold.net spin on basic concepts in GIS. If you already know GIS well, skip ahead to the main Key Ideas topic.

This topic introduces foundation concepts that apply to any modern GIS and which must be understood to use Manifold. We will explain these concepts by making analogies to software with which the reader is already familiar. For example, we will use Microsoft Word to make analogies to word processing software and AutoCAD to make analogies to CAD programs.

This is a very long topic, possibly the longest, wordiest and least-illustrated topic in this Help system. Don't panic. Almost all of the other topics you will encounter will be easier to read than this one.

Key Idea: Manifold is a GIS.

GIS is an acronym for Geographic Information System, which is software industry jargon for a program that combines a variety of mapping and editing functions together with database capability. Many of the functions of a GIS appear in other sorts of programs, such as CAD editors like AutoCAD, or database programs like Microsoft Access. It is the unique combination of capabilities within a GIS that gives this class of applications their unique power.

As a class of software applications, GIS has been around for about thirty years. Only recently have GIS applications appeared on desktop machines. As a result, only recently has the traditional GIS industry begun to undertake the social, technical and economic transition from minicomputer and mainframe cultures to Wintel clone culture that has occurred throughout the rest of the software industry.

Manifold is the first "Wintel" GIS ever created. It was deliberately created to focus exclusively on Wintel architectures, to leverage mass-market standards like Microsoft scripting languages and Windows interfaces, and to attack sleepy traditional markets with a mix of very high performance and very low cost.

Pronunciation: Most people in English pronounce the acronym GIS by saying its letters: "Gee Eye Ess." In other languages, the acronym is often pronounced as "Jis" using a soft "J" sound like in "Jester" or "Gis" using a hard "G" sound like in "Gate".

Key Idea: A GIS is like a CAD editor or word processor for maps.

We can use AutoCAD to create elaborate blueprints and diagrams. We can use Microsoft Word to create elaborate documents. In both cases, we can draw new items, we can edit existing items, and we can import items already created from other documents. With AutoCAD we can enjoy a host of editing capabilities that allow us to draw diagrams and blueprints more easily. For example, we can set "snap" characteristics so that the mouse cursor will automatically jump to the ends of existing lines. This makes it easier to draw lines that begin and end exactly at the ends of existing lines.

A GIS allows us to:

- Import existing maps. A good GIS will let us import existing maps from many different file formats, including those used by competitive software.
- Create new maps, and edit existing maps. This includes adding new items to a blank map, or to change the shape and position of items already in the map or to delete items from a map. For example, we might edit a map of counties in a particular state to show only three counties if that is our region of interest.
- Change the appearance of items in a map by changing their formatting.

The above capabilities are similar to any CAD or graphics editor, or, for that matter, any good word processor. In addition, a GIS has other capabilities. Using a GIS we can:

- Specify the geographic location of the map and the items in it.
- Use geographic projections to show a more realistic view of the map.
- Link the items in the map to a database table. This allows the graphics in the map to act like visual "handles" to reach into the database.
• Process the data and visual items in a map to create new items or to analyze the data. For example, we might create a "buffer zone" that shows all regions within 100 meters of a road or stream, or we might automatically add up populations of a given species of tree within a set of tree stands in a forestry application.

The above capabilities set GIS programs apart from ordinary CAD editors like AutoCAD or graphics editors like Adobe PhotoShop or Illustrator. Anyone can use PhotoShop to draw a map that is a fine illustration. However, that illustration is just a picture. There is no "intelligence" in the picture that connects a particular spot in the picture to a real geographic location. We cannot, for example, draw a picture of Europe in PhotoShop and then use that picture to find the precise latitude and longitude location of Geneva, Switzerland.

We could use a CAD editor to create a beautifully detailed diagram of streets in San Francisco. However, we could not automatically have each street linked to a record in a database table that for each street would have fields storing the name of the street, when it was last paved, what paving material was used and so on. All we have is a pretty and highly detailed diagram, but no linkage to a database.

With a GIS, on the other hand, we could create that diagram of streets, because a good GIS will have the same CAD drawing capabilities as any good CAD editor. In addition, we could place any drawing we create within a true geographic location and we could fill in the fields for each street line's record in the database table. We could then use this information in spectacular ways.

For example, we could find all streets within a mile of a given location that have been repaved in the last three months and then we could sort the database records for those streets by which street was most recently repaved. We could use SQL to find all the streets in the map that were last paved with concrete and highlight them in the drawing. We could show points on the drawing that are located at latitude and longitude coordinates taken from a GPS device that logged the movement of a bus. We could automatically calculate our costs for different time periods when paving will be necessary in the future. Once the system has a handle on both visual appearance and shape, location and database information the possibilities are virtually endless.

A GIS is therefore most different from static, purely visual applications like AutoCAD or Photoshop in that it is both a visual representation as well as a data representation, and it is at once both a presentation and visualization tool as well as being a control console and an analytic device, a limitless calculator of appearance, location, shape and data content.

**Key Idea: A GIS can work with many different maps.**

A GIS can work with many different maps. Just as we can use Microsoft Word to open any document in a file format understood by Word (such as Word Perfect or other word processors), we can use our GIS to open maps saved in any file format understood by the GIS. We can create our own maps and we can save them for later use or we can use maps created by others.

**Nomenclature:** When we use the word "map" in this topic we mean a digital document that is a drawing in some GIS format that may or may not also include database information. The phrase "GIS format" means some file format that is useful for saving maps in a way that's useful to a GIS. A real GIS, for example, will save its files using a file format that allows saving database information, projection information and other necessary details. Although people often will use a CAD program like AutoCAD to draw diagrams intended for use in maps, AutoCAD's .dxf format is not really a GIS format since it is clueless about geographic location, projections or database information. One can often import .dxf drawings into a real GIS and then manually add projection and database information using the capabilities of one's GIS but that is obviously not as convenient as having everything done up front.

We are often very interested in having everything done for us up front with maps in a nice, neat GIS format because sophisticated maps are often highly detailed drawings of immense complexity. Creating such a map from the ground up is not a job for the faint-hearted. Consider drawing a map that shows all the water features (streams, lakes, rivers, etc.) in, say, Texas. Creating such a diagram in AutoCAD or Adobe Illustrator would be a massive undertaking, requiring the creation of hundreds of thousands of lines in a precise way. Using a GIS can make the process easier, but it is still such a massive and expensive project that quite likely only the government can afford to do it.

So, even tough a GIS can be used to create new maps line by line we will probably spend our time searching Internet to find a pre-built map we can use. We can then use the GIS to change that map, to format it into pretty colors we like, add new features of special interest, combine it with other maps, or cut and paste features from the map into other maps. Editing and cutting and pasting is a lot easier than creating something from the ground up.

Because maps used with GIS can be so complex and such a hassle to create from the ground up, sometimes our ability to accomplish a specific project will depend on whether or not we can find the right pre-built maps or data.
sets to use. For example, suppose we have a database that lists the zip (postal) codes of customers who have called our 800 number to place an order for a product. We might want to display a map of the United States showing zip code regions with each region colored in to indicate how many customers called from that zip code last week. Zip codes with high numbers of calls might be colored bright green and those with lower numbers of calls could be colored in progressively darker shades of green until those zip codes with zero calls would be colored black. Right away, we could see on the map the geographic locations of high call activity.

That's a great idea and easy to do in Manifold (or any other modern GIS) if we have a map of zip codes as regions in the United States. If we can locate such a map we can do the project in about five minutes. If we don't have such a map, we can't do the project. It turns out that getting a map of zip code regions in the United States is not so hard to do, since we can download one for free from the US Census Bureau's web site. However, such maps of postal code regions for countries other than the US are extremely difficult to download for free from Internet. If we could not locate such a map for free on the Internet we might have to buy it from one of the commercial vendors who are in the business of supplying specialty maps and demographic data for GIS users.

Manifold's contribution to lowering the cost of acquiring maps is to provide import capability for essentially all GIS formats in use. If you can find it on the Internet for free in almost any form, it's almost guaranteed that Manifold can import it. In particular, Manifold can read all of the exotic federal government formats in which many maps are published for free. Because there are millions of maps and other GIS data sets that can be downloaded for free from Internet (many of which may be downloaded from government web sites for which your tax money has paid), this gives Manifold users access to the largest library of GIS information of any GIS system in history.

Key Idea: Manifold is a GIS, not an atlas.

Even if you have never used a GIS before, it is quite likely you have used some sort of mapping program such as Microsoft's MapPoint, Streets and Trips, or any one of a series of DeLorme products. Although such products display maps, they are best understood as atlas programs and not as GIS programs.

Atlas programs are mapping programs that work with one, built-in map. Microsoft Streets and Trips, for example, is a program based on the display of a built-in map of streets in the United States. It's easy to use because it is designed to work with that one, pre-formatted map. However, we cannot use Streets and Trips to create new maps nor can we use Streets and Trips to look at, say, a geologic map of the United States that we may have found on the Internet or at, say, a map of ocean depths off the coast of Corsica.

In contrast, a GIS like Manifold can be used to view many different maps from many different sources. We can use Manifold to create entirely new maps or to edit and combine existing ones. This is one of the major differences between a true GIS program and an atlas program.

This difference between a true GIS program and an atlas program is similar to the difference between Microsoft Word and an Adobe PDF document viewed with Adobe Reader. The Adobe PDF file delivers a "canned" document to a user. We can view the PDF file but we cannot change it. The PDF file is easy to use because it allows no changes - someone else did all the work of creating the text and formatting it in a pretty way. Double click on the PDF file and Adobe Reader will display it as intended. But that PDF file is forever limited to the one document it contains.

In contrast, Microsoft Word can open documents in any format understood by Word. We can create new text and new documents in Word, and we can use the extensive array of formatting and stylistic features in Word to give our documents exactly the appearance desired. We can even add images to our documents. Because Word can do a lot, learning Microsoft Word requires more thought than learning how to click open an Adobe PDF file. The additional thought required to learn and operate Word is rewarded with the freedom to create whatever document we like.

In the world of mapping software, atlas programs like Streets and Trips are like a PDF file; they provide one, built-in map that has been cleverly formatted by the authors of the program but which cannot be changed. An atlas map program automatically starts up with a specific map full of street symbols and roads and lakes and streams. That's certainly very handy if the sort of map you wish to use is exactly the map that is used within the atlas program; however, if you would like a different sort of map an atlas program cannot help you.

A common complaint from users of atlas programs like MapPoint or DeLorme products is that they would like to create maps that are different from the built-in map. For example, users might want to create a presentation that shows only one or two states that are the subject of a particular presentation, and they would like to remove all other states to provide a cleaner presentation. For that, a real GIS is necessary.
The illustration above shows many states, which can be confusing if we only want to show a presentation involving four states.

It takes mere seconds in a GIS package to edit it so that only the four states of interest appear but that is not possible in atlas programs. We can even add labels or have them automatically generated from database information, or otherwise edit the display as we see fit:

The GIS program’s ability to manipulate visual data as desired, to add items like labels in a full-custom way and to otherwise edit the display makes it a lot easier to create visual displays that are easy to understand and which have great impact. Even in simple things like the above illustrations, a GIS program can do what atlas programs cannot, and that is even without considering the immense power of linking database information to a visual interface.

A GIS program like Manifold is for maps and data what Microsoft Word is for text documents: it is a “word processor for maps.” Manifold can open nearly any type of document containing map data and it can be used to create almost any sort of new map. It can edit existing maps, combine them, cut and paste between them and otherwise perform a vast number of editing, formatting and analytic functions.

Key Idea: Mapping programs and map data are different things.

Atlas programs like Streets and Trips or MapPoint feature very tight integration between the functions of the viewing program and the map that it displays. There will even be “hardwired” menu choices in the program’s menu that refer to specific items in the map. For example, one might see a choice of menu items to “Show Streets” or “Show Hotels” that turn different items in the map on or off for viewing.

This tight integration is handy when one wishes to work only with one map, but it often leads newbies into confusing the program with the data it shows. Consumers will refer to Streets and Trips, for example, in a way that does not distinguish the content of the map data from the capabilities of the display and user interface program that shows us the data. They’ll say things like “When I click open the Streets and Trips map, the map won’t let me draw on the map.”
In GIS, both newcomers and even GIS people will at times confuse the GIS with the data upon which it works. Newcomers tend to make this confusion because of their previous familiarity with atlas-style, consumer map programs as discussed in the preceding section. Some GIS "old hands" will make this mistake because they are still stuck in the GIS technology of an earlier era.

In earlier times, GIS programs were so expensive and so difficult to use that very few people ever worked with a sophisticated map/database editor. Instead, most people who encountered a GIS or used mapping data would see the data already integrated with the GIS software. People would say things like "I want to create a GIS of Camden County" and by that would mean that they wished to create an integrated map, database, and viewing method. In earlier times, "GIS" did not mean just the software: it meant an ensemble of both software and data. In modern times, "GIS" now means the mapping / database program that is used to view, edit and manipulate maps and data of all kinds.

To the new user, this key idea may seem to be a small distinction without much meaning. However, when new users import maps into a GIS and commence using those maps, they may encounter all sorts of unexpected effects caused by the structure of those maps.

It's important to keep clear in one's mind the difference between the GIS program's function and any effects caused by the particular data set with which one works. For example, if one is working with a drawing that is made of lines only and has no area objects in it, then one cannot color the regions between the lines. That's not a limitation of the GIS. It is simply a reflection of the structure of the drawing that one has chosen to use. We could choose to use a different drawing, or we could use Manifold to create area objects if we wanted to color them.

**Key Idea:** Formatting changes the appearance of objects in maps.

Digital vector maps, the most common type of GIS map, are like CAD drawings in that they are "vector" data sets. The items in a drawing, such as a shape that shows an island or a line that shows a road are called objects. This word is not intended to connote any fancy meaning, such as the term "object" does in programming... it is simply a word that means "thing" or "item" and is used to mean the points, lines or areas that make up the content of the vector drawing, excluding, however, annotations such as labels or accessory elements such as legends, North arrows, scale bars, graticules of latitude / longitude lines and so on.

All objects seen in the map are drawn using points, lines or areas between precise coordinates in a connect-the-dots fashion. By default, such objects will appear in whatever default colors and display styles are used by the GIS system. To alter their appearance to make the map more legible, informative or prettier we can change the formatting of the objects. We can also add accessory elements such as labels.

Formatting in a GIS context is directly analogous to formatting in a word processor such as Microsoft Word. When we format text in a word processor we apply display attributes such as font style, font size and color to the text.

The quick brown fox

**The quick Brown fox**

If we import text into a Microsoft Word.doc it might first appear in Courier New font. We can format the text to change the appearance. Changing the font size, style and color can result in dramatic changes in the appearance of the text but the actual words stay the same. Just so, changing the formatting of objects in drawings can change dramatically their appearance even though the actual objects within the drawing stay the same.

In Manifold System, we will often import complex maps from formats that do not retain information about visual appearance. In such cases, Manifold will initially show the drawing using default formatting. Specifying formatting to create a pretty map from such raw drawings will require some work and good taste.
Both of the illustrations above show exactly the same drawing, which contains vector objects (areas, lines and points) that represent land areas, depth contours in water, road line, very small areas showing certain populated regions and points marking the locations of named populated places. The illustration on left uses default formatting. The illustration at right has had formatting applied so that land areas are colored green, ocean areas and depth contour lines are colored blue, road lines are shown in black and population points are shown as round yellow dots with the tiny populated regions in small areas of yellow color. Note how the application of sensible formatting makes the image on the right more comprehensible.

Formatting is often confusing to beginners who are familiar only with consumer atlas programs. They don’t realize that one reason the atlas program displays a pretty map is because a team of people spent many hours choosing good formats for the data set being used. In fact, since the atlas program is dedicated to displaying only one map, it may have special display features in it that facilitate clever formatting. The classic example is a special formatting engine that draws roads as thick lines with contrasting color borders, and which correctly splices the border edges at road intersections.

It's reasonable to wonder why a GIS program might not have a "built in" format that automatically makes maps very pretty. After all, if a $20 consumer atlas program can show a pretty map, why does a fabulous, state-of-the-art GIS program show maps by default in a stick-figure, simple style?

The reason is that because a GIS can open any map there is no way for the program to know how we would like that particular map to look until we tell it. One day we might work with a map of lines that are meant to be streets and another day we might load a map of lines that represent geologic faults along the Mid-Atlantic Ridge. It is very easy to create a fixed format for a fixed data set of the sort used in Streets and Trips. It is very difficult to create a format engine that can read our minds and make whatever map we load look pretty in a "correct" way.

Of course, once we format a map we can save it so that it will retain its appearance when reopened.

**A note on nomenclature:** As in most software, the word **format** has two meanings in GIS. One meaning is the scheme of organization of a computer file. One might say "Is that database in Access .mdb format or is it in dBase .dbf format?" Another meaning is the application of effects to change the appearance of something. In word processing we might say "I have change the font format so that it is all boldfaced Arial font in 8 points." In GIS we might say "All the points in that layer are formatted so they are small blue stars." It is usually obvious from the context of use which of the two meanings is intended.

**Key Idea:** A GIS links maps with databases.

In their visual appearance and diagram / map editing capabilities, GIS's are similar to a CAD editor such as AutoCAD. AutoCAD can also be used to create and edit maps. A GIS like Manifold adds another important capability: it incorporates database capability within the program. That database capability is used to link objects in the map with one or more database tables. The GIS links each object in the map to a record in the table.

This is probably the most powerful idea in GIS, the idea that a map can have the objects it shows linked to a database table. This linkage makes it possible to use the map as a visual interface to fetch and manipulate data in the database. In many important GIS applications the visual appearance of the map is a secondary consideration. What is most important is the ability to use the map as a visual interface to deal with the data "behind" the map.

The linkage also enables us to use the map as a presentation tool to make sense of otherwise incomprehensible data. For example, we might click open a map's table and sort the table by a column such as "population" or "sales" or some other field of interest. We could then select the top ten records in the table and see them highlighted in the map. Right away, we can use the map to display data that otherwise might be buried within endless database records.
Beginners often wonder how the data "gets into" the table and how the links are maintained with objects in the map, and whether a database system like Access must be installed on the machine. For now, leave that up to Manifold [the main documentation topics cover all details]. Manifold includes full database capability. No other software is required.

**Key Idea: Importing maps at times requires extra thought.**

This idea may sound discouraging, but it is actually a reflection of the immense choice and variety one gets with a real GIS.

Earlier we introduced the idea that Manifold can import maps and data from many different file formats. We noted that this was a good thing because it is a lot easier to grab cool maps from Internet for free than it is to create new maps. The good news is that Manifold can almost always import data in a usable way. The bad news is that some data is published using file formats that are so old or so inappropriate for conveying GIS data that they require extra work on our part.

Just like Microsoft Word can read many different document formats, Manifold System can read mapping data in many different formats. The analogy to word processing teaches much that is relevant in GIS. For example, although it is usually simple to import text documents from different formats into Word not all word processing document formats may be imported effortlessly.

For example, many people have experienced frustration when trying to import UNIX or Linux documents into Word (with weird solid block characters where the ends of paragraphs should be…) and have seen extra spacing between lines appear at the end of paragraphs when importing from or exporting to documents in HTML formats. Imported documents might use fonts that we do not have on our system so substitutions must be made. Experienced Word users will learn the idiosyncrasies and limitations of different formats they encounter on a regular basis so they can make adjustments when importing documents from those formats.

It’s exactly the same situation with map formats. Maps and mapping data are published in a very wide array of formats, some of which are very old and full of strange limitations and legacy idiosyncrasies. When importing map data from different formats we need to be aware of the limitations of those formats. Mapping data tends to be more complex than word processing data so there are many opportunities for the limitations of old formats to require extra work when importing from those formats.

In the case of a few modern formats, we can usually quite effortlessly import the core data for the map. However, even with modern formats it is very rare that we can duplicate the formatting and stylistic appearance (line style and color, for example) from one mapping program to the next. In GIS work, therefore, the main focus is to import the raw data of a map and then to apply whatever appearance is desired after the map is imported.

One annoying aspect of importing maps is that much map data has been published as projected maps using very old, technically obsolete formats. Some legacy map data formats do not save projection parameters. When working with projected maps in such formats, the necessary information therefore must be added manually based on notes provided in a "readme" file or other accompanying documentation.

Manifold has a very wide range of converters and options to deal with such legacy idiocy; however, some old formats used by legacy systems are so stupid that there is no avoiding the need for extra thought when dealing with such things. In particular, when working with older formats one must keep an eye out for any accompanying documentation that will be required later to make sense of the data.

Another way in which importing maps may require thought is that sometimes we must choose wisely which maps we will use in a given project.

There are often very many different maps of the same subject matter that have been prepared by different agencies. So, for example, there are often hundreds (if not thousands) of digital maps of the United States that may be downloaded via the Internet to show the same subject in different ways. If one is interested in a map of US shorelines there are many, many different maps that show the shorelines at various levels of detail with varying accuracy. Such maps have been created by different agencies at different times using different data sets for different purposes. So, although they all will correctly show Long Island and other parts of the US more-or-less correctly the maps may differ in various small details, their level of detail and so on.

Part of the total freedom of using a real GIS like Manifold is the responsibility of deciding which data sources to use for which projects. If all we want to do is illustrate some nationwide demographic trend on a map of US states it rarely matters which map we choose. On the other hand, if we are combining data from county maps and state maps from various sources to create a detailed wetlands map of Chesapeake Bay we likely will want to be more careful in the choices of maps we use.
For example, we might wish to use both state maps and local, high-resolution maps downloaded from the USGS servers. This would make it more likely that the shorelines would line up in a neat way with the state boundaries since the same agency prepared them. In contrast, if we used state boundary maps taken from the Bureau of Transportation Statistics (which has a greater interest in roads than in physical geography) and combined them with hydrology maps from the USGS, it is possible there will be subtle incompatibilities such as small misalignments at the boundaries between states or other features in the map.

This can be slightly confusing at first to a beginner, but GIS users quickly discover favorite Internet sites from which to download data and rapidly form strong opinions about which data they like and which data sets they don't like. It's not unusual for someone who has only used Manifold for a week to feel so much like a veteran that he or she will post answers on Internet GIS forums to beginner questions about good download sites for data.

**Key Idea: A street address is not a location**

The only way to locate something in a GIS system is to place it in terms of a specific latitude and longitude location. Street addresses are not the same as a specific latitude and longitude location. For street addresses to be usable within a GIS, they must first be **geocoded** so that each street address record also has latitude and longitude values showing where that address is located. For example, the following table is not geocoded, because there are no latitude and longitude values for each record.

<table>
<thead>
<tr>
<th>Name</th>
<th>Address</th>
<th>City</th>
<th>State</th>
<th>Zip</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sushi Ya</td>

</table>

It is easy to make the conceptual mistake of thinking of a street location as being an exactly defined location, the same as a latitude/longitude location. However, that mistake arises mainly from how people use addresses to find locations for the delivery of mail or to go to a particular restaurant or other location.

Street addresses, of course, do not really convey an exact latitude and longitude for the address. They simply provide a means by which a postal carrier or someone else physically traversing the streets can find a particular address. To find an address we have to find the street (with the help of a map if we don't know a particular town), orient ourselves to the address system used on that street, and then locate the address. As anyone who has tried to find an out-of-sequence address in an unfamiliar town knows, there is a great difference between hunting down a particular street address and going directly to a latitude/longitude location.
It is one thing to be able to find a given street address by physically going there (perhaps with the help of a local street map) and it is quite another thing to plot a table of street addresses, such as a table of restaurant addresses, on a map as seen above without ever going to the actual address. To plot each restaurant shown in the table we need to know the actual latitude and longitude address at which it is located. To do that, the table must be geocoded as seen below.

<table>
<thead>
<tr>
<th>Latitude</th>
<th>Long..., Name, Address</th>
<th>City</th>

</tbody>
</table>

In recent years the adoption of geocoding technology by consumer computer applications has also encouraged us to think of street addresses as being equivalent to a latitude/longitude location for the purpose of computer mapping. Internet mapping sites allow us to enter a street address, such as "525 Main Street, Central City," and instantly see a street map with the location of the address marked as if we had provided an exact latitude and longitude location. Low cost navigation systems that combine GPS technology with built in maps and street address geocoding systems allow us to specify a street address and navigate directly to that location, again, as if we had given exact latitude/longitude coordinates for our desired destination.

As a result, it is quite common for people to expect to be able to enter a street address into a web site or a map and to see a physical location for that address, a sort of "geocoding on the fly." Some applications may give the appearance of taking a list of addresses and displaying them straightaway as points in a map. However, in all cases the software will internally take the intermediate step of using the address to determine a latitude and longitude location for the record. The latitude and longitude location is then used to plot the location of the point.

Software packages use many different strategies to geocode street addresses into latitude and longitude locations. The basic approach is to maintain a large database of streets and address ranges so that the location of a particular address can be estimated from the database. Software that can perform street address geocoding may be built into a GIS package, it may be sold as separate geocoding software, or it may be provided as an Internet web service.

Manifold includes street address geocoding capability for the United States as a built-in capability of Manifold System. The Manifold street address geocoding engine becomes functional when the Manifold US streets geocoding database is installed. If we have installed the Manifold US streets geocoding database on our system we can take a table that contains valid US street addresses and geocode the table to the approximate positions of the address.

However, when using any street address geocoder it is important to understand that the output of the geocoder is an approximate location. See the About Geocoding topic for why this is so.

**Key Idea:** Images are poor substitutes for drawings in GIS.

So far we've used the word map as if it always means a type of drawing or diagram that showed geographic things. It's time to expand our awareness by learning there are really two types of data in common use in the mapping world: images and drawings. The main Key Ideas topic discusses the difference between images and drawings in an overview way and the various topics in this documentation discuss images and drawings in ever-greater detail and sophistication as we read further through this Help file.

Images are the familiar .jpg, .bmp, .tif and similar images we encounter in ordinary graphics arts work. When we scan a photograph we create an image, and when we draw something in Microsoft Paint or Adobe PhotoShop we create an image. Images are also known as rasters, a very old word arising from the television industry back in the dawn of time. Images are made up of pixels arranged in neat rows.

29
Drawings are created by CAD editors like AutoCAD and by cool GIS programs like Manifold. They are made up of points, lines and areas defined by precise coordinate points in a connect-the-dots fashion. Drawings are also known as vector data sets, the word "vector" also being very old jargon taken from the days when primitive computer monitors worked like radar monitors or oscilloscopes.

Drawings have an immense advantage over images in that the items that appear in drawings are readily identifiable (to the computer) "objects" that can be easily manipulated, moved, copied, pasted, edited and linked to database records. In contrast, there are no objects in images, only a sea of pixels. However, images in the GIS and mapping business have one seductive aspect that lures people into using them. Images are easy to make by scanning paper maps in a cheap PC scanner. In a world where most maps are still paper maps, there is a lot of appeal to the idea that one might be able to create a GIS map by simply scanning in a paper map.

Unfortunately, the idea is mostly false appeal. As anyone who has operated a scanner knows, scanning a photograph or map into a PC results in huge files (easily over a hundred megabytes) that have very limited utility. True, the resultant images can be displayed easily enough but they are virtually impossible to manipulate. Try, for example, scanning a road map into a PC and then using a graphics editor to grab a particular set of lines (like highways, or terrain contours, or the borders of a national park) and paste it into some other document. Even with a highly sophisticated graphics editor such as PhotoShop this is almost impossible to do.

The reason why is that we would be attempting to manipulate an illusion. There are no objects in an image, only pixels. The objects we see in them are not real artifacts but rather are inferences arising deep within the human cognitive system. When we see a "line" in a road map we average out the visual effect of thousands of pixels (some very ragged) and conclude we see a line. The computer sees only pixels of different colors.

People often would like to create a new, highly detailed drawing that can be used as a true vector GIS map, but they are put off by the major effort required to create such drawings. The idea of simply scanning in a paper map as an image and then waving some magic wand to make the computer recognize everything in the image and convert it to a vector drawing is a wonderful idea. But this is not yet reality. To date, computers cannot recognize objects in images and create vector equivalents in a way that automates the digitization of images.

If images have these drawbacks, why then does Manifold provide such a rich set of image manipulation capabilities? The reason is that images are very useful in GIS. People do undertake the effort of creating new vector maps despite the labor required. Images (satellite and aerial photos) are almost always the starting point. Not all drawings involve thousands of objects. Some drawings might show the layout of a farm or a few trails in a forest plot and could be created very rapidly by tracing over an image to create a new vector drawing. When assisted with smart editing tools (like those in Manifold) people can rapidly create very useful drawings from images in a matter of minutes. Images can also be used as beautiful backgrounds for vector layers in a map and can be used to provide realistic texture in 3D terrain simulations.

Raster data sets are also a very handy way of working with data that arises from remote sensors, such as those used for data acquisition from satellites. This and many other wonderful ways of using images are set forth throughout the rest of this documentation. For now, the new GIS user should trust us that images have their uses, but being a cheap substitute for vector drawings is not usually one of them.

**Key Idea:** The GIS landscape is still cluttered with living fossil ideas and products.

GIS as an industry is going through the same modernization that the computer hardware industry went through ten or fifteen years ago when aging, massive minicomputers from companies like DEC were replaced by personal computers from companies like Dell. Just as in the case of that hardware transition, the GIS software industry is now moving from a market populated by old-fashioned, overpriced legacy companies and products to a more modern market based on mainstream software ideas (such as those used within Manifold) that can deliver much greater capability at a much lower price.

However, just like minicomputer dinosaurs did not die off overnight the GIS market will take time to reach full modernization. Until that happens there will be many living fossils cluttering the GIS landscape. Such living fossils can range from the provision of government data sets in seriously obsolete formats to the tendency of conservative organizations, like some college faculties, to teach obsolete notions about GIS as if they were the latest thing. In fact, in some organizations GIS users may not even be aware that software has improved a lot in the last five or ten years.

Manifold users should therefore try to avoid being frustrated when they encounter GIS people talking about old-fashioned things as if they were the current state of the art. Be patient with such people and help them understand that software has evolved a lot in the mainstream and that GIS users can gain many benefits by using GIS software that leverages modern techniques and recent advances in mainstream computer software technology.
When learning more about GIS, keep in mind that GIS books and courses may be seriously obsolete. The reader should go forth and read all possible about GIS to gain deeper understanding and a better life. But at the same time, keep in mind that some "experts" and writers of books will falsely present obsolete GIS ideas and technology as contemporary stuff.

Some writers will also be so wrapped up in politically correct notions about "open" software that they will merrily ignore advances in the mainstream in order to advance obsolete notions about GIS which, although grievously behind the times, are "freeware." A useful touchstone in such cases is to see if the author gushes on about "GRASS," an obsolete program created by the US Army decades ago that is now freeware. If the author is excited about GRASS, that is almost proof positive it is time to turn the page and move on. On the other hand, if the author writes effectively about how to leverage modern software ideas like Microsoft's .NET framework, then that's a good indication the writer is in close contact with modern technology.

Note that manifold.net is not against learning all that can be learned from legacy software, or leveraging all that can be leveraged from "open" software: it is just that in doing so we should not give up the opportunity to leverage the mainstream and modern technology. It's a question of balance and inclusiveness, not religious mania for one thing or another. So, for example, it can be very cool to experiment with the open SourceForge .NET distribution of the Python language within Manifold even though this is not as "Microsoft" an approach as always using Visual Basic scripting.

As mentioned in the beginning of this topic, for many years GIS lagged far behind progress in mainstream computer markets. Until the PC revolution came to GIS, the GIS market was dominated by very old products from very old companies. Many of the books written about GIS and many college courses teaching GIS really do not teach GIS so much as they teach the ins and outs of working with specific, seriously obsolete software packages. It is as if one signed up for a course on computers and ended up in a college course that taught how to program IBM 370 mainframes in COBOL using punched paper cards.

Even in cases where books and courses do not take a "trade school" approach to teaching a specific obsolete package, the authors may be under the influence of obsolete technical ideas. Older generations of GIS programs required a massive amount of user activity to help the program do what in modern times we do with a point and click of the mouse. Quite a few people still teach GIS as if one still must program the GIS application using some command line interface to do elementary tasks. Avoid such teachers.

A handy rule of thumb to judge the modernity of GIS teachers is to assess the degree to which they focus on Microsoft Windows operating systems. If they are fluent in Windows concepts such as .NET and illustrate their lectures with practical examples of data interchange via OLE DB, ODBC, ADO.NET or other Windows concepts, it is likely that they have a contemporary view of software in general and GIS software in particular. If they start a lecture by delving into the intricacies of dead languages like AML or Avenue, they should be avoided.

We realize this comment may annoy those readers who favor non-Windows systems, but it is a useful rule of thumb nonetheless. As a software ecosystem, Microsoft Windows features intense competition between tens of thousands of applications. Windows markets include hundreds of millions of buyers who have extremely high expectations for maximum performance at rock bottom price.

The result is that Windows markets have featured faster evolution of user interfaces and many more new ideas for interactive software than any other market. Advances in user interfaces are one of the key measures of the modernity of a GIS, so expertise in Windows is a useful measure of the modernity of a GIS (and a GIS instructor) because only very modern user interfaces have a chance in the Windows ecosystem.

For additional radical manifold.net perspectives on GIS, see the Essays topics. To continue this introduction to Manifold System, proceed to the main Key Ideas topic.
Key Ideas

This topic assumes the reader is familiar with basic GIS concepts. If you are new to GIS, please read the Key Ideas in GIS topic before proceeding with this topic.

**Key Idea: Manifold requires Microsoft Windows fluency.**

Manifold is a Microsoft Windows application through and through. Success with Manifold requires fluency with Windows. This is good news, because Windows expertise built up with Manifold will serve you in many other applications as well.

Windows includes many helpful techniques and "power moves" to make life easier for people who work with computers. If you have not yet taken the time to master Windows, now is the time to do so. Most Windows power moves are used within Manifold. For example, when highlighting records in a table to quickly highlight a group of records simply click on the first record to highlight it and then SHIFT-click on the last record and this last record as well as all the records in between will be highlighted.

While some Windows power moves are a matter of convenience, other power moves (such as those involving Clipboard Copy and Paste As) are so important within Manifold that fluency with them is mandatory for success with Manifold. Read the Windows topic to learn essential Windows nomenclature and techniques as they are applied to Manifold.

Because this documentation uses exclusively Windows nomenclature, it is **absolutely essential** that users new to Windows read the topic to learn what terms like "the focus" mean. The Windows topic also describes essential Manifold power moves used by expert Manifold users, so it should be read even if you are already a Windows power user.

**Key Idea: Manifold uses context sensitive windows, toolbars and panes.**

The different windows and panes that are may be opened in Manifold all maintain their own contexts. Whenever we click on a window, Manifold knows what type of window it is and will automatically enable and disable menus and controls as appropriate for that type of window. Any control panes that are open will automatically switch their contents to show the correct information and settings for the active window. Toolbar buttons will appear and disappear as appropriate for the type of window that is active. Toolbar buttons that cannot be used in the current context will be disabled. For more on the philosophy behind Manifold's user interface, see the essay User Interface Design in the Appendices.

**Key Idea: Projects are the “documents” of Manifold.**

The key documents for Manifold are projects, saved as a single .map file. These are analogous to the .doc files that are the documents for Microsoft Word, or the .mdb databases that are the documents for Access or the .xls spreadsheets that are the documents for Excel. Whenever we do a File - New or File - Open or File - Save command in Manifold we are creating or opening or saving a .map project file.

Projects contain components. Components are items such as drawings, images, tables and maps within the project. The minimum series of steps to create a map in Manifold is to:

- Create a project.
- Import or create a drawing or image.
- Create a map based on that drawing or image.

All the components of a project are kept in one file, the .map format project file (".map" = manifold project).

We must resist the impulse to imagine that the different components listed in the project pane are different files. They may have been imported from different files but now that they are in the project they are all stored as one file. This makes it easy to transfer a project from one place to another without risk that some important part will be left behind.

There are three exceptions to above rule of keeping all data in the project file. The first exception is that tables can be either imported into the project or they can be left as external tables that are dynamically linked into the
The second exception is that linked drawings are automatically created on the fly from an external geocoded database table.

The third exception is the use of Enterprise Edition to save components within Enterprise servers. Enterprise Edition allows control over whether shared components are cached or not cached. If they are not cached, they will take up no space in the local project but rather will be stored only on the Enterprise server.

When working with a project that uses external tables or connections to Enterprise servers we take on, of course, the responsibility of correctly maintaining links if we move the project to a different computer system.

**Key Idea:** The differences between drawings and images.

**Drawings** are things like blueprints, CAD drawings and GIS vector maps. They are made up of precise points, lines and areas between exact coordinates that retain an exact, crisp appearance no matter what the zoom level. The points, lines and areas in drawings are objects that may be selected and manipulated as distinct entities. The objects in drawings are linked to database records so that the drawing can be used as a visual user interface to grab and display data in the database. Almost all GIS maps will be imported into Manifold as drawings.

**Images** are things like photographs, scanned documents, or raster satellite scans. Images are made up of pixels. Zooming into an image results in a less crisp view as the individual pixels blossom into view. What appears to be a sharp line or point at one zoom level will drastically change appearance when we zoom in: at high magnification it will be seen as a line-shaped or round cloud of pixels. There are no "objects" in images - only pixels. What appear to be distinct entities in an image is simply the result of human cognitive perception that averages many pixels into some recognizable thing.

To use a word processing analogy, a drawing is like a text in a Microsoft word document made up of individual letter "objects." By changing the font used in Word, we can make the same letter six points in size or 128 points in size without any loss of meaning. Changing the formatting of the letter does not change the letter from, say, an A to a B.

In contrast, an image is like a .gif or .jpg screen shot of a text document. If you've ever downloaded an image from a web site that includes writing, you know that such an image cannot be edited to change the font. One cannot highlight a "word" in a .gif image and copy it into Microsoft Word. If you open the image in Microsoft Paint or Microsoft Photo Editor, you know that the text it apparently contains is nothing more than a cloud of pixels in letter shapes. The appearance of text that we see is simply the result of how our eyes and brains average out the pixels to recognize letter shapes. We cannot "grab" the text and change the font, because there is no text really there…. it's just a cloud of pixels in letter shapes.

There is a similar difference between vector drawings used in maps and raster images used to show maps. If we have a "vector map" - a drawing - we can grab and move and change the elements of the map with great precision just like we can highlight a line of text in a Word document and change the font size. That cannot be done with images. Because it is easy to scan a paper map than it is to create a precise vector map, some older types of GIS programs use maps that are scanned raster images. These are easy to make at first (just scan a paper map in the scanner) but they cannot later be changed in precise ways. We can no more "grab" a road line in such a map and change its size than we can grab the pixels of a .gif that shows letters and change their font.

Manifold includes extensive raster capabilities that may be used to display and manipulate maps that are made up of scanned raster images. However, it is important to understand the strong points and weak points of using vector drawings and raster images in different situations. Very often a cool map will combine both drawing and image layers. For example, an aerial photograph image might be used as a background to provide context for a vector drawing of a road system.

See the individual topics on Drawings and Images for more detail on the differences between the two and how they are used.

**Key Idea:** Formatting determines the appearance of drawings.

Images look the way they do based on the colors and arrangement of their pixels. Drawings are different, because they are made of lines and points and areas that look like abstract figures until you tell them what they are supposed to look like.

Lines in drawings will look like plain, thin, black lines by default. We can format them to specify different colors, thickness or line style to achieve different visual effects. For example, we could format a line to look like a path of alternating red and black boxes. Points look like small dots by default. We can increase their size or change
their color or use different styles (including complex icons) to represent points. By default, areas look like gray shapes bordered by a thin boundary of darker gray.

Changing the formatting of objects in maps is analogous to changing the font formatting of text in Microsoft Word. In Word, we highlight text to select it and then we can apply formatting. In Manifold, formatting is applied throughout an entire drawing at once. To create a map that shows different objects in different formats we can stack many drawings as layers. Each drawing can use whatever format is desired so that the map creates the overall effect desired.

Formatting is easy and fun but it requires understanding that the formatting applied to the drawing is a different concept than changing the actual contents of the drawing. It’s like formatting a text in Microsoft Word: changing the font formatting of a text in Word can radically change the visual appearance of that text but the content (the actual words) stays the same no matter what formatting is applied.

A refinement: Drawings may also use thematic formatting, where the colors or styles of objects are automatically based on the data they contain. For example, a map showing provinces might be formatted so that the provinces are automatically colored by their per-capita income taken from a table of demographic information for each province.

Key Idea: Selection

Just about everything we do in Manifold involves selecting something first and then applying an operation to that something. We can select some pixels in an image, some objects in a drawing, or some records in a database. Manifold has a standard, uniform way of making selections and then combining them through selection modes and selection commands. It’s a simple idea that once understood opens the door to great power. How to use selection commands in Manifold is a key idea that must be mastered. See the Selections topic for the essential introduction.

There are many different ways to make selections in Manifold. Visual selection commands allow us to select what we see by clicking on something with a mouse or by drawing a mouse box that encloses items to be selected. If we wish to select items based on the data associated with them we can use SQL in a query to select something with industry-standard Structured Query Language (SQL) based on the data attributes. We can click on items we see in a chart or we can highlight individual records in a database table. We can even use solvers or programs to select items. Most importantly, we can combine these different methods to get exactly the right selection desired using the most convenient view of the data. So, we might select all the counties in a particular region with a mouse box and then view those counties in a database table so we can further select only those with the largest populations based on the values of a population field.

Visual selection uses selection filter buttons to restrict what is selected by the mouse. There are four filter buttons, one each for points, lines, areas and pixels. The filter buttons allow or disallow selection of that type of item. If the area and line buttons are pushed in but points and pixels are not pushed in, then any mouse motion will select only areas and lines and will ignore points and pixels.

Selection mode buttons specify how any new items picked out are combined with any previous selection. We can use selection modes to replace the previous selection, or to add or subtract items from the selection. More sophisticated modes such as Invert and Select Intersect give fine control in complex maps.

The Selections dialog provides a means of saving particular selections for each window. After spending much time to pick out exactly the right set of objects or pixels, it is nice to be able to save this selection so that if we ever need to work with this set of items again we can fetch it.

Key Idea: Maps and Layers

Maps are project components that are made up of drawings and images stacked in layers. Layers are a very cool and easy way of “stacking” drawings and images on top of each other to create exactly the visual effect desired in the final map. Clicking open a map shows it in a map window.

Double clicking on a drawing opens it in a drawing window, and double clicking on an image opens it in an image window. There is little difference between a drawing or image window and a map window when we have only one drawing or image in our map. Why bother to create a map if we will look at only one drawing?
some of them and move them to a new layer (this automatically creates a new drawing with the name of the new layer and moves the objects into that layer).

For virtually all projects it is best to work in a map window. This will encourage good organization through the use of layers.

**Key Idea:** Databases and Maps

Probably the single most distinctive idea in a GIS is the notion that the visual objects in a drawing can be linked to records in a database. If we have a drawing of provinces and a database of demographic records for each province, for example, we can link the picture of each province in the drawing with the database record for that province. We can then grab records in the database by pointing and clicking on objects in the map. This is a very simple idea of immense power.

Most Windows power users have a lot of experience with databases so it’s quite likely Manifold users already understand basic ideas like records, tables, data fields and so on. Using databases with maps involves a few additional ideas that are straightforward extensions. To support work with database information, Manifold includes many database management features (such as SQL) as well as some powerful database management facilities that are not available in ordinary database products.

Every drawing in Manifold has a database table linked to it. Each object in the drawing corresponds to a record (one row) in the database table. Every field in the database will be a column in the database table. Tables linked to drawings will have at least one field, the object ID field, which provides an identification number for each object in the drawing. Tables can contain other fields as well. For example, a drawing showing cities as points could have a Name and Population field in the table that gives the name of each city and its population.

A drawing’s table can be used like any database table. For example, it can be used to form relationships with other tables, including tables that are saved outside of Manifold in external database providers.

Manifold can also work with database tables that are not linked to objects in a drawing. Manifold provides a vast array of capabilities that may be used to manipulate and analyze database tables of all kinds.

**Key Idea:** Use the Transform toolbar for simple tasks.

The Transform toolbar provides a vast number of operators that may be applied to drawings, images or tables in a one-click way. Functions in the Transform toolbar either have no parameters or only one parameter that need be specified. This allows them to be fitted into a simple toolbar with three option boxes. The transform toolbar will automatically be configured with operators that make sense for the active window. To use the transform toolbar, choose an operator and press **Apply**. If there is no selection, operators will be applied to the entire component. If a selection exists, most operators will be applied only to the selection.

**Key Idea:** Use Layouts for printing

Although Manifold can print directly from any component window, we can achieve finer control over the print job by first creating a print layout and then printing the layout. Layouts provide a highly WYSIWYG (What You See Is What You Get) setting within which we can compose a print job while seeing exactly how it will look on the printed page.

**For More Advanced Users**

- **Projections and Coordinate Systems** - There’s no way around this one! If we want to combine images with drawings in a map we need to know some basics about coordinate systems used with maps and drawings. Sooner or later all intermediate or advanced mapping will involve geographic projections as well. In particular, importing maps often requires knowledge of projections because maps found on Internet are often published as projected maps using "dumb" formats that are poorly suited for publication of projected maps. If we want to be able to use such maps we will need skill with projections just to get around the foolishness of the publisher. (It's as if we needed to learn Latin to download MP3's from the net…) The best course when it is time to learn about projections is to dig right in and do the reading and experimentation that is required.

- **Customization** - Working with the Manifold user interface to change it requires understanding how to use add-ins and scripts to add new commands to the Custom toolbar. Users may also add their own point styles, palettes, custom units of measure and even custom ellipsoids, datums and projection presets.
• **Programming** - Manifold may be programmed within the system using Active Columns, scripts and script forms using ActiveX scripting, or we can program Manifold from external programs written in standard Microsoft languages such as Visual Basic. Manifold includes all software necessary for programming within the system using scripting languages such as Visual Basic scripting or JavaScript. Programming from an external development environment, of course, requires that you purchase and install the external development environment. The Manifold development team prefers working with Visual Basic or Visual C++ within Microsoft Visual Studio, but any Microsoft compatible development environment may be used.

• **Internet Map Server (IMS)** - Use Manifold IMS to publish your Manifold work to live, interactive web sites. Manifold IMS works together with Microsoft Internet Information Server to create spectacular web sites in Microsoft web-serving environments. Simple web sites using default templates can be created without any programming at all. More advanced webmasters, of course, have full freedom to edit the .asp files created by Manifold IMS or to write their own for fully custom applications. Because Microsoft IIS is delivered free on most Windows systems, it is quite likely that most Manifold users have the ability to create a web site on their machines. Such a web site can be viewed throughout the local network and, if the machine is connected to the Internet via a full time link (increasingly common in an age of DSL, cable and other broadband connections) can be published to the entire world. Every Manifold user should take the time to put up an IMS web site if possible. It's remarkably easy to do, very impressive to visitors and a great way to share your GIS work with others.
Introduction

Windows
This topic provides a refresher course in Microsoft Windows "power moves" used within Manifold. It also discusses the standard Windows nomenclature we use throughout the documentation. Finally, it introduces special Manifold power moves used within Windows.

Very Important: Before starting Manifold, go to the Windows Control Panel Display dialog Effects tab and make sure that the Show window contents while dragging check box is not checked. In Windows XP this option is found in the Control Panel's Appearances and Themes - Display choice under the Appearance tab by pressing the Effects button. Checking this box will greatly slow down the system when displaying complex maps and images because it forces a refresh of the window contents with each minor change in mouse position while dragging the window.

Windows Display Settings
Manifold uses many toolbars, some of which will not fit in the default arrangement in lower resolution display settings such as 800 x 600 or 1024 x 768. Rearrange toolbars into multiple horizontal rows or undock some toolbars when using lower resolution display settings. If you cannot find a particular toolbar button, check to make sure the entire toolbar is visible.

Although it's possible to work effectively with a 1024 x 768 resolution, a monitor and video card combination that can show 1280 x 1024 resolution or higher is recommended. You will be able to work faster and more conveniently if there is plenty of room for work area in addition to toolbars and panes a display resolution.

Windows Explorer Settings
Microsoft Windows Explorer by default uses settings that hide the three-letter extension that is part of most Windows files. For example, a file called readme.txt will be shown by default just as readme and will appear with an icon associated with Notepad.

Since the only way to identify many different GIS data files is by the three-letter extension at the end of the file (such as .shp, .mif, .mdb, etc.), it is a good idea to always display the extension. To do so, in Windows Explorer choose Tools - Folder Options and in the View tab uncheck the Hide file extensions for known file types option. This will cause Windows Explorer to always show the three-letter extension for all files.

Experienced users will also often change the setting in the View menu of Windows Explorer to Details so that they can immediately see the size and date of each file. This setting provides a more efficient view than a window full of large icons. The Details setting is also very handy when seeking the most recent file in a folder, because one can then simply click on the Modified column head to sort files in the folder by date of most recent modification.

Windows Files Copied from DVD are Read-only
When copying a file from a DVD to a folder on the hard disk, Windows will create the file on hard disk as a read-only file. To work with these files as one might like in Manifold take a moment to uncheck the read-only attribute. To do this, right click on the file in Windows Explorer, choose Properties and uncheck the Read-only box in the Attributes section. Press OK.

The Active Window
Manifold launches a main window that becomes populated with subsidiary windows as we open projects and components of projects. The illustration above shows the project pane and an image window within the main window as well as a floating toolbar. Toolbars can be floating or “docked” into position into the frame of the main window.

Windows and undocked toolbars have title bars, the blue colored region at the top with the name of the window or toolbar. Move windows about by clicking on their title bars and dragging.

Only one window at a time is the active window in Microsoft Windows. Clicking into a window or touching it in some way activates it to make it the active window. The active window is also said in some contexts to have the focus. When a window is active its title bar changes to the highlighted color specified for active windows in the Display appearance settings specified in your Windows Control Panel. The active window is always on top of other windows.

In addition to the change in title bar color, windows will often have subtle visual cues to help indicate when they do not have the focus. For example, in Manifold text windows such as comments, query or script windows that may have text selected in them with the usual “white on black” block indication used in Windows that the text is selected will have the dark background used to indicate selection faded to gray when the window does not have the focus. This makes it easier to immediately see the active window when many text windows are open.

Manifold windows are context sensitive. The main menu and toolbar controls will change to support use of whatever window is active. Manifold toolbars and toolbar buttons are designed to preserve commonality of function as much as is possible, so that when the focus changes from a drawing to an image window the selection buttons will retain their appearance. However, their function will change in subtle ways to support the slight differences in selection operations between objects in drawings and pixels in images.

Some applications will use a window’s title bar to report information about that window. Manifold does not do this because there is usually more information we like to see than will fit in the title bar. Instead, Manifold uses the main Manifold window’s status bar at the bottom of the screen to show information relevant to the active window.

**Resizing Windows**

Windows may be resized by clicking and dragging on their borders. Clicking and dragging on a window’s corner will resize it both vertically and horizontally at once.

Each window has three small buttons in the upper right hand corner. These are:
Minimize 
Minimize this window into a floating title bar.

Maximize 
Maximize this window to fill the main window.

Close 
Close this window.

Minimizing a window converts it to a small floating title bar positioned near the bottom of the main window. This is a useful method of getting a window temporarily out of the way when working with many windows at once. Minimized windows may be dragged about by their title bars to a new position.

The restore button will appear in the minimized window’s title bar. Click this button to restore the window to its previous size.

Maximizing a window expands it to fill the main Manifold window. The title bar will be combined with the title bar of the main window. We can also maximize a window by double clicking on the title bar. Note the default checkerboard background of an image window that appears wherever the image has no pixels. See the Layers pane topic for info on the background.
Maximized windows have their restore control buttons just below the window buttons of the main Manifold window.

Click on the **restore** button to restore the maximized window to its previous size.

When maximizing one window, Microsoft Windows assumes we want all windows to be maximized. Therefore, if we have several windows open and one of them is maximized and then we switch to another window (either by closing the “top” window or by using the **Windows** menu to switch to a different window) we will see that all of the other windows are maximized as well.

**Autohide / Popup Panes**

Panes used for controls can be minimized when docked so that they autohide themselves when not in use and automatically pop open when the mouse cursor moves over their tab. Virtually every experienced Manifold user employs this feature to maximize the amount of screen area available for working with component windows. See the **View - Panes** topic for details.

**Full Screen Mode**

Choose **View - Full Screen** or press the **F11** key to expand the main Manifold window to full screen mode, using the entire monitor screen and eliminating the title bar and menu bar. If toolbars are hidden using **Tools - Customize** and a window is maximized the result is a “full screen” display. Press **F11** to get out of full screen mode.

**Arranging Windows**

The **Window menu** allows us to arrange windows within the main Manifold window.

- **New Window** - Enabled when a component window is activated. Open a new window into that component.
- **Close** - Close the active window.
- **Close All** - Close all windows.
- **Next** - Activate the next window in the stack.
- **Previous** - Activate the previous window in the stack.
- **Cascade** - Arrange windows neatly in front of each other and offset slightly.
- **Tile Horizontally** - Arrange windows next to each other left to right and resize so they fill the main window.
- **Tile Vertically** - Arrange windows next to each other top to bottom and resize so they fill the main window.
- **Windows...** - Open a dialog that lists all windows.

See the Windows Dialog topic for additional info.

**Panes**

**Panes** are a type of window that can be left “always on top” or docked into the left or right edges of the main Manifold window. Panes are used to display information or controls that are always to be kept in view while work goes on in other windows. Panes may be repositioned by dragging their title bar to a new position. Panes may be resized as well.
Manifold has several panes, such as the project pane and the layers pane, that are important parts of the user interface and which are normally left open. Panes can be turned on/off using the View - Panes menu or with keyboard shortcuts like SHIFT-ALT-P (open/close the Project pane).

See the View - Panes topic for a list of panes and to open and close panes. Panes may also be closed by clicking the X box in their caption bars. Familiarity with panes and their use is a mandatory skill within Manifold.

Note: The word "panes" can also be sub-areas of main windows that might be used to keep some information in view while another part of a window shows a changing display.

Toolbars

Manifold duplicates many menu commands in the form of toolbar buttons. Manifold command buttons all have Tool Tips, which are quick labels that pop open if the mouse cursor lingers on the button. Toolbars may be turned ON and OFF under the Tools - Customize menu. A right mouse click on the main menu bar calls up a shortcut to the Tools - Customize menu.

Individual toolbars may be dragged to different locations on the display. They may be "docked" into the upper or lower screen edges or left "floating" in the middle of the display. Move a docked toolbar by dragging the 3D ridge at the left or top of the toolbar. Move a floating toolbar as you would any window, by dragging its title bar. Use a CTRL-drag to drag a toolbar past the normally docked position.

Manifold toolbar buttons are context sensitive and are not enabled unless they can be applied. For example, unless we are working on an image the Select Pixels selection mode button will not be enabled in the Selection toolbar.

The toolbar above is in its undocked form, with a title bar. In docked form, toolbars do not have a title bar. Toolbars may be undocked by dragging them (using the small 3D ridge at the left side or top of the toolbar) into the main Manifold window pane.

To quickly see which toolbar is which, use Tools - Customize to turn it ON and OFF. As the toolbar turns ON and OFF it will be obvious which it is.

Docking and Undocking

Toolbars and panes can be docked into the main Manifold Window. Because toolbars are very wide but not tall, they can only be docked into the upper or lower edges of the main window. Because panes are normally taller than they are wide, they can be docked only into the left or right edges of the main window. A docked pane will expand in height to fill (or share) the available vertical space at the edge of the main window.

Toolbars and panes may be docked into the top, bottom, left or right margins of the main Manifold window. Most toolbars are docked by default and most panes are not docked by default.

To move a docked toolbar, click and drag on the toolbar's move handle. To undock a toolbar, move it into the main work area.
An undocked toolbar may be docked by dragging and dropping it into the desired position in the main window's margins.

When a pane or toolbar is brought near to or on top of a margin using a click and drag, it will automatically dock itself. To override this, use a CTRL click and drag. This will allow you to drag a pane or toolbar over top of a toolbar row or near to a window margin without the pane or toolbar docking itself.

To undock a docked pane, click and drag it from the docked position into the main Manifold window area. Click and drag on the small 3D ridge at the left side of the docked pane to move it.

To undock a docked pane and drop it near the margin, use a CTRL click and drag onto the title bar.

Drag it to a position near the border while holding down the CTRL key. The CTRL tells Manifold not to dock the pane even though it is near the border.
Release the mouse at the desired position of the undocked pane. The illustrations above show a greatly minimized main Manifold window. In real life we would use a reasonably large computer display with high resolution so we can display many controls and panes while leaving room for practically sized working windows.

Panes may also be resized by dragging their horizontal or vertical borders. When panes are docked together, the borders between them may be dragged to resize them relative to each other.

**Mouse Moves and Context Menus**

A **left click** or left click and drag of the mouse is normally an "action" command that does something. A **right click** is normally an "information" command that requests information or a choice of options. Whenever we simply say "click" the mouse, we always mean a **left click**.

Right clicking into windows or onto parts of windows or other controls will often call up a **context menu** of available choices. For example, right clicking onto a layer tab in a map window will pop open a context menu of commands that may be applied to that layer. Right clicking onto a column head in a table will pop open a context menu of commands that may be applied to table columns, such **Sort Ascending** and **Sort Descending**.

**Using the Scroll Wheel on Wheel Mice**

Some mice are equipped with a scroll wheel, normally positioned between the two buttons of a mouse. The scroll wheel may be used in Manifold to zoom in and out of visual components like drawings or images and to scroll up and down in text components like tables.

Using a scroll wheel in a drawing, image, labels, layout, map, profile, surface or theme window zooms in and out. Holding the **Ctrl** button down on the keyboard while using the scroll wheel will force zooming near the center of the window.

When zooming, each zoom step will be made using the **Zoom magnification factor** specified in the Tools - Options - User Interface dialog. This factor specifies the change in magnification to use when zooming in or out in the range from **1.1** to **4.0**. The default value is **2.0**.

Using a scroll wheel with text components like tables or comments will scroll up and down through the text, just like moving a scroll bar up and down.

**Note**: When Manifold is used as an ActiveX control within other applications the scroll wheel will still zoom in and out.

**Windows Dialog Controls**

The various buttons, edit boxes, menus and other items that appear in a Windows dialog or other window are called **controls**.
**Color wells** are squares that provide a color choice. Click into a color well to choose it, for example, in the main Windows color dialog.

Color wells also occur in toolbars.

Clicking into a color well in a toolbar will usually call up the Color dialog to enable setting that color. Manifold’s toolbar color palettes will provide an array of colors where the first row presents variations of the current color. Choosing More calls up the classic Windows color setting dialog.

**Check boxes** are simply on/off controls. Click the box to turn that item on/off. A special type of check box is an option button or radio button, which is a small round control with a dot in the middle. Option buttons are used in groups where only one option button of the group may be checked. [Hence the slang term "radio button", since just like the channel choice buttons in old car radios pushing one button in pushes all other buttons out.]

**Text boxes** or Edit boxes allow users to enter or choose data. Edit boxes will often have lists that provide a choice of allowed options, in which case they are known as a List box. Click on the down arrow button to see the list and then click on the choice desired. Some list boxes will have so many choices that they will have a scroll bar that may be used to scroll through the list. Dropdown lists that appear are also known as drop down or pull down menus.

When navigating a long list of choices in a list box entering the first letter of a desired choice will scroll the list to the first entry beginning with that letter.
For example, the transform operators list box in the transform toolbar for drawings has many choices. With the mouse positioned in the list if we would like to scroll directly to the **Union** operator we can enter the "u" character at the keyboard.

The list will immediately scroll to **Union** and highlight that operator. We can then press **Enter** to choose that operator or click on it with the mouse to choose it.

Some edit boxes allow either choosing from a list or they will also accept a value entered by the user by clicking and entering text into the box. Such edit boxes are also known as **combo boxes**. If we can click into an edit box in Manifold, we know that we are not restricted to only those choices presented in the pull down list.

Edit boxes are often associated with **slider** controls in image commands. Moving the slider back and forth will automatically change the value in the edit box. Alternately, we can click into the edit box and enter a number directly.

Once clicked with a mouse to become activated, a slider bar can also be moved left or right using the **Left Arrow** and **Right Arrow** keys on the keyboard. This is a very handy method when working interactively with a previewed control. For example, when setting the level of water in a terrain window for waterline effects, we would open the **Terrain - Water** dialog, check the **Preview** box, click on the **Level** slider and then use the left and right arrow keys to move the slider up and down.

**Spin buttons** or **UpDown** controls are small up and down arrows inside some edit boxes. Clicking on the up arrow increases the value in the edit box by a pre-designated amount. Clicking on the down arrow decreases the value in the edit box. Most edit boxes with spin buttons will also allow direct user entry of the value by clicking into the box without using the spin buttons.

Once clicked with a mouse to become activated, the value in an edit box with spin buttons can also be increased or decreased using the **Up Arrow** and **Down Arrow** keys on the keyboard.

**Note:** Manifold's built-in programming environment allows us to create our own dialogs and forms using the above controls and many, many more. See the Form Controls topic for information.
When working with a Windows dialog, only one control at a time in that dialog will have the **focus**. The control that has the focus will normally be highlighted with a fine dotted outline or other indication that it has the focus.

![Yes No](image)

Clicking into an edit box will move the focus to that edit box, which is shown with the cursor in the edit box. Pressing **Enter** on the keyboard applies the action of that control. For example, in the illustration above the **Yes** command button has the focus, so if we press **Enter** on the keyboard it is as if we pressed the **Yes** button with the mouse.

Clicking the **Tab** key on the keyboard will move the focus between controls in the dialog using whatever **tab order** the designer of the dialog specified. Many windows dialogs will start out with the focus on the **OK** key or other "yes, do it" key in the dialog. This makes it easy for people to respond to dialogs by simply pressing **Enter** on the keyboard if they agree with the default settings shown.

The **ESC** ("escape") key on the keyboard is used to exit or abandon many mouse modes or commands in windows. The **ALT-Tab** key combination may also be pressed as an equivalent to **ESC** if some program or information dialog (such as a "download complete" when downloading files in background) has snatched context away from the Manifold window.

Pressing the **ESC** key will also escape from any tool mode, such as zoom tool or selection tool and will restore default "smart mouse" selection.

**Changing Values**

Many Windows dialogs will provide lists of items (files, components, properties, parameters, etc.) with a name or value for each item.

![Map 2](image)

Clicking on the item will usually highlight it.

![Map 3](image)

A rapid double click will often open the item (if it may be opened), whereas clicking once to highlight the item, pausing, and then clicking it again will open it for editing. For example, we can rename "Map2" to "Globe".

![Globe](image)

We enter the characters "Globe" and then press **Enter**. If we wished to abandon the edit we could press the **Esc** key.

![Globe](image)

The above edit sequence may often be accomplished by right clicking on the item and choosing **Rename** from the context menu that pops open.

**Jumping Through Long Lists in Combo Boxes**

When choosing items from a long list in a combo box, Windows allows us to enter a keyboard character and the list cursor will jump to the first item in the list that begins with that letter. Entering more than one character quickly will jump to the first match in alphabetical order to the text entered.
Windows uses a timer to tell the difference between typing single letters and typing a group of letters to be interpreted together as a word. For example, using the Query toolbar’s Operations combo box, if we click into the combo and press M the selected operator will change to Maximum, the first choice in the Operator list that begins with the letter M. If we wait a few seconds and press E on the keyboard the selection will change to Equal to, the first choice that begins with the letter E.

If we wait a few seconds more and then rapidly type ME the selection will jump to Median, the first choice that begins with the letters ME. Because the letters were typed rapidly together Windows knows we want them to be interpreted together as a text string and not as a desire to first jump to the Maximum choice and then to jump to the Equal choice. If we had paused between the two letters Windows would have understood them to be separate choices.

Conveniences in Windows Dialogs

Manifold provides a rich set of Windows features in most dialogs. The illustration shows a Windows 2000 dialog.

For example, the illustration above shows the File - Import - Drawing dialog set to import SHP files. The four icons in the left-hand pane of the dialog allow convenient jumps to different places in the file system.

The History icon is especially convenient because it provides shortcuts to folders and files previously visited. If we import files from two or three different folders (which could be located on different machines) the History icon lets us jump directly to any one of them.

Most Windows dialogs in Manifold are “live” Windows Explorer sessions as well. Right click into the pane to call of a list of commands. For example, within the Import dialog seen above we can rename files that are displayed, create new folders, copy and paste files and so on. [In the example above we see an ESRI .shp file. “Shapefiles” are actually a set of three files that have the same name but ending with a .shp, .dbf and .shx extension. If we are tempted to copy the .shp file seen to have a backup copy we would have to remember to
copy the .dbf and .shx files as well. One reason Manifold saves files to a single .map file is to avoid such opportunities for errors].

The Files of type box provides a filter that normally shows only those files ending with the specified extension. This is a useful way of seeing only those files that end with a .shp extension.

The illustration above shows a Windows 2000 dialog. Because Manifold uses the facilities of the host operating system to provide standard dialogs with standard controls, the appearance of dialogs will vary to match prevailing standards in whatever version of Windows is in use. Some features provided by Windows 2000 or XP will not be available in earlier Windows versions.

The Windows Clipboard

Windows operating systems provide a Clipboard, which is a temporary storage location to which almost anything in Windows can be copied. The Clipboard is common to all Windows applications. Expert use of Windows almost always involves the Clipboard.

Whenever something is copied using Edit - Copy or a Copy command in a standard Windows context menu the data that represents that something is copied to temporary system storage within the Clipboard. Using Edit - Paste or a Paste command from a context menu will paste whatever is in the Clipboard into the active window.

Applications programs vary in their sophistication and ability to use the Clipboard. Virtually all applications can handle copying of text to the Clipboard and pasting of text from the Clipboard. More sophisticated applications are able to copy more complex data, such as images, and to accept pastes of complex data as well.

Within Manifold we use the Clipboard for a very wide variety of applications. Virtually everything within Manifold is Clipboard-enabled. Use the Clipboard for simple things, such as copying the name of a file from Windows explorer and pasting it into a new name for a project or component. Use the Clipboard for more complex work such as copying geographic objects from one drawing and pasting them into another, or for copying pixels from one image and pasting them into another.

There may be some limitations to the universal use of Copy and Paste caused by incompatibilities between the source and destination. For example, when using Copy to copy multiple layers from a map one can only Paste back into a map.

Copy and Paste As

Manifold uses standard Windows Copy and Paste As to convert components. For example, the way we create a drawing of points from a geocoded table is to Copy the table in the project pane and then Paste As a drawing. See the Copy and Paste As topic for additional information.

Drag and Drop

"Drag and Drop" is Windows jargon for a simple user interface method that's widely used to copy things or to pick items from one window and insert them into another.

To drag and drop an item:

1. Make sure that both the source window and the destination window are open.
2. Click on the source window to make it active. Position the mouse cursor over the desired item.
3. Press down on the left mouse button and hold it down.
4. Without releasing the left mouse button, move the mouse cursor into the destination window. This is the "drag."
5. Release the left mouse button. This is the "drop."

Drag and drop is used within Manifold in several ways:

- Add components to a map by dragging and dropping them from the project pane into the map. If a map window is open and we would like to add another component from the project pane into the map as an additional map layer, we can simply click on the component’s name in the project pane and then drag
and drop it anywhere in the map window. We don't have to "drop" it onto the layer tabs. We can drop it anywhere in the map window. This component will then be opened as part of the map as a new layer within the map.

- Copy or move controls between forms components. Dragging and dropping a control from one form into another form will copy or move that control.

- Copy items between two different instances of Manifold. Launch Manifold once from the Start button and then launch it again. Resize both instances of Manifold so you can see them on screen. Items can now be dragged and dropped between the two different project panes.

- Adding components to a print layout by dragging and dropping them from the project pane into the layout.

Hot Scroll

Manifold does not use scroll bars in image, drawing, labels, surface or map windows because such windows are limitless in extent. Instead, Manifold uses hot scroll commands using the ALT keyboard button and right mouse clicks. ALT -right click near the edge of a window to move in that direction. Remember ALT as a mnemonic for the "A" in "Arrow keys."

Using ALT or SHIFT-ALT or CTRL-ALT with either a right click or with keyboard arrow keys has the following effect:

- **ALT- (right click)**: Scroll left, right, up, down or in diagonal directions in direction clicked by mouse.
- **ALT- (arrow key)**: Scroll left, right, up, down or in diagonal directions in direction of the keyboard arrow key.
- **SHIFT-ALT- (right click)**: Long scroll. Scroll in greater jumps at each step.
- **SHIFT-ALT- (arrow key)**: Long scroll. Scroll in greater jumps at each step.
- **CTRL-ALT- (right click)**: Jump to top / bottom / left / right edge of displayed data.

Wheel mice are supported in Manifold in cases where scroll bars appear. For example, tables showing horizontal scroll bars will scroll when the wheel is rolled on a wheel mouse.

ALT is also used to extend selections and Clipboard operations within maps to all visible layers (ALT is a mnemonic for "All").

Interactive Repositioning Methods

If the mouse is not occupied in a command mode, we may interactively reposition layers in maps using the following mouse and keyboard commands. To use these commands, the layer being repositioned must use the same projection as the map. See Repositioning Layers.

- **CTRL dragging**: Pressing the CTRL key while clicking and dragging with the mouse will reposition the layer. The method is similar to using the Grabber tool but whereas the grabber tool pans the view, using CTRL dragging moves the actual layer.
- **CTRL <arrow key>**: Pressing the CTRL key while pressing one of the keyboard arrow keys will move the layer in that direction.
- **SHIFT - CTRL <arrow key>**: Pressing both the SHIFT key and the CTRL key while pressing one of the keyboard arrow keys will move the layer in that direction in greater jumps.

Autoscroll

When the mouse is occupied in mouse motion operations such as selection, editing, painting, and so for we would at times like the window to automatically scroll when the mouse gets near the edge of the window. Manifold will
automatically autoscroll as the mouse nears the edge of a window. To turn this off, uncheck the **Autoscroll window on edit or selection operations** checkbox in **Tools - Options - User Interface**.

The sensitivity of autoscroll may also be set in **Tools - Options - User Interface** by specifying how close to the edge of the window the mouse can move before an autoscroll is triggered. The sensitivity is set by specifying the margin in pixels within which an autoscroll occurs.

**Additional Mouse Buttons**

Manifold component windows (such as a drawing, image or map window) will automatically work with standard commands issued by additional mouse buttons on mice so equipped, such as the IntelliMouse Explorer. For example, the fourth and fifth mouse buttons typically issue **Back** and **Forward** commands for views.

**Double Click Short Cuts**

Double clicking on a component in the Project pane will open the component in its own window.

Double clicking on legends, north arrows and scale bars will open the **Properties** dialog for those items. Double clicking on a legend, north arrow or scale bar within a print layout will open it for editing in a dialog.

Double clicking on an object in a drawing will launch your Internet browser using the contents of a **URL** field, if any, in the drawing’s table for that object. If there is no **URL** field or if it is not of type "URL" or if it is empty the **Fields** dialog will be popped open.

**CTRL**-double-clicking on an object in a drawing will launch the **Fields** dialog.

**Keyboard Shortcuts**

Learn to use Windows keyboard shortcuts to choose items in dialogs and in panes. Manifold supports the usual Windows "power moves" to choose items in tables, dialogs and panes. If you are new to Windows, these are essential power moves similar to those used in many applications:

- **Click** Click on a record handle to select it.
- **CTRL-click** CTRL-click on a record handle to select it without de-selecting other records. **CTRL-click**-clicking on a selected record handle will de-select it without changing selecting of other records.
- **SHIFT-click** SHIFT-click on a record handle to select it and to also select all the records between it and another selected record. This is often used to select a series of records: click on the top record handle and then **SHIFT**-click on the bottom record handle and all the records in between will also be selected.
- **CTRL-A** Select all items
- **CTRL-I** Invert Selection.
- **CTRL-X** Cut selected items and copy to the Clipboard.
- **CTRL-C** Copy selected items to the Clipboard.
- **CTRL-V** Paste the contents of the Clipboard into the active window.
- **CTRL-N** New. Open a new project.
- **CTRL-O** Open. Open a previously created project.
- **CTRL-P** Print.
**CTRL-S** Save. Use this to save projects regularly.

**CTRL-Z** Undo the last command (if undoable).

**CTRL-Y** Redo the last undone command (if redoable).

**CTRL-*** (Asterisk on the numeric keypad) With focus on an image component’s window, zoom an image to the native zoom, with one image pixel equivalent to one screen pixel.

**CTRL- +** (Plus sign on the numeric keypad or in the regular keyboard) Zoom in.

**CTRL- -** (Minus sign on the numeric keypad or in the regular keyboard) Zoom out.

**CTRL- 0** Control Zero (in the regular keyboard) - Zoom to Fit.

**CTRL- *** Pressing **CTRL- *** (Asterisk) with the focus on the Project pane expands all components.

**CTRL- /** Pressing **CTRL- /** (slash) with the focus on the Project pane collapses all components.

Note that the asterisk, plus sign and minus sign on the numeric keyboard are not the ‘same’ characters from a shortcuts perspective as the equivalent characters on the main keyboard. These shortcuts work only from the numeric keypad.

When used in maps, Clipboard commands operate only on the active layer.

**Keyboard Accelerators**

Menu and button commands in Windows will often have a keyboard equivalent, which is a single character pressed together with the **ALT** key. For mnemonic purposes, the character chosen is usually one that occurs in the command caption, ideally the first character in the caption if it is not already in use for another command.

Keyboard accelerator characters are normally underlined to let us know they are available. If they are not underlined due to Windows system option settings, underlining may be turned on by pressing the **ALT** key once.

In the example above at right, we’ve pressed the **ALT** key once to turn on underlining. We can see that the **Accept** command button has an **ALT-e** accelerator and the **Look Up** command button has an **ALT-L** accelerator. Pressing **ALT-L** on the keyboard will have the same effect as clicking the **Look Up** button with the mouse.

Windows can be instructed to automatically show underlines for accelerator keys by checking the **Show extra keyboard help in programs** box in the **Keyboard** pane of the Accessibility Options applet in the Windows Control panel.

**Hand Positions for Keyboard and Mouse**

Intermediate and expert users will often use keyboard shortcuts together with mouse motions. One hand is on the keyboard and one hand on the mouse. Keyboard shortcuts are best arranged for right-handed users.
For editing operations, keep the right hand on the mouse and the left hand on the keyboard. For example, with images the mouse is used to select regions of pixels and to click on different windows or to choose layers. The left hand is used to make CTRL-X, CTRL-C and CTRL-V commands to cut, copy and paste to and from the Clipboard. Touch typists will often do a one-handed CTRL-C with the little finger on the CTRL key and the forefinger on the C or V. A CTRL-Z is immediately at hand if an editing operation needs to be undone.

Navigation also goes faster with this arrangement. Use the CTRL key to hot scroll by CTRL-right-clicking with the mouse into the active window to scroll it in the desired direction. When the mouse is in Zoom mode, the ALT key is used to reverse Zoom from Zoom in to Zoom out.

**Keyboard Shortcuts for Panes**

In addition to the standard Windows keyboard shortcuts, Manifold provides a set of keyboard shortcuts for opening/closing panes within the overall user interface.

<table>
<thead>
<tr>
<th>ALT-SHIFT-(letter)</th>

</tr>
<tr>
<td>O</td>
<td>World</td>
</tr>
</tbody>
</table>
ALT-SHIFT keyboard shortcuts are very important for turning panes off and on when working with systems that have small screens. If your screen display area is limited in size it will be inconvenient to open panes and leave them open because they will cover up too much of the active window. ALT-SHIFT shortcuts will allow you to instantly pop open a pane when needed and to make it vanish when it is not needed.

These shortcuts are listed in the View - Panes menu next to the pane they control.

**Keyboard Shortcuts to Import Components**

<table>
<thead>
<tr>
<th>CTRL-SHIFT-(letter)</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>C</td>
<td>Comments</td>
</tr>
<tr>

</tr>
</tbody>
</table>

Expert users should learn the keyboard shortcuts and use them. They will really boost efficiency.

**Keyboard Properties Shortcut**

Clicking ALT - ENTER will open up the View - Properties dialog for the active window.

**Keyboard Modifiers with Selection Tools**

- **ALT**
  When making selections in maps, ALT extends selections to all visible layers.

- **SHIFT**
  Shifts selection to "open" mode.
  
  In drawings select all objects any part of which is within the selection cursor. In images (using Select Touch) the SHIFT key will apply the touch select to all pixels like that one touched even if they are not contiguous.

  In images, a SHIFT modifier selects invisible pixels as well as regular pixels.

  In tables, a SHIFT click on a record selects the range of records between the record and other selected records.

- **CTRL**
  No matter what selection mode is actually set, forces use of Invert Selection mode for that operation. When used with Select Touch in drawings or tables, for example, a CTRL click is equivalent to toggling the selection status of an object or record.

  Holding down the CTRL key while using Select Touch with images will select only that pixel that is touched. This is normally used when zoomed far into the image to select / deselect individual pixels.

**ALT Key in Maps**
Selection operations in maps work only on the active layer. To extend the action of these operations to all visible layers, press the ALT key. For example, drawing a selection box in a map will only select objects in the active layer. Holding the ALT key while drawing a selection box will select objects from all visible layers. Pressing Delete deletes selected objects in the active layer only. Pressing ALT-Delete deletes selected objects in all visible layers. Think of ALT as a mnemonic for "All."

**Keyboard Modifiers with Smart Mouse Selection**

"Smart mouse" selection occurs when the mouse is not occupied with any command mode. It is a default selection methodology used to pick out an object for editing in drawings. An object chosen for editing is also called the primary selected object.

- **Click** Equivalent to Select Touch in Replace mode. Click on an object to select it. All other objects are deselected. Clicking into an empty part of the drawing deselects all objects (with confirmation dialog).

- **CTRL-ALT-Click** Select an object for editing. Click on an object to select it as the primary selected object. All other objects are deselected. Clicking into an empty part of the drawing deselects all objects.

- **CTRL** Invert the selection state of the object without changing the selection state of any other object. Equivalent to Invert mode.

- **SHIFT** Select the object if it is not yet selected. Does not change the selection state of other objects. Equivalent to Add mode.

**Keyboard Modifiers with Paint Bucket Tool**

- **ALT** When used with the Paint Bucket, the ALT key causes the tool to ignore the tolerance setting. This is used to flood the paint bucket throughout the selection.

- **SHIFT** Pour color into non-contiguous pixels.

- **CTRL** Pour color while preserving the intensity level. Uses the Paint Bucket to colorize.

**Keyboard Modifiers with the Tracker Tools**

- **TAB** Jump to nearest snap location, if Snap To is on.

- **SHIFT** Close tracker line and show computed ellipsoidal area.

- **CTRL** Toggle display between native drawing units and real measurement units (metric or English).

See the Tracker topic.

**Bookmark and Breakpoint Keyboard Shortcuts**

Bookmarks may be set within any text component (comments, queries or scripts) window. Breakpoints may be set within scripts.

**Bookmarks**
Introduction

F8  **Toggle** - Set a bookmark if one is not present. Clear a bookmark if one is already set for this line.

SHIFT-CTRL-F8  **Go to Previous** - Go to the previous bookmark.

CTRL-F8  **Go to Next** - Go to the next bookmark.

**Breakpoints**

F9  **Toggle** - Cycle the breakpoint at this line between "no breakpoint", "breakpoint set" and "disabled breakpoint."

SHIFT-CTRL-F9  **Go to Previous** - Go to the previous breakpoint (includes both disabled and enabled breakpoints).

CTRL-F9  **Go to Next** - Go to the next breakpoint (includes both disabled and enabled breakpoints).

**Keyboard Shortcuts for Editing Scripts and Queries**

Comments, query and script windows support Ctrl-[] and Ctrl-Shift-[] key combinations.

Ctrl-[] Check the character near the cursor and, if it is a bracket character, jump to the matching bracket.

Ctrl-Shift-[] Check the character near the cursor and, if it is a bracket character select the text between the bracket and the matching bracket.

Recognized bracket combinations are { and }, [ and ], ' and ', " and " and # and # (used to delimit dates in queries).

**Keyboard Modifiers for Selection in Tables**

(mouse click) Click on any record handle to select the record in accordance with selection mode currently set (Replace, Add, Subtract, Invert or Intersect). Click on a cell to move the focus to that cell.

SHIFT SHIFT-click on a record handle to apply the selection to a range of records.

CTRL Equivalent to clicking on a record handle when clicking into a cell. CTRL-click on a cell selects the record in accordance with the selection mode currently set. CTRL-SHIFT-click on a cell selects the range of records.

**Keyboard Zoom Commands during Selection and Editing**

When making selections or editing objects (such as inserting areas using the Autocomplete feature) we will often want to zoom in or out in the middle of a selection or editing command. Use the + and - keys on the keyboard to do so. Usually the + and - keys in the numeric keypad are used.

+  "Plus" key: Zoom in at the current tool position.

-  "Minus" key: Zoom out at the current tool position.

The current tool position is the position of the mouse at the time the + or - key is pressed. When editing, using these keys allows us to easily zoom into a desired location, make a few precise clicks and then zoom back out and proceed at the usual scale.
Keyboard Shortcuts for Toolbars

When working with a toolbar like the transform toolbar it is often convenient to work directly from the keyboard and to use keyboard shortcuts to move around between combo boxes, etc.

**TAB**  Jump to next control (combo box or button or other control).

**SHIFT-TAB**  Jump to previous control (combo box or button or other control).

**ENTER**  Clicks the nearest button next to the current control. For example, pressing **Enter** when in the target combo box in the transform toolbar is the same as clicking the nearby **Apply** button.

**SPACE**  Click the button that has the focus. No effect if no button has the focus.

**(arrow keys)**  The **left** and **up** arrows move the choice up in a menu while the **right** and **down** arrows move the choice down in a menu.

**(letter key)**  In a menu, jump to the first item beginning with that letter, if it exists. For example, in the transform toolbar’s operator box pressing the **m** key will jump us to the **Maximum** operator at the head of the list of operators beginning with an “**M**” (case insensitive).

**Home**  Jump to the top of a list.

**End**  Jump to the bottom of a list.

**Page Up**  Jump one “page” upward in a list.

**Page Down**  Jump one “page” downward in a list.

The letter key, **Home**, **End**, **Page Up** and **Page Down** shortcuts are particularly handy when finding commands in lengthy combo box menus, such as the list of operators in the transform toolbar’s operator box.

Keyboard Navigation in Terrain Windows

In addition to the keyboard arrows, Manifold uses keyboard navigation shortcuts to control the 3D view seen in the Terrain window.

**W**  Move forward.

**S**  Move backward.

**Q**  Strafe Up. (Move vertically up)

**E**  Strafe Down. (Move vertically down)

**A**  Strafe Left. (Move horizontally left)

**D**  Strafe Right. (Move horizontally right)

**SHIFT**  Pressing the **SHIFT** key with any of the above key commands will increase the effect of that command.

**Up / Down Arrow**  Tilt view up / down to +60 or -60 degrees from horizontal.

**Left / Right Arrow**  Rotate view left / right.

  +  Increase field of view (up to 130 degrees).

  -  Decrease field of view (down to 30 degrees).
* Reset field of view to 90 degrees

/ Move camera position to center of terrain.

The keyboard shortcuts are designed to allow "two handed" fast keyboard navigation as favored by experts in various computer tactical games. *Strafe* is gamer-speak for moving sideways or up/down without rotation. A *Q* move is thus the same as moving straight up, as in a helicopter.

To fly upward from the terrain surface, make sure that *Terrain - Snap to Surface* is unchecked. Next, either use *Q* to fly directly upwards or use the keyboard up arrow to rotate the view upwards and then use *W* to move forward. The *Q* move lifts us up as if in an elevator or helicopter moving straight up. The up arrow followed by a *W* is like angling an airplane upwards and then flying forward and up the angle.

**Keyboard Shortcuts for Z Scale in Terrain Windows**

With the focus on the terrain window we can use the following keyboard shortcuts to modify *Z scale*.

<table>
<thead>
<tr>
<th>Shortcut</th>
<th>Effect</th>
</tr>
</thead>
<tbody>
<tr>
<td>Page Up</td>
<td>Increase Z scale by .01</td>
</tr>
<tr>
<td>SHIFT-Page Up</td>
<td>Increase Z scale by .10</td>
</tr>
<tr>
<td>Home</td>
<td>Set Z scale to 1.0</td>
</tr>
<tr>
<td>Page Down</td>
<td>Decrease Z scale by .01</td>
</tr>
<tr>
<td>SHIFT-Page Down</td>
<td>Decrease Z scale by .10</td>
</tr>
</tbody>
</table>

**Launching Help from Windows**

Manifold Help can always be launched directly from Windows. Press the Windows *Start* button in the Windows taskbar, and then choose *All Programs, Manifold System* and then *Manifold System Help*. It is often convenient to launch Help directly from Windows. Some Manifold users will launch Help in this way and keep that Help session available on their Windows taskbar for easy reference.

**Windows Styles**

Illustrations in this manual use a variety of Windows styles in an attempt to appeal to a diversity of Manifold users, many of whom continue to use older Windows releases.

Many screen shots are based on Windows 2000 and the "Classic" style in Windows XP. Since many users still use Windows 2000 or (through force of habit) use classic style in Windows XP the intent is to make the illustrations seem more familiar to as many users as possible.

When installed in Windows XP Manifold will automatically configure itself to use Windows XP style for controls, as seen below in a screen shot of the column formatting dialog for table windows.
Buttons in Manifold will adjust their appearance according to the current Windows theme in use and so may differ slightly from illustrations depending on the theme specified by the user.

With Manifold releases beginning with 7.00 in 2006, topics covering newly-introduced features began using native Windows XP style in screenshots. The expectation is that as Manifold evolves the number of screenshots using more modern Windows styles will evolve along with the number of users of such styles.
Introduction

Getting Started

Very Important: Before starting Manifold, go to the Windows Control Panel Display dialog Effects tab and make sure that the Show window contents while dragging check box is not checked. In Windows XP this option is found in the Control Panel's Appearances and Themes - Display choice under the Appearance tab by pressing the Effects button. Checking this box will greatly slow down the system when displaying complex maps and images because it forces a refresh of the window contents with each change in mouse position while dragging the window.

Projects

Manifold's main documents are projects, which use Manifold .map project file format (.map = manifold project). Within Manifold the standard Windows menu items File - New, File - Open and File - Save commands will create, open and save .map project files.

Projects contain a portfolio of components. Components are images, drawings, tables, labels, charts, maps and other items.

Creating a New Project

1. Create a new, blank project with File - New. This opens the project pane.
2. Using File - Import, import any drawings, images, tables and other components desired.
3. To add blank components, use the File - Create menu to add new blank drawings or other components.
3. Use File - Create - Map to create maps that show the components in the project.

By default, when Manifold System starts up it will open with a new, blank project. To open an existing project, simply use File - Open to open the new project.

The Project pane

The project pane shows all components we have in our project. Open/close the project pane with SHIFT-ALT-P or with View - Panes - Project.
In the default hierarchical view used for the project pane, components that are linked to other components will be shown indented below their parent component. Drawings, for example, are always linked to a table that contains the data fields for the objects in the drawing. Images that are palette images will have a palette linked to the image. Surfaces will have a terrain component created by default for the surface and may have one or more subsidiary terrain components.

Names of components are marked with an asterisk * if they have been added to the project or changed since the last Save command.

Manifold works with only one project at a time. To work with different projects (say, for example, to copy and paste data between projects) we can launch two Manifold programs and switch between them.

**Images**

Images are photographs or scanned data composed of pixels and normally imported from "raster" file formats like .bmp, .gif, .jpg and similar. Most people are familiar with pixel image editors such as Microsoft Paint, Microsoft Photo Editor or Adobe PhotoShop.

Multichannel data sets will be imported as a series of images, one for each channel. Images can also be created from surfaces and other components. See the Tools - Make Image topic.

**Drawings**

Drawings consist of points, lines and areas and are normally imported from "vector" file formats like .dxf, .shp, .mid/mif, .mfd/mdb, DLG, SDTS and other formats. What many older GIS systems call "maps" are called drawings in Manifold. Many people are familiar with vector editors such as classic CAD editors like AutoCAD, or from vector style graphics editors like Adobe Illustrator. See the Import and Export topic for more information on specific import dialogs.
Unlike simple CAD or vector graphics editors, Manifold can attach database information to objects in drawings. Every Manifold drawing has a table linked to it. Each row in the table is a record that corresponds to an object (point, line or area) in the drawing. Each column in the table is a data field. Tables linked to drawings have at least one field, the object ID field that gives the unique, numeric identification number for each object in the drawing.

**Labels**

Labels are components that contain text annotations that can be manually created or automatically created from the information in a drawing's table.

Manifold has a vast array of label capabilities to allow us to create labels using different fonts, colors, styles and other characteristics. Virtually every characteristic of a label can also be controlled automatically based upon information in a parent drawing. For example, labels can be placed on lines so they follow the shape of the line as seen in the above illustration.

Automatic creation and control of label characteristics is very important because many times the projects we create in Manifold will be seen through views that are automatically created. For example, if we create a map with many layers in Manifold and that map is displayed to people through a Manifold Internet Map Server web site, each view seen in that web site will be automatically created based upon however that particular user zooms or pans into the map.

In such cases, what is seen in the map view, be it the lines of drawings or the positions of labels, will be automatically created by Manifold. If we learn about Manifold facilities for the automatic control of labels we can create a map that will look good and serve its purpose regardless of how it is viewed.

**Surfaces**

Surfaces are like images in that they consist of pixels. Surfaces are used to represent continuously varying data such as terrain elevation data and are imported from a variety of formats such as DEM, SDTS and similar.

Manifold shows surfaces by default in 2D displays like the one above, where the surface is seen from overhead with shading to make the ups and downs of the surface more evident. By default surfaces are shown using grayscale coloring, but Manifold makes it very easy to color the surface by its height such as in the illustration above.

**Terrains**

Terrains are 3D views of surfaces. Whenever Manifold imports or creates a surface it will automatically create a terrain for that surface as well.
By default a terrain is a ground-level view looking North from the approximate center of the surface, with the 3D terrain uncolored. It's easy to color the terrain as we like and to "fly" about the terrain to whatever view we like.

Maps

A map displays one or more drawings, images, surfaces or labels stacked up as layers. The "white space" in drawings is normally empty space that is transparent so objects in lower layers can be seen. Images and surfaces do not normally have any "white space" (although some images or surfaces may have regions of transparent pixels) so these are normally used as the lowest layer in a map or shown with partial transparency so that layers below them can be seen. Layers in maps may be made partially transparent using an Opacity setting.

Maps can show drawings and images in any projection desired. Even if a drawing was created in one geographic projection, a map using that drawing can show it in a different projection. Different maps using the same drawings or images can show those same drawings or images in different projections at the same time.

We can create as many maps as we like within a particular project, and those maps can mix and match components from the project however we wish. The maps do not duplicate the components they contain as layers. Maps are just a way of viewing and organizing components in layers. Maps can contain layers that are drawings, images, surfaces or labels.

Creating a New Map
We can create a new map using whatever source materials we like:

1. Create a new project using File - New. This opens a project pane.
2. Using File - Import, import any drawings and images into the project the new map will use.
3. Create a new map in the project using File - Create - Map. We must specify the name of at least one drawing or image this map will use. In the Create Map dialog, check all the drawings or images from the project you would like to appear in this map.
4. Double click on the new map in the project pane to open it in a map window.
5. Drag and drop any additional drawings and images from the project pane into the map window. This adds them to the map. To add layers to the map we can also right click on any existing layer tab and choose Add - Layers from the context menu.
6. If images are not already georeferenced, they must first be georegistered so that they appear in the proper geographic location at the correct size.
7. If desired, change the projection used by the map.

When a map is created it is always based on at least one drawing, image, labels component or surface. When a map is first created in a project it uses the projection of whatever component(s) it uses. If it was created using only one component the projection of that component will be used for the map. If a map is created using multiple components at the same time, then the map is created using the projection of the largest image or surface in the map. If there is no image or surface a random choice of one of the native projections of one of the constituent components will be used.

If we would like the map to use a specific projection that's used by one of the components it shows we can easily specify the projection to be used by right-clicking on any layer and choosing the Use Projection choice from the context menu. The map will automatically switch to using the native projection used by that layer.

Importing Drawings, Images and other Components

Use File - Import to import a new drawing, surface, table or image into a project. Importing a drawing will automatically create a table that is linked to that drawing. Import more than one item of the same type by using CTRL-click to choose more than one file when browsing in the Import dialog. We can also click on one file and then SHIFT-click on another to highlight all the files in between if we wish to choose several files for import.

Importing a component into the project copies the data into the project file. All of a project's components are normally kept in a single file, the project's .map (map = manifold project) file. Importing an image, for example, copies the data from the original image file into the .map file, making the .map file increase in size. Keeping all components within one file makes it easy to copy projects and to send them to other people.

Database tables may be either imported into the project or linked to an external database file or data source. Tables that are linked to an external source are not copied into the project even though they appear to be inside the project just like any other table. Data in externally linked tables is fetched "on the fly" from the external file or data source as it is needed.

We can also create linked drawings that are automatically created based on external database tables. We can also create linked images that are brought into a project from a variety of external sources.

Finally, when using Manifold Enterprise Edition a project can include any component that is linked into the project from a Manifold Enterprise server.

To save a component from the project into a non-Manifold format, use the File - Export command. For example, any image in Manifold can be saved into popular graphics formats such as .bmp or .jpg, and drawings can be exported into popular GIS formats.

Creating New Components

The File - Create menu will insert a "blank" component. It is often used to create blank "layers" for incorporation into a map or to receive objects that were copied from another drawing and are now being pasted into their own drawing.
A nuance: drawings, images, surfaces and labels components within geographic systems must be created with an awareness of geographic location and scale to be used together in a sensible way. Manifold will try to do this automatically by using either reasonable defaults or by taking into consideration the location and scale of the component that is active when the new component is created.

If no component is open the **File - Create** dialog will create the new component with a default Orthographic projection centered at the 0,0 world latitude/longitude origin. If a map, image, drawing, labels or other component window is active when the new component is created, the new component will be created using whatever projection is used by that active window. This context-sensitive setting of default projection parameters makes it much easier to create new components using projection parameters that are hassle-free by default.

We can also create a new, blank layer in a map by right clicking on any existing layer tab and choosing **Add - New Drawing** or **New Image** or **New Labels**. This will create a new component of the desired type in the project and add it to the map as a layer just above the active layer. The new component will be created using the map's projection except in the case where a **New Labels** command is used to create bound labels from a drawing. In that case the new bound labels component will use the same projection as the drawing upon which it is based.

### Components

Components are items such as drawings or images that appear in the project pane and make of a Manifold project. The data for components is normally stored inside the .map project file; however, some components (images, drawings, tables and surfaces) can be linked components that are created based upon data sources, such as database tables or streamed data from image servers, from outside the project. In that case, the linked component's data is not stored within the project but is dynamically fetched from the source.

Note that linked components can also be created from local components stored inside the project. For example, we might create a linked drawing that is created based upon a query where the query acts on a local table inside the project.

### Components include:

**Drawings**

Often referred to as **vector** documents or vector "maps" in older GIS systems, drawings are used in CAD systems for blueprints or in vector GIS systems for mapping. Drawings are made up of **objects** that may be points, lines or areas based on specific coordinates. Every Manifold drawing is linked to a table. Every object in the drawing corresponds to one record in the table. Manifold can import drawings from a vast array of different GIS and CAD formats. Drawings that are automatically created from database tables are called **linked drawings** and are shown using an icon that includes a yellow "database" cylinder.

**Themes**

Themes are displays of a drawing shown using different formatting. Manipulating a theme is just the same as manipulating its parent drawing. Themes make it possible to show drawings colored or presented in different ways without having to duplicate the drawing.

**Images**

Images are composed of **pixels** arranged in orderly rows and are often referred to as **raster images** in older GIS systems. Most of us know images as the familiar pixel-based images we edit in Microsoft Paint, Adobe Photoshop or Microsoft Photo Editor. Images in Manifold can also be multi-channel raster data as well as visual images. Images are normally imported into a Manifold project. One special type of images, **compressed images**, may be linked into a Manifold project from external files or compressed image servers. **Linked images** may also be created from queries and database tables as well as from image servers such as TerraServer or OGC WMS servers, in which case they are indicated with an icon that incorporates a "database" cylinder.

**Tables**

Database tables may be included either within a project or linked from external database providers so that the
data they contain is fetched "on the fly" as it is needed. Tables linked from external sources are shown with an icon that includes a yellow "database" cylinder. Manifold includes an immense array of database capabilities that work with tables and which may be used for database manipulation of tables from almost any database management system.

Labels

Labels components show text labels that are either entered manually or are automatically created from data fields linked to drawings. Labels components may be created in a variety of ways, such as making a Copy of drawing objects and then Paste As a Labels component.

Maps

Maps show drawings, images and text labels as layers in a map window. An important function of maps is showing the data they contain in projected form, where the native coordinates of drawings are transformed into a desired geographic or other projection and where images are referenced into the desired coordinate system and shown in projected form. Map windows are the main user interfaces within Manifold. Maps are used not only for geographic presentation but also for working with non-geographic images and drawings in many layers.

Surfaces

Surfaces are raster data sets that contain data values, such as elevations, for each location. They are almost exactly analogous to images except that instead of a color value for each "pixel" they contain a data value. The default way to show a surface is as a shaded relief 2D image. Surfaces are called "grids" in some GIS packages. Surfaces may also be linked from queries or tables, in which case they are indicated with an icon that incorporates a "database" cylinder.

Terrains

Terrains are surfaces shown in three-dimensional views. Every terrain has a parent surface. Terrains are most often used to show 3D views of the surface of the Earth based on terrain elevation data; however, they may also be used to see abstract data such as population gradients, temperatures or other data as 3D surfaces. Each surface can have an unlimited number of terrain views created for it.

Profiles

Profiles are subsidiary components of surfaces that show a path over the surface. They are used to compute elevations, which show the cross-section of height along the path. Profiles are visible in a project only if the optional Surface Tools extension has been installed.

Elevations

Elevations are subsidiary components of profiles that show the cross-section of height through the surface along the path. Elevations are visible in a project only if the optional Surface Tools extension has been installed.

Charts

Charts allow database table visualization and data mining using a simple 2D charting style.

Palettes

Certain types of images compress data by saving a single number for each pixel that is an index into a lookup table of colors. A palette is the lookup table that specifies what colors to use for different pixel values. Manifold allows different palettes for use with images. These may be kept within the project as separate components. This is especially useful when using "false color" to view multispectral raster data images.

Layouts

Layouts allow the creation of different arrangements for printing the project or exporting a layout to a format such as .pdf or .ai. One might save several different layouts for different sizes and resolutions of printers, for example.
Queries

Queries are saved queries written in Manifold SQL. Manifold includes a complete SQL engine as extended with high-performance spatial, networking, logical and "fuzzy" predicates. Query windows are unusual in that they support multi-level Undo / Redo.

Scripts

Scripts are written in any Microsoft .NET language or any ActiveX scripting language such as Visual Basic Scripting Edition, JavaScript (both included by default with Manifold System) for which an ActiveX scripting engine is available on the system. Scripts may be used to extend the capabilities of Manifold System or to customize the appearance and function of existing capabilities. Script windows are unusual in that they support multi-level Undo / Redo.

Forms

Manifold includes the ability to create script-based forms or dialogs that provide various controls and call other scripts. Forms are often used to create simplified interfaces for inexperienced users.

Comments

Written notes and comments we wish to make. Comments components are also used whenever text reports are created within Manifold. For example, importing from formats such as SDTS will often create comments components that contain the metadata text embedded into the SDTS files. Comments windows are unusual in that they support multi-level Undo / Redo.

A Window for Everything

Double click on a component in the project pane to open it within its own viewing window. Alternately right click on it and chose Open. If a component is already open, double clicking on it in the project pane will bring that component window to the foreground. To open multiple copies of a component, right click on the component and choose Open in New Window.

Components will open in a window with characteristics appropriate for that type of component. Tables will open in table windows, surfaces will be seen in 2D shaded relief, terrains will be seen in 3D view windows and drawings, images and labels will be seen in their own types of windows.

Most Manifold windows will use progressive rendering, which enables other commands to function even while the window is still being painted. This is very useful with large, complex components that might take some time to render. For example, even before a large drawing finishes rendering we can begin zooming in to a region of interest. When a component is small enough to render very quickly, progressive rendering will not be noticed because the component will be rendered in a single pass.

Maps are seen in a special type of window that has layer tabs at the bottom. Maps are the main user interface in Manifold because maps show components like drawings, images, surfaces and labels components in layers. Maps show their contents in a stack of multiple layers and can apply a variety of effects such as opacity / transparency that work only with layers. Drawings and images are normally viewed through the map that includes them. Labels components are almost always used within maps.

If desired, we can double click directly on any drawing, image, surface or labels component and see it in its own window. There are two main differences between a map window and opening a component by itself in its own window:

- Maps can contain multiple drawings and/or images in layers, so map windows have layer tabs and other controls for working with layers. Each drawing window or image window works only with one drawing or image so it has no tabs or other controls for multiple layers.
- Maps can use projections that are different than the native projections of the drawings and images they contain. Map windows will re-compute coordinates on the fly so that all layers appear properly within the projection used by that map. A map window can work faster if the map and the components it contains all use the same projection.

We can open as many windows as we like, including multiple windows for the same map, drawing, image, table or other component. Each window may be operated independently to allow different views into the same
component. All windows viewing a given component will be updated to reflect any changes made to the component as they are made in any window for that component. Components will "remember" their previous settings, such as selections that were made, and show them in any window in which they appear.

3D Rendering Speed

Terrain windows require a video graphics card using a reasonably modern graphics processor and OpenGL acceleration in hardware for smooth response in their 3D display. The cost of modern graphics hardware, like a graphics card using a fast nVidia graphics processor, is very low so it pays to get a really fast card.

No Scroll Bars

To navigate within Manifold image, drawing or map windows use the Center button, the Grabber or hot scroll commands using a ALT-right click. ALT-right-clicking near the edge of the screen will scroll it in that direction. Hot scroll works faster than scroll bars and requires less accuracy with mouse clicks. It also saves screen space that is wasted when many windows are open at once and each has scroll bars.

See the Windows topic for more information on hot scroll.

The Startup View

By default, component windows will open up to show the view used when the component was last opened. If the last time we opened a map the window showed a zoomed in view and then we close the window, the next time we open that map the view will also be zoomed in. This behavior is controlled by the Save last used view in component option in the Tools - Options - User Interface dialog.

If desired, we can also designate a startup view to be used whenever that component is opened regardless of how it was last displayed. See the Views pane topic for more information.

Panes

Some dialogs are so frequently used within Manifold that they are implemented as panes. Panes may be left open "always on top" or docked into the main Manifold window. The Selections pane, for example, shows any saved selections for the current component. The Layers pane provides a extended list-style presentation of layers that is easier to use than layer tabs when a map contains many layers. Panes will automatically update their contents to apply to whatever window has the focus.

Use SHIFT - ALT keyboard shortcuts to turn panes on and off rapidly. Experienced Manifold users will almost always turn panes on and off with SHIFT-ALT commands (such as SHIFT-ALT-S to turn the Selections pane on and off) instead of using the View - Panes menu. See the Windows topic for more information on keyboard shortcuts.

Intelligent Menus and Toolbars

Manifold knows which window is active. Toolbars and menus will automatically adjust so that the commands they present are appropriate to that window. Commands that do not make sense (such as pixel selection when working in a drawing window) will automatically be disabled. Panes that are left open will automatically update their contents to show status for the active window.

System Activity Indicator

The System Activity indicator in the status bar at the lower right hand of the screen changes shape whenever Manifold is busy executing a command.

When the system is busy it will show a 3D "bump".

If desired, unchecking the Quiet system activity indicator in the Tools - Options User Interface page will change the indicator to use colors.
The default color for system idle status is green. This may be changed by changing the **System Activity Indicator Idle** color in the **Tools - Options - Colors** page.

The default color for system busy status is red. This may be changed by changing the **System Activity Indicator Busy** color in the **Tools - Options - Colors** page.

Some users prefer a less-intrusive 3D bump, while others prefer a dot that changes color. Some users may want a quiet indicator when the system is not active but a colored indicator when the system is busy. To achieve this effect, uncheck the **Quiet system activity indicator** option and to specify the same gray color as is used for Manifold window frames as the **Idle** color. The dot will then change from a "quiet" indicator to red when the system is busy.

If not in quiet system activity mode, the system activity indicator will show a busy color indication if the system is doing something in the background. For example, if the system is fetching tiles from an OGC WMS image server in background (see the Linked Images from OGC WMS Servers topic) it will show a busy indication.

**Sounds**

At times we may launch a very demanding command that will take some time to accomplish. Some jobs may be so computationally intensive that they may require hours or longer to run. It is often convenient to set such jobs running while we continue work on another computer; however, in such cases it is also convenient to have Manifold play a sound or otherwise alert us when the job is done.

The **Tools - Options - Sounds** dialog allows us to specify whether or not we want a sound to be played at the conclusion of a lengthy process, how long the process must be before a sound is played and, optionally, a **.wav** file from which a sound can be taken.

**The Status Bar**

The status bar at the bottom of the screen displays information on command status, location and other useful information. The leftmost region of the status bar is used to display brief descriptive phrases or captions relevant to the current command, somewhat like extended tool tips. Not all commands will show such descriptive phrases.

The rest of the status bar provides readouts that apply to the currently active window. Not all readouts will be active for all types of windows. For example, the **Location** and **Scale** readouts will not be active for table windows. The **Scale** readout will be active only for projected components and maps. Options specified in the status bar page of **Tools - Options** may be used to turn on and off the readouts in the status bar shown below.

<table>
<thead>
<tr>
<th>Orthographic</th>
<th>-108.8464 25.4957</th>
<th>&gt; 1:610000</th>
<th>Selected: 0</th>
<th>Snap</th>
<th>Replace</th>
<th>Zoom</th>
<th>⏯️</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Projection</strong></td>
<td><strong>Location</strong></td>
<td><strong>Scale</strong> or <strong>Size</strong></td>
<td><strong>Selection</strong></td>
<td><strong>Snap</strong></td>
<td><strong>Selection</strong></td>
<td><strong>Command</strong></td>
<td><strong>Mode</strong></td>
</tr>
</tbody>
</table>

- **Projection**: The name of the projection (coordinate system) in use.

- **Location**: The current location of the mouse cursor, usually in longitude and latitude. Can be in X, Y native coordinates for the projection. Locations are always given **Longitude** first and then **Latitude** in the traditional X, Y order, since longitudes are X, horizontal coordinate values and latitudes are Y, vertical values.

- **Scale or Size**: Enabled only if the component is projected. Show the current scale using the format chosen in **Tools - Options - Status Bar**. Options are:
  - **absolute scale** (:#:#) - Absolute scale in 1:xxx form.
  - **relative scale** - Relative scale as ratio between one centimeter or inch and the scaled number of meters/kilometers or feet/miles, as in 1 in : 364.84
miles

**horizontal extent** - Shows the horizontal size of the current window.

Choice of English or metric units is set in **Tools - Options - User Interface**.

**Selection**

The number of objects selected, if any in drawings, labels components and tables.

For surfaces, this status bar position will show the height of a surface layer at the current mouse cursor position. For map windows containing multiple surfaces, if a surface layer is active the status bar will report the height of the uppermost visible surface layer.

**Snap**

Shows “Snap” if a snap mode is active.

**Selection Mode**

Current selection mode: Replace, Add, Subtract, Invert or Intersect.

**Command**

Name of the current mouse mode command.

**System Activity**

Changes shape into a 3D “bump” whenever Manifold is busy executing a command.

The location readout may be changed in Tools - Options to show the location in different ways. Likewise, a **Tools - Options - Status bar** setting allows switching between different styles of showing scale.

The illustration above shows alternate choices for location and scale readouts. The location shows the longitude and latitude in degrees, minutes and seconds format. The scale readout shows the width of the current view in kilometers.

**Select objects within box given by two corners**

The leftmost portion of the status bar has multiple uses. It normally is used to show extended messages that accompany tool tips when the mouse cursor hovers over a command button. With commands like the Tracker the leftmost portion of the status bar will show the tracker readout.

**2135.9333 x 1996.6333 m**

For some commands, like selection commands, the leftmost portion of the status bar will be used to show the dimensions of the area selected in the units used for the current projection taking into account the local scale and units settings in the **Edit - Assign Projection** dialog for that component. If the component is georegistered the sizes shown will be true dimensions.

"On center" commands that start with a central point and then draw a circle, box or ellipse will report both the dimension and the central location used by the command.

**8824.8762 x 8824.8762 m @ -109.2391 25.6456**
For example, in the Select Circle command seen above the circle fits into a box 8824 meters wide and high and it is centered at approximately -109 longitude and 25 latitude.

**Projections**

Manifold can work with data saved in both projected and unprojected coordinate systems from all standard GIS formats. Unprojected maps are usually easy to import automatically no matter how geographically unaware the GIS format being imported. GIS data saved as projected maps might require user intervention in some cases if the format does not save the projection parameters necessary to use the data.

Any image or drawing or map can be re-projected using a virtually unlimited choice of standard projections offered by Manifold. See the Projections and Imported Components and Projections topics for details.

**Georegistering Images and CAD Documents**

Many images and CAD documents that we would like to use in GIS projects will come to us stored in file formats that, unfortunately, fail to save the projection and georegistration information that is required to easily use such images and CAD documents.

Perhaps, for example, we have an aerial photograph of a school campus that we would like to use as a backdrop for a nice map of the campus. Or, perhaps we have architectural plans of a new factory that we would like to show within a site map. Manifold has tools to enable us to use such data even if it originates in formats that are geographically unaware.

The process of adding these non-geographic documents to a geographic map and moving, re-projecting or resizing them to the correct position is called georegistration and is covered in the Georegistration topic. Although the process is simple, it must be learned and correctly applied if images are imported from formats that do not save georegistration information.

Manifold will automatically apply a projection to all images and CAD drawings (by default, the Orthographic projection) imported from geographically unaware formats. This is the right starting point for most non-geographic images and drawings that are to be used in maps. If desired, another projection may be specified if it is a better fit to the data, or images or drawings may be georegistered into a more precise match to any given component.

**Database Operations**

Manifold includes a very rich set of capabilities for working with databases either as separate tables or as tables linked to objects in maps. Although a major use of Manifold is to work with tables linked to drawings within maps, the database capabilities of Manifold are so strong that many users will use Manifold to view, analyze and manipulate database tables that have nothing to do with drawings. Quite a few people use Manifold as a personal information manager, since tables are easy to create in Manifold.

Database operations are accomplished using a combination of table windows and the table commands used in table windows, the Database Console, SQL queries, transform toolbar, Active Columns within tables, and ViewBots applied to tables. Some of the menu commands used with tables can be quite large subsystems, for example, as in the case of the Decision Support System. See the Rank Columns / Decision Support System topic for an example using Decision Support.

A useful Manifold subsystem used with databases is the Chart system. Charts are created from tables and then configured using a variety of presentation options and data grouping options.

**Programming**

Manifold may be programmed in several ways:

- "Ad hoc" programming using Active Columns in tables or ViewBots.
- Using SQL queries to perform analyses, alter table structure and otherwise make updates.
- Writing scripts using Visual Basic scripting, Javascript or other ActiveX scripting languages.
• Calling Manifold System from external programs.

There is no additional programming language or toolkit to purchase in order to program Manifold. Every system includes the ability to use Visual Basic scripting or JavaScript to write sophisticated, forms-based programs using standard Windows controls. If you do have a programming environment such as Visual Studio, you can use that as well without the need to purchase any other options.

See the Programming Manifold topic for more information on programming.

**Printing**

There are two ways of printing within Manifold:

- The contents of any component window can be immediately printed using default settings and simple options.
- For more sophisticated control over print layout, a **Layout** is created and opened. Components that are to appear in the layout are dragged and dropped into the layout and then resized, moved and adjusted as desired. We can then print the layout.

The most sophisticated print layouts will normally feature a main compositional element that is a map. This map will consist of many drawing, image and labels components to create the visual effect desired. Because maps provide very rich editing capabilities they are the natural "console" within which to work when creating desired effects.

Experienced Manifold users will therefore often put most of their compositional efforts into arranging the main map as desired. They will then use that map as the main element in a layout and will add other components to the layout rather sparingly. It is often a matter of taste and convenience whether a particular compositional element is placed within a map or is dropped into the layout as a separate element.

Suppose for example we have a map of wetlands that is to be printed and we wish to have a title block that includes a main text title hovering over a corporate logo. We could create the entire ensemble with both the wetlands drawings and the text labels and image used as the title block as a set of layers in one map, as illustrated at the end of the Layers topic. This map could then be dropped into a print layout that consists of just that one component.

Alternately, we could create a map showing the wetlands and then create another map that just consisted of a few labels and image layers that made up the title block. We could then drop the wetlands map into a layout and also drag and drop the title block into the layout. We would then print the layout that now is made up of two components.

The former approach allows creating everything within the same map window so that all layers are immediately at hand to allow adjustment of any visual aspect of the map. The second approach allows us to create a standard title block that could be recycled into other print layouts. Most production print jobs will include a combination of the two methods.

**Typical Workflow**

The workflow in mapping projects aimed at visual presentation consists of a few basic steps:

- Decide which drawings are to be used.
- Import those drawings into the project.
- Format those drawings for a pleasing and efficient basic appearance.
- Arrange the drawings as layers in a map.
- Project the map into an appropriate projection, if desired, and project the layers to match the map's projection (for speed).
- Create any new drawing layers in the map as necessary.
- Edit drawings to remove or adjust objects or to move them between map layers.
- Working in the map window, refine the formatting of the drawings for the exact visual effect desired.
- Improve the presentation with additional layers that contain text labels or images.
• Create a print layout and drag the map into the layout.
• Edit the print layout, adding any elements, resizing elements and placing elements as desired.
• Print the layout or export it to a .pdf or other file format such as .ai for further processing in other programs.
• If desired, publish the map to the web using the Manifold Internet Map Map Server.

Each of the above steps may involve nuances. For example, we will likely open and review various drawings before we decide which will be used in our project. If we don’t have necessary drawings on hand we will have to locate them or create them.

Importing drawings from other GIS or CAD formats may be very easy, or it may involve some detective work to uncover what projections or other parameters were used to create them and manual adjustment of drawing properties.

It’s often the case that drawings we use in a map will require editing. For example, perhaps we want to create a map of France and Germany but the only drawings we have available show all of Europe. We can copy only the objects for France and Germany and paste them into a new drawing that we will use.

Or, perhaps we are using a large, complex data set like TIGER/Line where part of the art of using the drawings is getting rid of very many unwanted items such as lines that show various grids or special zones in which we have no interest.

Editing will often make use of numerous Manifold tools and will require more advanced skills. For example, we might want to create a map of a single county that shows streams and rivers in the county, but perhaps the drawing of streams that we have shows streams as continuous lines that extend past the boundaries of individual counties. In that case, we’ll have to learn enough about Manifold editing tools to “cookie cut” the streams with county outlines so that we can delete those parts of the streams lines that extend past the county boundary.

Formatting will often involve thematic formatting, which uses data fields from the table linked to a drawing to automatically color or otherwise format the drawing. Depending on the visual effects desired, we may spend a substantial amount of time making adjustments in formats, editing drawings, creating new layers (drawings) and moving objects between layers to achieve exactly the effect desired.

When Manifold is used for serious analytic work we will often work with tables and the data they contain. In addition to the above workflow steps we will usually open tables associated with drawings and make selections, create ViewBots or perform other analyses. For example, we might use drawings as a visual means of selecting data in tables and then export that selected data into external database tables or Excel .xls spreadsheet tables.

When maps are used for visual exploration of data we may add facilities such as Zoom Ranges to improve navigation or to better present the data.

.map File Compression

By default, .map files are automatically compressed when saved to disk and automatically decompressed when read into Manifold. The compression ratio achievable varies depending on the types of data (components) that are in the .map file. A typical mix of components and data will usually result in a factor of five or seven compression compared to the size of a .map without compression. .map files consisting of large, mostly empty images and surfaces can result in compression ratios of up to 1 to 100.

Compressed .map files will automatically be decompressed when loaded into Manifold. Uncompressed .map files will be read directly into Manifold.

Compression does require additional time when opening and saving .map files. Users blessed with very large disk storage space may wish to turn off compression (in Tools - Options ) to enjoy faster loading and saving of .map files. In addition, compression requires additional working space on disk because compressed .map files are first decompressed to a temporary file and then loaded into Manifold. One must therefore have enough free space on disk to have a copy of the fully decompressed temporary file on hand. Considering that a 20 megabyte compressed .map file can decompress into a 100 megabyte temporary file, one should always have ample free space on disk for temporary files.

Manifold’s compression algorithms are lossless and do not cause any changes in the data. They are similar to the compression algorithms used in PC and UNIX “zip” style programs and result in similar compression ratios. When saving a compressed .map file to disk there is no gain to be had in further compressing it with a “zip”
program. One can therefore send compressed .map files through the Internet without feeling a need to further compress them with WinZip or similar utility to save space and transmission time.

**Setting Background Color**

The default background color for all components is set in the Tools - Options dialog. Each individual component can have its background color set by opening the component in a window and choosing View - Properties.

**Notes**

The Tools - Options dialog contains many options to control Manifold configuration. For example, if desired, we can use Tools - Options to tell Manifold not to launch with a blank project.

Some options are very important. For example, the Import empty columns in tables option is not checked by default. Columns in tables that contain no values will not be created when a table is imported. To preserve identical table structure even if the table does not contain any data in some columns, check this option.
Creating a Project

Manifold documents are projects. A project is a Manifold .map (for “manifold project”) format file that can contain many different types of information. There is no maximum limit to the size of a Manifold project.

Projects may contain various components such as maps, drawings, images, surfaces, labels, tables, palettes, terrains, themes, charts, print layouts, SQL queries, scripts and script forms. The Project pane shows all components in the current project. By default, the project pane will show a hierarchical view where components linked to other components are shown indented below their parent component.

File - New and File - Open are used to create new projects or to open existing projects. Creating a project or opening an existing project automatically opens the project pane. The main component is a map, which shows drawings and images as layers within the map.

Clicking a component in the project pane highlights it. CTRL-clicking a component toggles its selection state, thus allowing highlighting of more than one component, which is very useful if we would like to delete several components at once.

Creating a New Project

1. Create a new, blank project using File - New. This opens the project pane.
2. Using File - Import, import any drawings, images, tables and other components you plan to use.

3. To add blank components, use the File - Create menu to add new blank drawings or other components.

3. Use File - Create - Map to create maps that show the components in the project.

By default, when Manifold System starts up it will open with a new, blank project. To open an existing project, simply use File - Open to open the new project.

Creating a New Map

We can create a new map using whatever source materials we like:

1. Create a new project using File - New. This opens a project pane.

2. Using File - Import, import any drawings and images into the project the new map will use.

3. Create a new map in the project using File - Create - Map. We must specify the name of at least one drawing or image this map will use. In the Create Map dialog, check all the drawings or images from the project you would like to appear in this map.

4. Double click on the new map in the project pane to open it in a map window.

5. Drag and drop any additional drawings and images from the project pane into the map window. This adds them to the map. To add layers to the map we can also right click on any existing layer tab and choose Add - Layers from the context menu.

6. If images are not already georeferenced, they must first be georegistered so that they appear in the proper geographic location at the correct size.

7. If desired, change the projection used by the map.

When a map is created it is always based on at least one drawing, image, surface, theme, or labels component. When a map is first created in a project it uses the projection of whatever component(s) it uses. If it was created using only one component the projection of that component will be used for the map. If a map is created using multiple components at the same time, then the map is created using the projection of the largest image or surface in the map. If there is no image or surface a random choice of one of the native projections of one of the constituent components will be used.

If we would like the map to use a specific projection that's used by one of the components it shows we can easily specify the projection to be used by right-clicking on any layer and choosing the Use Projection choice from the context menu. The map will automatically switch to using the native projection used by that layer.

When importing a component into a project, the entire contents of that component are stored in a special section of the project file. For example, when importing a 10MB .bmp image into a project, the project .map file will increase in size by 10MB. While this may seem wasteful of disk space, given the very large sizes and low costs of modern hard disks it makes more sense to keep all project components organized within a single file. This makes it easy to backup files, to organize files well for version control and to know that no necessary information is forgotten when a project file is sent to someone else.

There are two exceptions in which data for components is stored outside the Manifold project file:

- Some components (images, drawings, tables and surfaces) can be linked components that are created based upon data sources, such as database tables or streamed data from image servers, from outside the project. In that case, the linked component’s data is not stored within the project but is dynamically fetched from the source.
- Enterprise Edition allows keeping all project components saved in a remote Enterprise server.

Beginning users are cautioned, however, that using linked components or Enterprise Edition requires slightly more attention than simply keeping all components in one project file as is done by default. If a project contains all components it is a simple matter to send the project to someone else or to move the project to a different location by simply sending or moving the .map file involved. If external database tables or other sources are linked into the project more thought and attention are required to share the project with a colleague.

Maps are Free

Creating a map in the project adds very little to the size of the .map project file. A map component contains very little data, since the contents of the map are taken from the drawing and image components it contains. The
actual map component consists of pointers to the relevant drawing and image components as well as a very small amount of housekeeping information (layer ordering, projection parameters, etc). Therefore, making copies of maps or making lots of maps in a project is an efficient way of creating and saving different views into the same data. There is virtually zero storage cost to adding another map to a project.

.map Files and Compression

By default the .map format used to save Manifold projects automatically compresses the data contained in the .map file using techniques similar to those used by popular "zip" compression utilities. Therefore, usually there is no need to "zip" a .map file with utilities such as WinZip to save disk space or to speed up transfers over Internet - the .map file is already compressed.

Compression takes some time when saving a .map file and when opening a .map file to decompress the contents for use within Manifold. For large files the time required for compression and decompression may be significant. If speed in loading and saving is more important than saving space on hard disk we can turn off automatic .map file compression by unchecking the Compress .map files to save space option in Tools - Options. Except for speed in loading or saving there is no difference in system performance if .map file compression is turned on or off.

Processors are getting faster much more rapidly than disk drives are getting faster. In fact, some processors are already so fast that they can compress and decompress data faster than disk drives can read or write data. In such cases it is quicker to compress a .map file so that the relatively slow disk drive needs to spend less time reading or writing a smaller file. Therefore, with some fast systems it is wise to leave compression always turned on because that will not only save space on disk but it will also be faster. With slower systems, on the other hand, it could be that the compression option will result in more time required saving or loading .map files.

There is no indication that a .map file is compressed or uncompressed other than it takes more or less space. It is strongly recommended that if compression is turned off that the user establish operational practices to distinguish between compressed and uncompressed .map files. Newer processors are already so fast that it is almost always better to leave compression turned on all of the time.

The.map files on the Manifold downloads site were all saved with .map compression turned on in order to place more files onto the CD. When opened for use the resulting projects may be considerably larger than might be expected from the size of the .map file on CD.

ODBC and .map Files

Manifold includes an ODBC driver. This driver allows other applications to work with data in tables and queries in a Manifold .map project file. See the Using the Manifold ODBC Driver topic.

Tech Tips

Files ending in a .map extension may be used by other applications on your computer. When you install Manifold it will automatically tell Windows to open .map files with Manifold. If you would prefer to retain the assignation of files ending in .map to some other application, in Windows Explorer right click on a .map file and choose Open with and then Choose Program. Choose the program you wish to use to open .map files and check the box Always use this program to open these files and press OK.

We can rename project components by right clicking on them and choosing Rename in the context menu, which gives us the option to automatically adjust (rename) the names of any dependent components. An even faster way of doing this is to highlight a project component, pressing the F2 key (the usual Windows shortcut key to rename an item) and then after providing the new name finishing with a SHIFT-ENTER. Pressing ENTER alone after renaming an item renames only that item. Pressing SHIFT-ENTER after renaming an item renames that item as well as any dependent components.
Introduction

Components

Manifold System keeps the information it needs to keep track of items for a given project in a single file called a Manifold project file. Projects are the "documents" of Manifold, just like .doc files are the documents of Microsoft Word or .xls spreadsheets are the "documents" of Excel. A Manifold project contains all the different types of data with which we work, or, in the case of linked components, links to the source of the data used for that component.

The different types of data kept in a Manifold project are called components. Components are the drawings, images, surface, labels, comments, tables, scripts, queries, themes and other items in a Manifold project.

There are the following types of components in a Manifold project:

- **Local components** are components that exist entirely within the project. These are created in the project using Manifold dialogs, or they are imported into the project from some other file. For example, we might import a drawing from a shapefile. The data for local components resides entirely within the .map project file. If we import a 50 MB drawing from some external file and then save our .map project file, it will grow in size to accommodate the imported drawing.

- **Linked components** and **shared components** are components that are created on-the-fly from some other data source, usually some external database file, image server or from some other external source. The data for linked components usually resides outside of the .map project file. For example, if we link an image into a Manifold project from an external .ecw file that is 50 MB in size, when we save the .map project file it will not grow in size. The data for shared components always resides outside of the .map project file, but the project file may contain a cached copy of that data.

Manifold saves information to keep track of all of a project's components in the project's .map file. When a project is saved, any changes made to any component will be updated as well.

Because components are often imported from systems or formats where they exist as separate files (for example, .bmp or .gif images), it is tempting to think of components as being separate files. That's not the case. Even though components appear to be separate things they are all part of one Manifold project .map file. With the exception of linked components and Enterprise Edition projects they are all saved in the single .map file as well.

It is also tempting to think of components as somehow retaining the characteristics of their originating formats. For example, one might think that because a table was imported from a .dbf database format file it somehow is still limited to having restricted field names as if it were still in the original .dbf format. Or, perhaps we've imported a drawing from shapefile format and think the drawing must now be limited to the antique restrictions of that format.

That is not the case for components that are imported into a Manifold project. Once a component is imported into Manifold it is now in Manifold as a local component and has no tie to the original format or file from which it originated.
However, there may well be some restrictions on linked components depending on their origin. For example, linked images coming into the project from TerraServer will be read-only, and tables that are linked into a project from an external data source will be subject to the limitations of that data source. If we don't like such restrictions, we can always unlink the linked component to change it into a purely local Manifold component. We can then do with it what we please.

The Project Pane

Using File - Open to open a Manifold project or File - New to create a new project will automatically open the project pane. The project pane shows a list of all components in a project. Double click on a component in the project pane to open it within its own viewing window. Alternately right click on it and choose Open. If a component is already open, double clicking on it in the project pane will bring that component window to the foreground. To open multiple copies of a component, right click on the component and choose Open in New Window.

Some components in a project pane will be linked to other components and will be shown indented underneath those components in the project pane. For example, every drawing has a subsidiary table that will be shown indented underneath it and images using palettes will have their palette components linked to them. In the illustration above, the image SanFran is a palette image that uses the palette underneath it.

To rename a component, right click on it in the project and choose Rename. The Component Name dialog that pops up includes a checkbox to Adjust names of dependent components, which, if checked (the default), will automatically rename any subsidiary components. For example, if we rename a drawing called Mexico Drawing to Central Mexico Drawing, then the drawing's table that was originally called Mexico Table will automatically be renamed Central Mexico Table.

Components in the project pane may also be renamed by a “slow double-click” or by pressing the F2 key. Press Enter to commit the renaming operation without renaming dependent components, or press SHIFT-Enter to commit the renaming operation and to also adjust names of any dependent components as if the Adjust names of dependent components option in the Component Name dialog had been selected.

Types of Components

Components are items such as drawings or images that appear in the project pane and make of a Manifold project. The data for components is normally stored inside the .map project file; however, some components (images, drawings, tables and surfaces) can be linked components that are created based upon data sources, such as database tables or streamed data from image servers, from outside the project. In that case, the linked component's data is not stored within the project but is dynamically fetched from the source. Linked components are shown with a cute little database cylinder graphic added to the icon.
Introduction

Note that linked components can also be created from local components stored inside the project. For example, we might create a linked drawing that is created based upon a query where the query acts on a local table inside the project.

Components include:

**Drawings**

Often referred to as vector documents or vector “maps” in older GIS systems, drawings are used in CAD systems for blueprints or in vector GIS systems for mapping. Drawings are made up of objects that may be points, lines or areas based on specific coordinates. Every Manifold drawing is linked to a table. Every object in the drawing corresponds to one record in the table. Manifold can import drawings from a vast array of different GIS and CAD formats. Drawings that are automatically created from database tables are called linked drawings and are shown using an icon that includes a yellow “database” cylinder.

**Themes**

Themes are displays of a drawing shown using different formatting. Manipulating a theme is just the same as manipulating its parent drawing. Themes make it possible to show drawings colored or presented in different ways without having to duplicate the drawing.

**Images**

Images are composed of pixels arranged in orderly rows and are often referred to as raster images in older GIS systems. Most of us know images as the familiar pixel-based images we edit in Microsoft Paint, Adobe PhotoShop or Microsoft Photo Editor. Images in Manifold can also be multi-channel raster data as well as visual images. Images are normally imported into a Manifold project. One special type of images, compressed images, may be linked into a Manifold project from external files or compressed image servers. Linked images may also be created from queries and database tables as well as from image servers such as TerraServer or OGC WMS servers, in which case they are indicated with an icon that incorporates a "database" cylinder.

**Tables**

Database tables may be included either within a project or linked from external database providers so that the data they contain is fetched "on the fly" as it is needed. Tables linked from external sources are shown with an icon that includes a yellow "database" cylinder. Manifold includes an immense array of database capabilities that work with tables and which may be used for database manipulation of tables from almost any database management system.

**Labels**

Labels components show text labels that are either entered manually or are automatically created from data fields linked to drawings. Labels components may be created in a variety of ways, such as making a Copy of drawing objects and then Paste As a Labels component.

**Maps**

Maps show drawings, images and text labels as layers in a map window. An important function of maps is showing the data they contain in projected form, where the native coordinates of drawings are transformed into a desired geographic or other projection and where images are referenced into the desired coordinate system and shown in projected form. Map windows are the main user interfaces within Manifold. Maps are used not only for geographic presentation but also for working with non-geographic images and drawings in many layers.

**Surfaces**

Surfaces are raster data sets that contain data values, such as elevations, for each location. They are almost exactly analogous to images except that instead of a
The default way to show a surface is as a shaded relief 2D image. Surfaces are called "grids" in some GIS packages. Surfaces may also be linked from queries or tables, in which case they are indicated with an icon that incorporates a "database" cylinder.

**Terrains**

Terrains are surfaces shown in three-dimensional views. Every terrain has a parent surface. Terrains are most often used to show 3D views of the surface of the Earth based on terrain elevation data; however, they may also be used to see abstract data such as population gradients, temperatures or other data as 3D surfaces. Each surface can have an unlimited number of terrain views created for it.

**Profiles**

Profiles are subsidiary components of surfaces that show a path over the surface. They are used to compute elevations, which show the cross-section of height along the path. Profiles are visible in a project only if the optional Surface Tools extension has been installed.

**Elevations**

Elevations are subsidiary components of profiles that show the cross-section of height through the surface along the path. Elevations are visible in a project only if the optional Surface Tools extension has been installed.

**Charts**

Charts allow database table visualization and data mining using a simple 2D charting style.

**Palettes**

Certain types of images compress data by saving a single number for each pixel that is an index into a lookup table of colors. A palette is the lookup table that specifies what colors to use for different pixel values. Manifold allows different palettes for use with images. These may be kept within the project as separate components. This is especially useful when using "false color" to view multi-spectral raster data images.

**Layouts**

Layouts allow the creation of different arrangements for printing the project or exporting a layout to a format such as .pdf or .ai. One might save several different layouts for different sizes and resolutions of printers, for example.

**Queries**

Queries are saved queries written in Manifold SQL. Manifold includes a complete SQL engine as extended with high-performance spatial, networking, logical and "fuzzy" predicates. Query windows are unusual in that they support multi-level Undo / Redo.

**Scripts**

Scripts are written in any Microsoft .NET language or any ActiveX scripting language such as Visual Basic Scripting Edition, JavaScript (both included by default with Manifold System) for which an ActiveX scripting engine is available on the system. Scripts may be used to extend the capabilities of Manifold System or to customize the appearance and function of existing capabilities. Script windows are unusual in that they support multi-level Undo / Redo.

**Forms**

Manifold includes the ability to create script-based forms or dialogs that provide various controls and call other scripts. Forms are often used to create simplified interfaces for inexperienced users.

**Comments**

Written notes and comments we wish to make. Comments components are also used whenever text reports are created within Manifold. For example, importing from formats such as SDTS will often create comments components that contain the metadata text embedded into the SDTS files. Comments windows are
Introduction

unusual in that they support multi-level Undo / Redo.

**Importing Components into a Project**

To add a component from an existing file (such as a GIS format drawing or image file) choose File - Import to import a component from an existing file.

When importing or linking components we can usually import more than one item of the same type by using CTRL-click to choose more than one file when browsing in the Import dialog. We can also click on one file and then SHIFT-click on another to highlight all the files in between if we wish to choose several files to import.

Whenever we import a component such as a drawing, image or surface that can have a projection, if it has been imported from a format that does not store projection information when we first open it Manifold will remind us to verify the projection used for that component by popping open an information bar in the component window. Click on the bar to verify the projection using the Edit - Assign Projection dialog. If the projection shown in the Assign Projection dialog is what we think it should be, we press OK. Thereafter, we can open the component without Manifold nagging us to verify the projection.

*Note*: We can get rid of the info bar without launching the Assign Projection dialog by clicking the X sign at the right side of the info bar; however, Manifold will know that we've not yet verified the projection of this component and the info bar will appear again the next time the component is opened in a window.

If we do not want to verify projections of new components, once we acquire enough expertise not to want to verify projections anymore unless it is absolutely necessary, we can get rid of the info bar by changing the Prompt to verify projections of new components option in the Tools - Options dialog.

Conversely, if we would like Manifold to remind us to verify the projection of all new components, even those imported from formats that correctly store projection information, we can uncheck the Suppress prompt for non-default projections option in the Tools - Options dialog. See the discussion of info bar options in the Tools - Options dialog for details.

**Linking Components into a Project**

Choose File - Link to create linked components such as linked tables, linked drawings, linked images or linked surfaces within the project that take their data from external sources. Linked components will appear in the project like local components, but their data will come from an external source. Depending on the nature of that source, there may be limitations on those linked components. For example, linked images from image servers will be read-only and cannot be re-projected. Tables linked from external data sources using ADO.NET connection technology will be read-only. Drawings linked from geometry in database tables will normally be read/write and fully editable but usually cannot be re-projected.

**Creating New Components**

At any time we can create a new component in the project by choosing File - Create. Except for maps, the File - Create dialog takes the projection parameters for the new component from whatever window is active at the time the new component is created.

If no existing component is active, the new component will be created using the system default projection of Orthographic centered at the 0,0 world latitude/longitude origin. If a map window or other component window is active when the new component is created, the new component will be created using whatever projection is used by that active window. This context-sensitive setting of default projection parameters makes it much easier to create new components using projection parameters that are hassle-free by default.

When a map is created it is always based on at least one drawing, image, labels component or surface. When a map is first created in a project it uses the projection of whatever component(s) it uses. If it was created using only one component the projection of that component will be used for the map. If a map is created using multiple components at the same time, then the map is created using the projection of the largest image or surface in the map. If there is no image or surface a random choice of one of the native projections of one of the constituent components will be used.
If we would like the map to use a specific projection that's used by one of the components it shows we can easily specify the projection to be used by right-clicking on any layer and choosing the **Use Projection** choice from the context menu. The map will automatically switch to using the native projection used by that layer.

A very common way of adding components to a project is to create them from other components using **Copy** and **Paste As**. See the Copy and Paste As topic.

We can also create a new, blank component in a project by using the context menu for layer tabs in a map. Right click on any existing layer tab and choose **Add - New Drawing** or **New Image** or **New Labels**. This will create a new component of the desired type in the project and add it to the map as a layer just above the active layer. The new component will be created using the map's projection except in the case where a **New Labels** command is used to create bound labels from a drawing. In that case the new bound labels component will use the same projection as the drawing upon which it is based.

**Maximum Component Size**

No single drawing, table, image or surface can exceed 16 EB (exabytes) in size. Since one exabyte is $2^{60}$ bytes, about a trillion gigabytes, as a practical matter there is no size limit for these components. One will run out of disk space before the size limit is approached. There is no limit to the number of components that may be in a project.

Comments, queries and scripts are limited to approximately 1 GB. Labels are limited to 16 EB when initially created, but any changes made to a labels component after it is initially created cannot exceed approximately 1 GB.

Limits on comments, queries, scripts and labels component sizes are approximate because the precise limit depends upon details of the specific Windows system in use and the operation of that system. For example, in certain systems the 1 GB approximate limit on such components can expand to 2 GB or even 3 GB on machines run with a /3GB boot option. However, because such expanded uses depend on many complex interactions the stated limit size for comments, queries, scripts and changes in labels components is only 1 GB (a vast amount for such things).

Note that the 1 GB limit on "queries" is the size of the actual SQL query text, not on the results of a query. This is somewhat of an absurd "limit" since it is very rare that one writes an SQL query longer than a few hundred lines, let alone more than a megabyte in size.

**Opening or Running Components**

The different types of components that appear in the project pane can be opened for viewing or editing or, in the case of scripts, queries or forms, for execution (running) through mouse clicks, menu commands or toolbar buttons.

- **Double click** on a map, drawing, image, surface, terrain, table, comment, chart or palette to display it in a window.
- **Right click** and choose **Open in New Window** to open the component in a new window.
- **Click** on a form, script or query and press the Run button to execute it.
- **Double Click** on a form, script or query to edit it.
- **Right click** onto a component to pop open a context menu of choices for that component.

**Component Windows**

Double clicking on a component in the project pane will open that component in a window. Double clicking a map, drawing or image, for example, will launch the component within a window designed to display and manipulate that type of component. Component windows will automatically open with the correct set of toolbars or other controls appropriate to that type of component. Clicking on a form, script or query to highlight it and then pressing the Run button will execute that form, script or query. Queries will appear as tables when run. To edit the SQL text that generates a query table, open the query for editing by double-clicking it or by right clicking on it and choosing **Open**.

We can open multiple windows at once into the same component by right clicking and choosing **Open in New Window** from the pop-up menu. Each window can maintain its own independent view into that component. So, for example, we could open two windows to view the same image and zoom in on one window for a very close up
view while panning the other window to see a different part of the same image. Changes in any one window to a component (such as changing the formatting to change the colors it uses) will update all other windows for that component. If we change the background color for areas to bright green in a drawing all windows that show that drawing will show the areas in bright green background color.

Some components have other components that are associated with them. For example, every drawing is connected to a table for that drawing. If the drawing is open, we can open the associated table by choosing **Drawing - Open Table**. If the table is open in a window, we can open the related drawing by choosing **Table - Open Drawing**. These menu choices will be enabled only for components that are related to other components. For example, a table that is not connected to a drawing will not have an **Open Drawing** command available.

**Context Sensitive Controls**

Only one window at a time has the **focus** in Microsoft Windows. Clicking into a window or touching it in some way moves the focus to that window in the standard Microsoft way to make it the **active window**. When the focus is on a particular window its title bar changes to the highlighted color specified for active windows in the Display appearance settings specified in your Windows Control Panel. See the Windows topic for more on typical Microsoft Windows behavior.

Clicking on a component window moves the focus to that window. Simultaneously, the main toolbar controls will change context or form to support use of whatever component window has the focus. Manifold toolbars and toolbar buttons are designed to preserve commonality of function as much as is possible, so that when the focus changes from a drawing to an image window the selection buttons will retain their appearance. However, their function will change in subtle ways to support the slight differences in selection operations between objects in drawings and pixels in images.

When the focus moves to a new window, any panes open will automatically switch their contents to apply to that window.

**Saving / Exporting Components**

Once components (like drawings and images) are imported into Manifold they become part of the project **.map** file. Saving the project saves the components within the **.map** file. At times we would like to import images or drawings into Manifold and to later save them as independent drawing or image files.

To do this, we open the component in a window and then use the **File - Export** command to export it to the desired format. For example, we may import drawings in **.shp** format, manipulate them within Manifold, and then use **File - Export** to save them in **.shp** format for use with other, archaic software.

Note that not all formats can handle the full range of information possible in Manifold components. For example, tables in Manifold can contain field names that are fine for export to Access **.mdb** files but which are longer than allowed in the less-capable **.dbf** format used in **dBase** files. Such field names should be changed before attempting export to **.dbf** format.

Since **.shp** "shapefiles" are actually an ensemble of files that include the use of **.dbf** files for data attributes, this means that exporting a drawing (and, of course, its associated table) to **.shp** format means that field names in tables may need to be shortened.

By default, Manifold includes many more formats available for import than for export. Optional products from **manifold.net** will add additional formats for export. Visit the **manifold.net** web site for information on optional products.

**Tech Tip: Organize Projects with Folders**

The **create folder** button in the project pane toolbar creates folders within the project. Use folders to organize components within the project and to keep the project pane manageable.

This is especially important when importing drawings from complex file formats such as those used with VMAP and TIGER/Line, where a single import will create numerous drawings and maps. Imports will create components within the current folder. Before importing from such formats, create a new folder in the project to highlight it and then choose **File - Import**. Imported components will be created within the folder specified.
To move files between folders, drag components and drop them into a folder (drop them onto the folder icon itself and not the hierarchy beneath the folder). Folders may be created within other folders. If a folder is highlighted in the project pane and the create folder command is issued, the new folder will be created within the highlighted folder. Folders may be dragged and dropped into other folders. To move a folder out from within another folder, drag it and drop it into the "white space" of the project outside another folder.

.map Files and Compression

By default the .map format used to save Manifold projects automatically compresses the data contained in the .map file using techniques similar to those used by popular "zip" compression utilities. Therefore, usually there is no need to "zip" a .map file with utilities such as WinZip to save space or to speed up transfers over Internet - the .map file is already compressed.

Compression takes time when opening a .map file (to decompress the contents) and when saving a .map file. For very large files the time required for compression and decompression can be significant. If speed in loading and saving is more important than saving space on hard disk we can turn off automatic .map file compression in Tools - Options.

Use this option with care, since there is no indication that a .map file is uncompresses other than it takes more space. It is strongly recommended that if compression is turned off that the user establish operational practices to distinguish between compressed and uncompressed .map files. For example, one might never use compression on a particular machine, or one might keep all uncompressed .map files in a folder called "uncompressed."

Tech Tip: Save Frequently Used Components in .Map Files

We can keep collections of frequently used drawings or other components in .map files and then use File - Import - Component to import them from the .map file into the current project whenever desired.

Enterprise Edition

Manifold System Enterprise Edition also allows storage of components within centralized databases. With Professional Edition, every component that is in use in a Manifold project (with the exception of linked components such as linked tables, linked drawings, linked images or linked surfaces) is saved in a .map file that is used by one user at a time. If different users want to use the same drawing they must make a copy of it for use within their map files.

With Enterprise Edition, components may be saved within a centralized database, the Enterprise server, so that the same component can be shared by more than one user at a time. Enterprise users can also keep a single copy of a component within the Enterprise server and use it within many different projects. See the Enterprise Edition topic for more information. See the Data Storage Strategies for a discussion of desktop, shared enterprise and server storage models available within Manifold.

Choosing a Connection Technology

When linking components from an external data source we would like the link to be as fast and as capable as possible. Manifold supports a very wide array of connection technologies to allow informed users to choose the best possible connection method as they see fit. This can be somewhat daunting to new users who may not even know what ADO .NET is, let alone when to choose it over OLE DB.

In cases where general-purpose connection technologies such as ODBC or OLE DB are used to connect to data sources it is tempting to think of such technologies as "black boxes" that provide a seamless, two-way pipeline for data that provide the connection invisibly. In real life, however, there are very great differences between connection technologies and even within a particular connection technology there can be great differences between drivers that lead to significant performance differences or other limitations.

To cite just one difference between technologies, connections via ADO .NET can be 600 times faster to some data sources than the equivalent ODBC driver. To cite another difference between connection technologies, using Oracle's native Oracle Call Interface (OCI) provides better performance and allows using features not exposed through generic database interfaces, such as ODBC, OLE DB and ADO .NET. That is why Manifold uses OCI by default to connect to Oracle.
To cite a difference within the same technology, not all OLE DB drivers for the same data source are created equal: for example, the OLE DB driver provided by a DBMS vendor may be superior in terms of speed or capability to generic OLE DB drivers for that data source bundled within Windows.

The rule of thumb is to always use OCI for connections to Oracle. Manifold will do this by default whenever we choose Oracle data sources, and this default choice should not be replaced by something else unless the user is a serious expert on connections to data sources. For read/write connections to SQL Server, choose OLE DB using the SQL Native Client OLE DB driver.

For other data sources, use ADO .NET if a read-only connection is OK (such as when importing a table) and OLE DB otherwise. If you don't know whether a particular connection will be read-only or not or are worried whether any unexpected results you have (such as an inability to edit) result from using ADO .NET, use OLE DB always. If you think there may be a significant performance difference, visit the online forum for Manifold and discuss what you are doing with your fellow Manifold users and see what more experienced users advise.

Not all data sources may have either an ADO .NET or an OLE DB connection available, but virtually every data source anyone has ever heard of has had an ODBC driver written for it. Use ODBC when OLE DB or ADO .NET connections are not available.

Manifold has a lot of internal code devoted to working around various limitations that exist within some drivers for well-known data sources. For example, there is special code within Manifold to facilitate using OLE DB connections to upload binary data to MySQL even though it is not one of the "Big 3" DBMS packages officially supported by Manifold. To cite another example, establishing a database connection for a component linked from an ODBC data source will automatically degrade to read-only mode if connecting in read-write mode results in a connection that cannot be used to operate the component.

About the Nomenclature

Component was chosen as a deliberately neutral word to refer to the drawings, images and other items in a project. Manifold can work with so many different types of data that an existing GIS word like "layer" did not fit them all. For example, it doesn't make sense to talk about the "layers" in a project if some of the things in the project are scripts or comments or terrains, which can't appear as layers in a map. Also, some existing GIS words, like "theme" to take just one example, already mean something specific that doesn't necessarily work the same way in Manifold.

The word component is not intended to convey any special technical meaning other than indicating an item that is a part of a Manifold project. There is no fancy secondary meaning having to do with object-oriented programming or anything like that. It's just a generic, neutral word that ended up getting picked years ago.

If you are joining Manifold from some other GIS, please make an effort to use the word component and not some other word from that other GIS. It will be natural for ESRI people, for example, to want to use words like "theme" when referring to the drawings in their projects, but that will only get confusing because the words you use won't match what is written in the documentation.
Drawings, Images and Maps

Most files imported from other GIS systems into Manifold will appear as drawings. Most raster data and other images imported into Manifold will appear as images. The drawings imported into Manifold were likely called "maps" in their originating GIS programs.

Within Manifold, drawings, images and other components (such as labels or tables) can be clicked open into windows. Within those windows virtually all Manifold commands, including editing, transforms and more can be applied.

Drawings can be opened within a drawing window. Drawing windows always show the drawing as represented by the native projection used by that drawing. The drawing window above shows a drawing called bay_hydro that shows hydrography lines for the San Francisco Bay region.

Images can be opened within an image window. Image windows always show the image as represented by the native projection used by that image. The image window seen above shows the SanFran image that is a Landsat photograph of the Bay area. Images may be grayscale, palette, RGB, RGBA, or compressed images. Many image editing commands work only with RGB or RGBA images. See the Image Types topic.
Maps are made up of layers where each layer is another component in the project. Opening a map in a map window will show the components within the map in layers with a layer tab for each layer. Maps can use any projection, even projections that are different from the components they contain. The map illustrated above uses the bay_hydro drawing and the SanFran image as layers.

Important: For different layers to be seen together in a map window in correct alignment they all must be correctly georegistered. If the drawings or images used in a map have been imported from a geographically-aware format that saves projection information within the format, then there's nothing to think about and we can use such drawings and images together right away. On the other hand, if the drawings and images are stored in geographically-unaware formats, such as, say, DXF for drawings and JPG for images, well, then we may have to use the Edit - Assign Projection dialog to tell them what projection they are to use. We may even have to georegister them correctly within Manifold before we can use them together in a map.

Advantages of Maps

Maps have several characteristics that set map windows apart from drawing or image windows:

- Maps can consist of an unlimited number of layers where each layer is a drawing, labels, theme, image or surface component. Drawing and image windows consist of only one component.
- Context menu commands for layer tabs in maps allow us to create, duplicate and otherwise manage components in the project for use as layers in the map.
- Maps can be re-projected on the fly to present a different appearance of their contents without actually changing the data of the components within them. In contrast, drawing and image windows always show their contents using the native projection of the data set they contain. Changing the projection seen in a drawing or image window changes the coordinate data within the data set.
- Maps can alter the Layer Opacity of the layers in them to achieve different visual effects.
- Maps can use Zoom Ranges to automatically turn different layers off and on for display as the zoom level changes.
- Maps provide a user interface for commands that involve more than one layer at a time, such as the Match function, the Transfer Selection command and Tracing between layers.

Using many layers allows us to compose maps that are visually very sophisticated while retaining simplicity in the building blocks used. Each layer may be independently turned on, off, moved or otherwise controlled. For example, we can change formatting in a drawing layer without affecting other drawing layers. Using labels components we can build up many layers of text and annotations where each different text layer uses a different font, size or color for the text.

For certain casual uses, it may be easier to simply click open a drawing or image in its own window without opening it within a map. At times we will work with a drawing or image in a map and also have it clicked open within its own window. Within the map window we can see the drawing or image in a combined layer stack together with other components. Within its own window we can see and work with the image on its own.
This is also a great way of resolving visual ambiguity or making selections when working with many layers of complex drawings in a map. We can always click open a particular drawing in its own window and make a selection there in addition to seeing the drawing in a map and working with it in the map as well.

Maps and the components they contain as layers are dynamically linked. If we change something in a drawing's layer in a map, that change will instantly apply to the drawing open in its own window as well and vice versa.

Advantages of Component Windows

Opening a component in its own window does have some advantages.

- Component windows provide the very fastest interface in Manifold, which can be handy when working with very large images or surfaces that use a projection different from a map that might include them as a layer. However, in most cases when working with large images or drawings users will take care to assure that any map that includes them as a layer uses the same projection as well. Doing so will provide performance in the map window that is effectively the same as in the component window.
- Because the component is always shown in its native projection the exact relationship of objects within their native coordinate system is always evident. If a map uses a projection that is very different from that used by a component the change in visual appearance when seen through the map's projection might be disorienting.
- Certain commands must operate within the component window. For example, zoom ranges must be specified within the component window because otherwise the component would be invisible at certain ranges when seen within the map window.

Surfaces and Labels

The comments in this topic apply to themes, surfaces and labels components as well as to drawings and images. Themes, surfaces and labels components can be opened in their own windows as well as being used in maps.

Labels components, in particular, tend to be used mostly as layers in maps and are rarely opened in their own windows. Drawings by themselves can only show points, lines or areas. To show other visual elements, such as labels, we use a labels layer together with a drawing layer in a map.
Working with Maps

Maps show drawings, images, surfaces or labels as layers in a map window. Maps are the primary user consoles in Manifold because they allow us to work with many layers, and thus many components, at once. For example, we can edit drawings by working in a drawing layer to trace over items seen in an image layer below.

Maps can show their contents using any desired projection no matter what the native projections might be of their constituent layers. Maps work faster if they use the same projection as their constituent components, but they are not required to do so.

Creating a New Map

We can create a new map using whatever source materials we like:

1. Create a new project using File - New. This opens a project pane.
2. Using File - Import, import any drawings and images into the project the new map will use.
3. Create a new map in the project using File - Create - Map. We must specify the name of at least one drawing or image this map will use. In the Create Map dialog, check all the drawings or images from the project you would like to appear in this map.
4. Double click on the new map in the project pane to open it in a map window.
5. Drag and drop any additional drawings and images from the project pane into the map window. This adds them to the map. We can also add a component from the project by right clicking on any existing layer tab and choosing Add - Layers from the context menu.
6. Add a new blank drawing to a map by choosing Add - New Drawing. This will also create the drawing in the project.
7. If images or drawings are not already georegistered, they must first be georegistered so that they appear in the proper geographic location at the correct size.
8. If desired, change the projection used by the map.

Note: As a convenience, if a component is highlighted in the project pane when the Create Map command is launched it will automatically have that component checked for use in the new map.

Projections

When a map is first created in a project it uses the projection of whatever component(s) it uses. If it was created using only one component the projection of that component will be used for the map.

If a map is created using multiple components at the same time, then Manifold will use the projection of the largest image or surface as the default projection. This is because images and surfaces are slower to re-project than drawings so the map will run faster if it takes the native projection of an image or surface and then re-projects any drawings to match.
If only one image or surface is used to create the map then the projection of that image or surface will be used. If several images or surfaces are used to create the map then the projection of the largest of those images or surfaces will be chosen as the initial projection of the map.

We can change the projection used by a map by using the Edit - Assign Projection dialog. This dialog changes the projection used to display the map without changing the projections used by the components that are layers in the map.

If we would like the map to use a specific projection that's used by one of the components it shows we can easily specify the projection to be used by right-clicking on any layer and choosing the Use Projection choice from the context menu. The map will automatically switch to using the native projection used by that layer.

On the other hand, if we would like to re-project a component to use the same projection that is used by the map, we can right-click on the layer tab for that component and then choose Project to Map.

**Layers**

Maps show components stacked in layers.

The "white space" in drawings, themes and labels components is transparent so objects in lower layers can be seen. Images and surfaces can also contain regions of invisible pixels that allow items on layers below them to be seen. Images can also use RGBA pixel transparency to provide continuous gradients in transparency on a per-pixel basis.

Any layer may also have transparency specified for the entire layer via Layer Opacity settings. For example, we might show a surface layer in partial transparency over an image layer that provides a background image and so use the surface layer to provide a sense of "hill shading" and thus a sense of depth to the image to give it greater visual impact.

Each component dropped into a map appears as a layer identified by a layer tab.

Maps show layer tabs at the bottom of each map window. The layer tabs are automatically named the same as the drawing or image they contain. The leftmost tab is the top layer. Layer tabs may be used to manipulate the layers in a map:

- **Click** on a layer tab to make that layer the active layer.
- **Double click** on a layer tab to turn that layer on / off for display.
- **Click and drag** a layer tab to move that layer to a different position in the layer stack. Alternately, right click on the layer tab and use one of the Order commands.
- **Right click** on a layer tab to pop open a context menu of useful commands.
The **active** layer tab is white. Other layer tabs that are being displayed will have default contrasting color. Layers that are turned off will appear in a "disabled" display style. Only one layer is active at a time. New objects are always drawn in the active layer.

Manifold will automatically reconfigure all system controls for correct operation with the active layer. If the active layer is an image, for example, the Transform toolbar will be loaded with image operators. Click on a drawing layer tab to make it active and the Transform toolbar will switch to drawing operators.

When working with many layers, many users will also use the **Layers Pane** to control layers in addition to using layer tabs. See the Layers topic and the View - Panes - Layers topic for more information.

The layers pane also includes checkboxes for two system "layers" - a background color layer and a border layer that shows an enclosing box for all map layers. If any print layouts have been created using the map the layers pane will also include additional "layers" with checkboxes that may be used to show which regions of the map are included in the layout.

**Commands and Layers**

Selection commands and Windows Clipboard commands (**Delete**, **Cut**, **Copy**, **Paste**) work on the active layer only by default. To extend the action of a selection command or a keyboard shortcut Clipboard command to all visible layers hold down the **ALT** key while executing the command. Think of the **ALT** key as a mnemonic for "All" layers.

For example, using **Select Box** in a map window selects objects in the active layer only. Pressing the **ALT** key while using **Select Box** will select objects from all visible layers. The **ALT** key does not affect menu commands such as the **Modify Selection** commands in the **Edit** menu or the Clipboard commands in the **Edit** menu.

**Layer Restrictions**

The **Restrictions** button in the layers pane displays and sets **layer restrictions**. Layer restrictions may also be set by right clicking on a layer tab in a map window and choosing **Restrictions**. Each layer within a map may be specified to be clickable, editable or selectable (in any combination) with mouse commands. The restriction specified operates only on mouse commands. Other commands such as keyboard shortcuts, menu commands or query toolbar commands are not affected.

Layer restrictions are used to show layers in maps while preventing some layers from participating in mouse commands. This makes it easier to edit desired layers in complex maps. Another use for layer restrictions is in Manifold IMS to restrict the action of hyperlinks or the **Info** tool to a limited set of layers.

**Adding a New Layer**

Manifold provides several ways to add layers so that the most convenient method is always at hand:

- Drag and drop a component from the project pane into the map. This is a fast way to add just one component. The layer will be dropped into place just above whatever was the active layer.
- Right click onto any existing layer tab and choose **Add - Layers** from the context menu. A dialog with checkboxes for all of the currently unused components in the project will pop open. Check one or more boxes to add one or more components as layers just above the active layer. This is a fast way to add more than one component. It is also a fast way to add just one component if the project pane has been closed (say, to maximize screen real estate available for the map window).
- Right click onto a layer tab and choose **Add - New…** to add a new drawing, image or labels component. This creates a new, blank component of the desired type in the project and inserts it as a layer above the active layer. This is a fast way of creating a blank labels component to insert labels manually, or to insert a blank drawing to which items from other drawings may be pasted, etc.
- Right click onto a layer tab and choose **Duplicate**. This makes a copy of the active component (that is, the active layer) in the project and inserts it as a layer above the active layer.

**Zoom Ranges**
We can tell Manifold at which zoom level a layer becomes visible or invisible by using zoom ranges. Clever use of zoom ranges can set up a map so that as users zoom into the map different information comes into view. See the Zoom Ranges topic for details and examples.

**Transparency / Opacity in Layers**

Any part of a drawing or theme that is not occupied by an area, a line or a point and any part of a labels component not occupied by a label is transparent. This normally appears as "white space" because the default background color of Manifold windows is white. It is possible to use white as a background (fill) color for areas, in which case it is a good idea to change the background color to something other than white. If this is not done, it will be too difficult to tell what regions are areas and which regions are simply empty regions bounded by lines.

Images and surfaces have no empty space. Every part of an image or surface is filled with pixels. To allow "see through" regions in images and surfaces, Manifold images may have invisible pixels (which are used to show regions of missing data in surfaces) through which any items in lower layers may be seen. Invisible pixels are simply placeholders that do not appear. It is as if there are no pixels in that part of the image. To make part of an image transparent, we select the desired region and then Delete those pixels. Invisible pixels may be used with any of the four types of images.

**RGBa** images can have each individual pixel assigned a percent pixel opacity value using **RGBa Pixel Transparency**. This is normally accomplished through masks and other tools. When combined with Manifold image editing tools this effect can be used to compose amazing images by combining many layers of other images. See the Layers topic for an example.

Any layer can be made partially transparent by changing its opacity from 100% to 0% in steps of 1 percent by right clicking on the layer and choosing **Opacity**, or by using the controls in the Layers pane. This is a great way to create spectacular effects. Transparent layers work with all types of components that may appear in maps. See the Layer Opacity topic.

To summarize, there are several types of transparency that may be found in a map:

- Drawings and themes are transparent in **empty space** not occupied by an area, line or point.
- Labels components are transparent in **empty space** not occupied by a label.
- Any image or surface may be made fully transparent in regions of **invisible pixels**.
- **RGBa** images may be made partially transparent using **RGBa pixel transparency**.
- Any layer may be made partially transparent using **layer opacity**.

**Selection in Maps**

Selection in maps works the same as it does in all other windows, except that by default only items in the active layer are selected. Anything that is visible may be selected with mouse selection methods such as **select box**, so long as enabled by the selection modes in use. To make selections in more than one layer at the same time, hold down the **ALT** key.

For example, we can draw a box that encloses both lines in one drawing layer and areas in a different drawing layer. If the active layer is the lines layer, only the lines will be selected. If we hold down the **ALT** key while drawing the selection box with the mouse, both the lines and the areas will be selected.

**Multiple Map Windows**

We can open more than one window for the same map. Except for independent pan and zoom, each window into a map is perfectly synchronized with all other windows into that same map.

- Each map window may be resized, panned and zoomed independently of the other windows into that map.
- Changing layer tab order or visibility in one window changes it in all windows into that map.
- Changing the projection used in one map window changes it for all windows into that map.
- Any changes in drawings and images in one map window will appear in all windows into that map.
- Any selection made in one map window will appear in all windows into that map.
To see the map in a different window or with different layer ordering, make a copy of the map in the project pane and then change the projection or layer ordering in the copy.

**Map Windows are Synchronized with Components**

Maps are simply views into more than one component at once. Any changes to a component within a map window will appear throughout all other windows in which that component is seen. Components may be opened in one or more native windows at the same time they are seen in one or more map windows. For example, a drawing might appear in two drawing windows (each of which could be zoomed into a different part of the drawing) at the same time it appears in several different map windows.

- Any changes made to the component in any window will simultaneously appear in all other windows showing that component.
- Any change to the component in its layer in the map window will also instantly appear in any of its component windows as well.
- Any selection made in the component will be shown in all other windows where the component appears.

Note that re-projecting a component within its native coordinate system will change its appearance in any native component windows in which it appears but will not change its appearance in any map in which it appears. There is no apparent change because maps always re-project on the fly all components into the projection specified for the map regardless of what native projection is used by the component.

**Maps can use Projections**

Projections are a way to provide realistic views of the Earth, a 3D sphere, on 2D surfaces like paper maps and monitors. Projections are also used in paper maps to make measurements. It comes as a surprise to many people that there is no way to draw large regions of the Earth on a 2D surface without distorting what is shown. Geographic projections provide a standard way of presenting the features on the Earth's surface in 2D form that minimizes distortion in desired ways.

An unprojected map of the Earth may be shown using the Latitude / Longitude projection, which plots the features of the Earth as if latitude degrees were Y coordinates and longitude degrees were X coordinates. This presents a highly distorted representation of the Earth in higher latitudes, since obviously Antarctica does not have as much land area as Eurasia and Africa together.
Maps in Manifold can automatically show their contents using whatever projection is desired. All layers used in the map, including any image layers or drawing layers, will be displayed in the desired projection. For example, the illustration above shows the Earth as projected using the Hammer projection.

When a projection is changed in a map there is no change in the actual data of the components involved. The new projection is simply a change in the way the map window displays the components. Components such as drawings or images might be in their own projections that are different from the projection used by the map. The map window will dynamically (“on the fly”) recalculate projections used by components in the map so the map can display all layers together in the desired projection.

Users experienced in GIS know that re-projecting a drawing or an image changes the data. Many re-projections will slightly reduce accuracy. Changing a projection in a map in Manifold does not have this effect because the original data in the drawings or images used in the map is not changed: only the view of the data as seen through the map window changes. This allows us to change projections in a map as often as we like.

Different projections have different characteristics and are usually selected for a particular purpose because they minimize a particular type of distortion at issue in the subject matter of the map. The Hammer projection seen above, for example, distorts the shapes of items on the periphery of the projection but it maintains the relative area of each feature. It is a good choice to provide a better impression of the relative size of Antarctica compared to other continents in the context of an entire world view. However, it is a poor choice to portray the shapes of North American features as they would be seen on a globe.

No one projection can serve all purposes equally well. The topics in the Projections chapter discuss projections and provide a guide to choosing a good projection for one's intended use of the map.

Projections are a more sophisticated topic than can be covered in this introduction. Please see the Projections topics for information about geographic projections and their use in Manifold.

**Matching Map and Component Projections**

Maps can work faster if the drawings and images they contain as layers use the same projection that is requested of the map. If we always use a particular projection within a map it will be worth re-projecting larger drawings or images into that particular projection as well. To permanently re-project a layer in a map to match the projection used by a map, right click on that layer tab and choose *Project to Map*. This will automatically re-project that layer into exactly the same projection used by the map.

In order for maps to run faster when the constituent drawings or images are in the same projection, they must use exactly that same projection in all parameters. It does not help if different components use Lambert Conformal Conic projection but with different datums, for example. Most users will choose a particular projection and parameters they like and will use that as their standard for a given subject area.

The *File - Create* dialog takes the projection parameters for the new component from whatever window is active at the time the new component is created. If no existing component is active, the new component will be created using the system default projection of Orthographic centered at the 0,0 world latitude/longitude origin. If a map window or other component window is active when the new component is created, the new component will be created using whatever projection is used by that active window. This context-sensitive setting of default projection parameters makes it much easier to create new components using projection parameters that are hassle-free by default.

In particular, if the map we are working with has the focus when we use *File - Create* to create a new, blank component we will assure that the new component matches the map's projection for good performance. If we create a new component using the layer tab context menu's *Add - New...* commands we will automatically create a new, blank component that matches the maps' projection.

Another way of making sure a map matches a particular component's projection is to create that map based on the component. Right click on the component in the project pane and then choose *Create - Map* and check the component's box in the map creation dialog. In fact, when creating a map that will incorporate some large images or drawings, it is a wise idea to first create the map based on the biggest image that will be used.

**Maps are Free**

A "map" in the project contains very little data, since the contents of the map are taken from the components it contains. The actual map component consists of pointers to the relevant components as well as a very small amount of housekeeping information (layer ordering, projection parameters, etc). Therefore, making copies of
maps or making lots of maps in a project is an efficient way of creating and saving different views into the same data. There is virtually zero storage cost to adding another map to a project.

**Maps in CAD and Image Editing**

Manifold uses the word map to name the component that shows other components in layers and that can display its contents in whatever geographic projection is desired. We use the word map because displaying drawings and images in a geographic projection is quintessentially the function of a "map."

However, if we set aside the idea of projections what we have left is a viewing window that can show and manipulate components in layers. That's exactly what is done in the main viewing windows of CAD editors like AutoCAD or graphics editors like Adobe PhotoShop or Adobe Illustrator. It's just that ordinary CAD editors like AutoCAD or image editors like PhotoShop lack the projection and other geographic capabilities of Manifold maps.

Layers are a very important part of maps (and of the analogous viewing windows in AutoCAD or PhotoShop) because they allow us to compose very complex visual effects by combining images and drawings in layers. They also allow us to keep different types of vector objects within different drawings (for a more orderly workspace) and to re-use images or drawings in different combinations.

Layers are a great way of creating spectacular visual effects by combining multiple images. Through the use of pixel transparency, layer opacity and invisible pixels we can manipulate and position pixels within stacks of image layers in an almost magical way. We can also use Manifold as a superb CAD editor by working with drawings in the same way. Finally, we can combine drawings and images to create complex and visually elegant documents for presentation purposes.

The layer structure of Manifold maps was originally intended to make possible the creation of any sort of geographic map. As the image and drawing editing capability of Manifold grew it has now become possible to use Manifold "maps" as a framework for fairly sophisticated image and CAD drawing editing. In this sense, Manifold "maps" are much more than just geographic maps: they are general purpose, multi-layered documents that may be used in image editing and CAD editing as well.

**Tech Tip**

Although maps are free in that copying and pasting a map won't make duplicate copies of the components within that map, when a map is copied Manifold will remember the layers that are supposed to be in that map until it is pasted. So, for example, if we Copy a map and then before it is pasted we delete one of the components that is a layer in the map from the project pane, if we then Paste the map the deleted component will be restored.
Working with Large Images or Surfaces

Manifold can work with immensely large images and surfaces. Because the maximum size of images and surfaces is so large (16 exabytes, that is, 16 trillion gigabytes), as a practical matter the size limitation imposed on images or surfaces will be the amount of free disk space available or the speed with which a given machine can process the tasks desired. As images or surfaces become very large operations involving them will slow down because more pixels must be processed.

See also the Performance Tips topic to maximize performance in this or any other Manifold operation.

Manifold has several strategies to increase the speed with which large images or surfaces may be manipulated:

- Use of compressed images - Compressed images will load and display much faster than other types of images. The cost of using compressed images is that they are "display only" and cannot be modified.
- Use of intermediate views - When working with all non-compressed images and all surfaces Manifold can use pre-built intermediate displays to increase the speed of redisplay, panning and zooming. The cost of using intermediate views is that the first time an image or surface is displayed the system will pause while intermediate views are constructed.
- Use of linked images from image servers - Linked images usually store their data outside of Manifold, which allows using highly scalable external sources for both the actual image data and also intermediate views. Linked images are frequently "display only" and cannot be modified. However, when using an image server accessed through the Internet or other slow network keep in mind that the slow speed of the network may prevent fast operation of linked images from the image server.
- Use of linked images from Oracle GeoRaster capable servers - Oracle's GeoRaster technology, available within some Oracle products such as Oracle Spatial and Oracle Enterprise Edition, is extraordinarily fast. Linking a drawing from such an Oracle server allows working with images that up to terabytes in size.

Compressed Images

Compressed images use sophisticated wavelet compression technology to not only compress the amount of data an image requires but also to reconstitute the image on the fly on demand. At any given zoom level the desired view of the image is reconstituted from the compressed data store. At the present time, Manifold supports use of compressed images using ECW (the same as used with ERMapper) and JPEG 2000 formats, the emerging open source standard.

Compressed images can be either stored within a Manifold project or linked into the project as a linked image from a compressed format file stored outside of the project.

This technology allows astonishingly fast loading and display of such images but this speed is achieved at the cost of significant limitations. The main limitations of compressed images are:

- Display only - Compressed images may be viewed but not manipulated.
- No selection - Compressed images cannot be altered and their pixels may not be selected.
- Limited projection systems - Compressed images may be viewed only within a map that has a non-curvilinear coordinate system. As a practical matter, maps that will display compressed images should be created from those images.
- Reduced information content - The compression process eliminates the original pixel information in the image. Although compressed images when reconstituted for display may appear visually identical to an original uncompressed image, the reconstituted pixels are a synthetic approximation of the originals.

Compressed images also provide significant benefits:

- Fast display - The reconstitution process provides for very rapid recomputation of an image view at any desired zoom or pan.
- Fast loads and saves - Projects containing compressed images load and save much faster than projects using uncompressed images.
- Linked images - Compressed images may be left in their original .ecw files and, instead of being imported into the Manifold .map project file.
Introduction

- **Reduced disk space** - Compressed images require much less room than uncompressed images. Using linked images to utilize a single image file in many different projects will also save much disk space as compared to duplicating that image within many projects as an imported image.

- **Streaming links** - Compressed images may be linked into a Manifold project from an ECWP server URL, loading from a data stream served by an ERMapper Image Web Server.

- **Multi-channel images** - Some types of compressed images can store many more channels than just three channels that are always used for R, G and B channels. The *Image - Display Options* command in Manifold allows selection of which channels from a multi-channel image will be used for R, G, B and alpha channels.

Compressed images are a good choice for images displayed for their visual merit only, such as when images are used to form a background layer for a map, or when a background image layer will be traced to create a new vector map. Compressed images, especially those that are linked into the project, provide rapid response even when the image data is tens of gigabytes in size.

**Intermediate Views**

For simplicity of language this topic discusses intermediate views in the context of images; however the following applies to surfaces as well.

Manifold has several strategies for working with very large images to improve interactive performance and to reduce the patience required of a user. The most important strategy is building intermediate views of an image in advance and storing those intermediate views invisibly along with the image for future use. The intermediate views are then used to display the image for faster panning and zooming.

To understand intermediate views, consider the case of an image that is 21600 x 43200 pixels in size. Such an image is about 3.7 gigabytes in size if it is an RGB image.

A 21600 x 43200 image cannot be seen in full resolution on a computer monitor because there are not enough pixels on even a 1280 x 1024 monitor to show the entire image in full resolution. When a very large image is zoomed out so the entire image can be seen what is displayed is an interpolation, like a large thumbnail, that summarizes the vast number of pixels in the real image within the relatively few 1280 x 1024 pixels available on the monitor.

As we zoom further into the image we see it at resolutions that are closer and closer to the real resolution. When we zoom far enough into the image so that one image pixel uses one pixel on the monitor we see it in "native" resolution, but we only see a small part of the image (about a thousandth of it) at a time. Every time we show a very large image at less than full resolution the system must compute an approximation that fits into the view window size being used. The process of computing a correct interpolation at various zoom levels to smoothly zoom and pan the image can require a lot of time.

Manifold shortens this time by computing in advance a series of intermediate views of the large image for use at intermediate zoom levels and saving those intermediate views as a built-in part of the image. The intermediate views allow much faster action than if the entire large image must be manipulated for every change of view or other action.

When the image is saved as part of a *.map* file, the intermediate views will also be saved with the image. The next time the *.map* file is loaded and the image is opened the image will display very rapidly because the intermediate views are already available.

The use of intermediate views allows much faster action when working with large images but at the cost of a slower "startup" when the image is first created and opened. After importing a large image (which can take a considerable period of time for very large images) the very first time the image is opened a lengthy pause will occur as Manifold computes and saves intermediate views. After that, subsequent actions with the image will be very fast. When an image is saved as part of a *.map* file the intermediate views will be saved within the *.map* file as a built-in part of the image.

Whenever a map file is loaded and an image in the *.map* file is opened it will open instantly, because the intermediate views are already ready for use and are cached within the *.map* file. The use of intermediate views therefore makes it profitable to keep very large images saved in *.map* files.

Except for the delay in opening an image when it is first created or imported, there is no impact on the user of intermediate views except for the much faster performance they make possible. They are a completely "built in" part of Manifold that is handled automatically within the program with no user intervention required.
Many other technologies also incorporate the idea of intermediate views. See the Intermediate Levels and Pyramids topic for additional discussion and examples.

**Linked Images**

**Linked images** are images that are created using information from database tables or which are created using data streamed into the project from an image server. Linked images can also be used to reap the benefits of compressed image technology as discussed above.

The main advantage of linked images is the potential for great display speed of images that can, in some cases, be virtually unlimited in size. In addition to the potential for great speed, a secondary advantage of linked images is that multiple users can use the same image at the same time in different projects.

As far as disadvantages go, the main disadvantage is that in almost all cases linked images will be display only and **are subject to the same limitations as compressed images**.

Linked images from image servers are a way of bringing images into Manifold from external servers. The advantage of such linked images is that we can use data from immensely large image servers that save terabytes of information and which might be using hundreds or even thousands of machines in parallel to serve the views we want. Images linked from image servers will be displayed using a mosaic of image tiles that are automatically downloaded from the image server and seamlessly put together for us by Manifold to show the view we want.

The process can be remarkably fast because for any given level of zoom or panning into an image the tiles that comprise that view will be composed for us by the image server and then tossed down the network connection into Manifold. All Manifold need do is compute what tiles at what zoom levels are needed and then tell the image server what to send. The extraction of data for the tiles and the composition of tiles will be done by what is likely to be a very fast group of machines.

The main disadvantage of using image servers is that whatever views we want to see must be sent to us via a network connection to that image server. If we are using some public image server like TerraServer, each tile must reach us via what is often a rather slow Internet.

A further disadvantage of using image servers is that although public image servers like TerraServer or Google Earth will often use extraordinarily fast arrays of machines, all that fast hardware is very often overburdened by an extraordinarily large number of users. Response, therefore, can be slow.

Finally, when we link in what might be a very large image from an image server we will not likely ever get all of the data for that image from the image server unless we do a deliberate download at full resolution of the linked image into an ordinary local image.

Linked images created from database tables can be created using any database technology, but usually in the case of very large images they are created using Oracle database products that incorporate Oracle’s **GeoRaster** technology, such as Oracle Spatial.

**Linked images from Oracle servers** can be breathtakingly fast even for immensely large images. Even when an ordinary desktop machine, such as that using an entry-level 64 bit AMD processor, is used to host both the Oracle server as well as running the Manifold session, even gigabyte sized images linked from that server will zoom and pan virtually instantly.

The main advantage of storing images as linked images within Oracle databases using **GeoRaster** technology is that Oracle’s technology scales very well. Oracle databases are very well suited for clustering architectures that enable creation of very large, very fast Oracle servers. In such cases, images of virtually limitless size, even terabytes, can be stored and displayed with great speed. Even in relatively small and inexpensive machines the size of images that can be stored within Oracle is truly impressive.

The disadvantages of storage within Oracle **GeoRaster** capable databases are cost and some additional administrative overhead. As of this writing, freely redistributable versions of Oracle Express Edition do not include **GeoRaster** capability, so one must acquire a suitable Oracle product. That is not normally an obstacle as usually those applications that involve many gigabytes or terabytes of image data have sufficiently high value that the cost of requisite Oracle licenses is a small part of the overall budget.
**Note:** Manifold also allows storing images within database tables in databases other than those using Oracle GeoRaster technology and then reconstituting those images as **linked images** created from those database tables. However, image storage within databases other than Oracle GeoRaster storage has relatively poor performance and is not usually done except for specialized applications where fast performance or very large image size are not required.

### Image Size and Compressed Formats

Some formats, such as **TIFF** or ordinary **JPEG** will use compression to reduce the amount of disk space required for the image even if the format does not otherwise use compression or intermediate level strategies to increase display speed as do more sophisticated formats like **ECW** and **JPEG 2000**. Whether or not compression is used for speed, just as a matter of saving disk space very large images are almost always saved in some compressed format.

Because of the limits of what a particular format can do, Manifold must use different strategies when importing images from different formats. Most compressed formats, such as **TIFF**, will be automatically decompressed upon import into a Manifold project. **ECW** and **JPEG 2000** format compressed images are not decompressed but are imported into Manifold as a special compressed image type. The difference between decompressing an image upon import and not decompressing an image can be substantial.

For example, a 21600 x 43200 pixel image requires about 3.7 gigabytes as an RGB image but it might be saved as only a 400 megabyte file in .tif format. When such images are imported into Manifold they must be decompressed into a real image to be ready for display and editing. That can come as a surprise if we only look at the size of the compressed .tif file on disk and don't consider how big the image will be when decompressed on import into the Manifold project.

Because a 400 megabyte .tif file can easily decompress into a 3.5 gigabyte RGB image it is essential to have plenty of free disk space when working with large images. If we work with images that are hundreds of megabytes in size when saved in compressed formats like .tif, we should have gigabytes of free space on hard disk, preferably dozens of gigabytes if we will be working with several such images at once.

In contrast, images stored within .ecw format will be brought into Manifold with their compression retained. They will not expand in size because they will be brought into Manifold (either imported or linked) as **compressed** images.

Likewise, **linked** images of all kinds that take their data from outside of the Manifold project will not have high storage requirements upon import. The price we pay, of course, for such reduced storage requirements is that such images are display only and cannot be edited, selected or otherwise manipulated.

### Disk Utilization

Because large images and surfaces that are imported will not usually fit into system RAM, they will normally be kept on disk, either in the .map file or in temporary disk files created when the .map file is loaded. Whenever a large image or surface is opened Manifold will first conduct a rapid calculation to check the amount of RAM available and to determine the optimum way to balance usage of RAM with disk space for working with a particular image.

Obviously, since RAM is cheap if we are working with large images it makes sense to install the maximum amount of RAM we can into our systems. If our system can host four gigabytes of RAM then we should install four gigabytes.

With larger images unless compressed images or linked images are used just about any operation with such images will inevitably involve using large amounts of disk space, whether it is as a result of using the system pagefile or the use of fast, temporary files set up by Manifold itself on disk. Of course, if the images are to be manipulated in any way (other than just merely displayed) compressed images or linked images cannot be used.

This heavy usage of disk for large images and surfaces makes it imperative that users desiring optimum performance with large images should invest into fast hard disks. A good strategy is to buy large hard disks, since larger hard disks are faster than smaller ones, to choose faster-rotating disks such as 7200 RPM or faster to reduce rotational latency and to invest in SATA or other fast interfaces. Using multiple hard disks in striped RAID arrays can also increase disk performance. Although most users will not invest in elaborate RAID configurations, simply adding a second hard disk to host the TEMP folder separately from the system pagefile will provide some performance gains because the two disks will be able to independently perform overlapping seek operations.
Tech Tips

Expert readers may wonder how much space is used up in the .map file to cache intermediate views. The usual rule of thumb is that the compressed size of the image within the .map file will increase by about 30%. Although that seems like a lot, considering that the overall compression of the image will continue to be somewhere between a factor of three and ten, it is not a bad tradeoff to achieve much faster panning and zooming.

Keep in mind that there are not enough pixels on the screen in computer monitors to display all of a large image at once. When zoomed out so the entire image can be seen the large image will be shown as a summary, intermediate view using fewer pixels. The summarization process necessarily loses detail. This is not a limitation of Manifold but rather the result of a limitation in the resolution of the computer display. If the image is printed at full resolution (inkjet printers can now routinely provide real resolutions of over 1400 or 2800 dots per inch) it will appear much sharper and clearer than it can appear on screen in an intermediate view.

Manifold uses the unlimited size ECW SDK to support use of ECW and JPEG 2000 images of unlimited size for all loading, linking, saving and display operations. Images may be converted to and from compressed mode using the Image - Convert To command. Keep in mind that converting a compressed image into another image type, such as an RGB images, can vastly expand the size of the image.

If images are to be used for display only, it make sense to store them in the form of ECW format files and to link them into a Manifold project as compressed images. That's a highly effective and free strategy for working with images up to several tens of gigabytes in size.

In contrast, if images must be manipulated in some way (for example, for editing), then they should be stored in some other format and imported into Manifold as an RGB or other non-compressed image type.

For extremely large images in the hundreds of gigabytes or terabyte range the best strategy is to use an Oracle server cluster with Oracle Spatial or Oracle Enterprise Edition with GeoRaster capability. Oracle servers are also the preferred strategy if very many users must simultaneously access the linked image. For example, if we have thousands of Manifold users in our organization that need to use parts of a particularly large image as a background it is wise to host that image on an Oracle server.

Performance Tips
Selection

Many operations in Manifold begin by selecting something and applying an effect to that something.

The "something" might be a region of pixels in an image, a particular group of lines in a drawing or some special selection of records in a database table.

The "effect" could be an operation that transforms what’s in the selection, such as brightening only those pixels selected in an image or it could be a request to analyze what’s in the selection and make a report. For example, we might select a group of records in a database table and ask what the average is of the "Population" field for those records.

Choosing that "something" on which we wish to work is making a selection. There are two key ideas connected to selections in Manifold:

- **Making a Selection** - Use the mouse to point at something or to drag open a rectangular, circular or free-form box to select everything inside the box. Selection Tools let us do this. We can also make selections with the transform toolbar, with scripts, using the Query toolbar or from SQL.
- **Changing the Selection** - After we’ve made a selection we may want to add to it, subtract from it or otherwise change it. This is what selection modes and selection commands help us do.

The examples below are illustrated using images. The concepts and methods they show work with drawings as well. To follow along, use File - Import - Image to import the bronze.jpg sample image into the project. Double-click on the bronze image component to open it in an image window. The bronze.jpg image may be found in the Manifold examples downloads.

**Note:** Selection can only be done in components that are read/write. Selection is not supported in images or drawings that are read-only. For example, Compressed images are a special type of read-only image that may be displayed but not otherwise manipulated. Compressed images do not support selection.

**Making a Selection**

1. Choose the selection tool. We’ve picked the Select Box rectangular box selection tool.

2. Make the selection by clicking and dragging open a box with the mouse.
3. The selected pixels will be shown in red selection color.

**Note:** we can change the display style used to show the selected region so that the red crosshatch pattern does not get in the way of graphics editing. This is discussed further down in this topic.

Other tools allow making the selection in different ways. In the image above we've used **Select Touch** to click on the blue sky and thus selected all blue pixels within the touch selection’s tolerance. Following is the full set of mouse selection tools available in Manifold:

- **Select Touch** - Click to select pixels like the one clicked, give or take the tolerance that may be set in the Tool Properties pane. See the following note on touch selection in surfaces.
- **Select Shape** - Left click to draw a closed shape and right click to end and select all pixels within the shape.
- **Select Freeform** - Select objects within the mouse cursor region defined by clicking and dragging, followed by a right click.
- **Select Box** - Click and drag to select items within a rectangular selection box
- **Select Box on Center** - Click and drag open a selection box that’s always centered on the point of first click.
- **Select Circle** - Click and drag open a selection circle within the rectangle implied by the mouse motion.
- **Select Circle on Center** - Click and drag open a selection circle that’s always centered on the point of...
first click.

- **Select Ellipse** - Click and drag open a selection ellipse within the rectangle implied by the mouse motion.

- **Select Ellipse on Center** - Click and drag open a selection ellipse that’s always centered on the point of first click.

**SHIFT key**

Shifts selection to "open" mode. In drawings, selects all items any part of which is within the shape drawn with the mouse.

In images (using **Select Touch**) the SHIFT key will apply the touch select to all pixels like that one touched even if they are not contiguous.

---

**Touch Selection**

Touch selection in drawings will select the objects touched. In images and surfaces, touch selection will select pixels within the tolerance setting in the Tool Properties pane. We can also select ranges of elevations in surfaces using the transform toolbar. See the Editing a Surface for Visual Effect topic for an example.

**Regular and On-Center Commands**

Note that some commands, like **Select Circle**, also occur in an "on-center" version such as **Select Circle on Center**.

Like selection tools, painting tools occur in both on-center and regular versions. We can see the difference between the regular tool and the on-center tool by painting a circle. Painting tools are used in these illustrations with tool opacity of 50 (half-transparent painting) to better show the difference in operation between regular and on-center commands.

Using **Paint Circle** to click near the center of the monument above and then dragging to the spot shown will open a preview circle as shown. Releasing the mouse button paints within the indicated preview circle. With regular commands, the mouse shows the desired diameter of the circle.
We can use **Paint Circle on Center** to click at the same beginning location and then drag to the same ending location. Note that the preview circle is larger than the previous circle. With on-center versions of commands the initial click is the center of the circle and the mouse motion shows the desired radius of the circle.

**Select Objects Buttons**

Select objects buttons allow us to specify what types of objects are selectable. This is very useful when working with complex maps with lots of objects in sight, because it allows us to enable selections only for certain items, such as pixels. These buttons work like filters: what's pushed in is allowed and what is not pushed in is not.

![Select Objects Buttons](image)

Choose the type of items that are to be selected by pushing the selection filter buttons for the desired types. The buttons above show selection enabled for points and disabled for areas, lines and pixels. If we drew a selection rectangle over a region in the map that contained all four types of items, only the points within the rectangle will be selected. Areas, lines and pixels within the rectangle will be ignored.

- **Select Areas** - Enable selection of areas by mouse selection tools.
- **Select Lines** - Enable selection of lines by mouse selection tools.
- **Select Points** - Enable selection of points by mouse selection tools.
- **Select Pixels** - Enable selection of pixels by mouse selection tools.
- **Select Text** - Enable selection of text labels by mouse selection tools.

All five filter buttons will be displayed and may be used in maps. When working in drawing windows, the **Select Pixels** and **Select Text** buttons will not be visible since there are no pixels or text labels in drawing windows. When working within image windows, there are no select objects buttons displayed since images consist only of pixels. In images, selection of pixels is always enabled.

**Selection Modes**

![Selection Modes](image)

The selection mode buttons control how a new selection made with a selection tool is combined with any existing selection. One selection mode button is always pushed in.
Select Replace - Replace the existing selection with whatever is now selected.

Select Add - Add whatever is now selected to the existing selection.

Select Subtract - Subtract whatever is now selected from the existing selection.

Select Invert - Deselect whatever is now selected that was already in the existing selection and otherwise add what has just been selected.

Select Intersect - Select only the region of overlap between what is specified by the tool and what is in the existing selection. If there is no overlap, nothing will be selected.

The default is Select Replace, where any new selection replaces the previous one.

With Select Replace on, if we click several times using Select Touch we would get a new, different selection each time depending on where we clicked.

If we use Select Add we increase the selection every time we touch a different region of like-colored pixels.

Let's look at a series of examples to illustrate the other modes. In each case we will start with a selected region (made with Select Touch between the horse's legs). A dark circle has been added to show clearly the selection circle drawn with the mouse.
We will then choose a selection mode and use **Select Circle** in a new selection to see what happens:

With **Select Replace**, the circle replaces the previous selection.

With **Select Add** the circle is added to the previous selection.

**Select Subtract** removes the part of the previous selection that was overlapped by the circle.
Invert Selection takes any part of the circle that overlaps the previous selection and removes it from the selection and otherwise adds the circle. If all the pixels in the bronze statue were selected and we wanted to deselect that and instead select all pixels not in the statue, we could use invert selection and draw a rectangular selection box that covered the entire image.

Select Intersect takes the intersection of the circle and the previous selection. Select Intersect is very handy when using different combinations of selection tools and selection modes.

The Selections Pane

Once we pick out a selection, we can save it in the Selections pane. We can then re-use it or recombine it with an existing selection using the Selection Commands. The Selections pane may be popped open from the View - Panes menu. It is often left open and docked into the main Manifold window together with other control and information panes.

Saving a Selection

1. Choose View - Panes - Selections to open the Selections pane.
2. Make a selection.
3. In the Selections pane, click New to save the selection into the list in the dialog.
4. If you don’t like names like "Selection1" and "Selection2" double click onto the selection’s name and change the name.

Shortcuts: Open the Selections pane with ALT-SHIFT-S. Close it with another ALT- SHIFT-S or click onto the x Close button in the upper right hand corner of the pane.
The selection pane is very important when working with the transform toolbar. Saved selections can appear in either the target box or the parameter box.

**Selections Pane Examples**

In the examples that follow, we have used the above steps to save three selections that we have renamed to be called “Sky”, “Clouds” and “Box.”

We can build up the selections quickly by using **Select Touch in Select Add mode**. We could click on different parts of the blue sky, for example, to add all the different blue regions quickly to one selection that we saved as Sky.
Once the above selections have been saved into the Selections pane we can retrieve them at any time.

To see what a saved selection looks like without actually using it, press in the Preview button in the Selections pane. The saved selection will be shown in the drawing window using a blue hatched pattern in addition to any selection that may already be there:

The image above is what the Clouds saved selection looks like as a preview.

This image shows the Box saved selection as a preview.

Selection Commands
Five selection command buttons are arrayed at the top of the Selections pane. These commands apply to whatever saved selection has been highlighted in the dialog. If we click on a saved selection to highlight it and then press one of these buttons, it will be combined with whatever is the current selection in the image. The selection commands allow us to use the saved selection to replace the selection, to add to the selection, to subtract from the selection, to invert with the selection and to intersect the selection.

- **Select Replace** - Replace the existing selection with the highlighted saved selection.
- **Select Add** - Add the highlighted saved selection to the existing selection.
- **Select Subtract** - Subtract the highlighted saved selection from the existing selection.
- **Select Invert** - Deselect what is in the highlighted saved selection that was already in the existing selection and otherwise add the highlighted saved selection.
- **Select Intersect** - Select only the region of overlap between the highlighted saved selection and what is in the existing selection. If there is no overlap, nothing will be selected.

For example, if we click on the Clouds saved selection to highlight it and then press **Select Replace**, the Clouds selection will replace whatever was the previous selection:

This is a common method of retrieving a saved selection: simply click on it in the Selections pane and then press **Select Replace**.

We can also use the selection commands to combine the saved selection with whatever is the current selection in the image. In the examples that follow, we have first made the Clouds selection and then we have highlighted the Box selection which is shown in the preview blue color. After that, we click on one of the selection mode commands to see what happens:
**Select Replace** - The pixels in the saved Box selection are selected and all others are deselected.

**Select Add** - The pixels in the saved Box selection are added to those already selected. Note how the legs of the horse were not selected before and are not selected after the Add operation. Pretty neat, isn’t it?

**Select Subtract** - The pixels in the saved Box selection are subtracted from the existing selection. Note how the new selection has had the region of overlap removed.
Select Invert - Any pixels in the region of overlap are deselected while all those that are in the box or in the previous selection are selected.

Select Intersect - Select all pixels in the region of overlap between the Box and the previous selection. If there is no overlap, no pixels will be selected.

Example: Selection Tools, Selection Modes and Saved Selections

This example shows various selection capabilities used in combination.

Using Select Touch and Select Add we click on different parts of the image to add pixels to the selection as desired. If we "overshoot" and add some pixels we don’t want, we use Select Subtract with a convenient tool such as Select Rectangle to remove the undesired pixels from the selection.
Next, using **Select Intersect** we use **Select Circle** to grab only those previously selected pixels that fall within the circle. We can save this selection into the Selections pane.

When a selection is made in an image, editing effects apply only to those pixels selected. Here, we've used **Hue / Saturation** to change the hue of the selected pixels.

We then clicked **Deselect** to deselect all pixels. Nice, but not bright enough.....

Using the Selections pane, we can recall the selection we used previously. When shown as a preview the saved selection is drawn in bright blue color. We are happy we saved it, since we want to change the saturation and
lightness of exactly those pixels that were in this selection earlier. We press **Select Replace** to use this saved selection in the image.

We've used **Hue / Saturation** to increase the saturation and lightness of the selected pixels and then clicked **Deselect** once more to get rid of the selection hatch pattern. That's better!

**If the Selection Pattern Interferes**

A dense red grid shows the selection well without any ambiguity; however, it can obscure the effect of changes that are applied to the selected pixels. There are two ways to deal with this:

- **Change the selection style to a less intrusive pattern or color or other style.** The pull-down arrow next to the **Use Selection Color** button opens a menu of possible selection styles, including simple border and various pattern densities.

- **Toggle the Selection Style button.** This button turns the selection style ON and OFF. When OFF, the selected pixels are still selected but no red crosshatch pattern will be shown. When ON the red selection pattern will appear over the selected pixels. When making changes such as hue and brightness changes it is often quite obvious which pixels are selected by the changes being applied.

Try making a selection and then toggling the **Selection Style** button to turn off use of the selection pattern. The pixels are still selected but there is no pattern showing. We can then apply effects with a preview box checked and see the results directly within the image.
If we begin with a circular area of pixels selected we might wish to see the effects of lightness changes without visual interference from any selection style, so we toggle the Selection Style button.

At first we see nothing, since the selection style pattern is gone. However, the changing visual appearance on moving the lightness slider control in the Hue / Saturation effect makes it easy to see which pixels are affected.

**Selection in Drawings**

The examples above use images because it’s easy to see what is going on with selection in images. The same techniques will work throughout Manifold System with drawings, tables, charts and connections between them. For example, selections can be made and saved into the Selections pane for drawings as well as for images.

In almost all cases, every window in Manifold that shows data will have selection tools for mouse selection, the cumulative action of which will be controlled by selection modes.

Suppose we have a drawing of the United States. We can use Touch Select together with Select Add mode to click on states to add them to the selection…

First we click on California.
Next we click on Utah.

Arizona…

… and finally, Nevada. We can save this selection above as a saved selection in the Selections pane for the drawing.

Let's call this saved selection **South West States**

We can then make another selection in the drawing.
If we like, we can save this new selection in the Selections pane as well. We will call this new saved selection Mountain West.

At any time we can now click on either of the two saved selections in the Selections pane and, with the Preview button pushed in, see them previewed in the drawing.

For example, previewing the South West States saved selection will show it in the drawing in blue preview color.

**Saved Selections and the Transform Toolbar**

Saved selections will appear in transform toolbar boxes that can work with selection sets. For example, if a drawing has two saved selections called South West States and Mountain West then these will appear as choices in the transform toolbar when that drawing has the focus.

When drawings appear together in a map, if any drawing layer has the focus the transform toolbar for the map will list all saved selections in all drawings. This is a great convenience, but it also leads to a slight complication in that all saved selections using the same name are treated alike. Saved selections in the same drawing are required to have different names, but saved selections in different drawings might use the same name.

The transform toolbar for the map will treat all drawing saved selections using the same name as one, combined saved selection. For example, if we have two drawing layers in a map, one called East and the other called West and they both have a saved selection called Cities, then using the transform toolbar to create a convex hull using the saved selection choice called Cities will use the objects from both the East and West drawings that appear in their respective Cities saved selection.

Therefore, it is a good idea to use unique names for saved selections in drawings that might appear together in the same map. For example, we could name the saved selection in one drawing East - Cities and that in the other drawing West - Cities.

**Selection by Type**

The Edit menu for drawings includes a Select by Type choice. Use this command to select all of one or more types of objects, that is, all areas, lines or points in the drawing. The Select by Type command applies whatever Selection Objects and Selection Modes settings are in force.

For example, to select all of the points in a drawing we would push in the Select Points button and the Select Replace button and then choose Edit - Select by Type. All points in the drawing will be selected, replacing any previous selection.
If we simply wanted to add all the points to the current selection we would have pushed in the Select Add mode button and then chosen Edit - Select by Type.

CTRL-T is a keyboard shortcut to select by type. Other handy shortcuts are CTRL-A to select all and CTRL-I to invert the selection.

**Smart Mouse Selection**

Smart Mouse selection is used to select objects for editing. An object selected with smart mouse selection will appear with edit handles that can be used to move or reshape the object. An object chosen for editing is also called the primary selected object.

Commands involving the mouse are normally controlled by whatever toolbar button is engaged. To use Select Box for example, we push the Select Box button in and then use the mouse in this mode. To provide fast operations when the mouse is not engaged in any other command, Manifold allows “smart mouse” selection in a way that mimics ordinary Windows point and click mouse highlighting and motion methodology as is used in Word and other applications.

For example, CTRL-ALT clicking on an area object in a drawing will select it for editing. See the Editing Objects topic for examples and more information on interactive editing with smart mouse selection.

**Keyboard Modifiers with Smart Mouse Touch Selection**

Because a selection may already exist in the drawing when we wish to select an object for editing, smart mouse selection uses keyboard modifiers to allow a richer set of commands.

- **Click** Equivalent to Select Touch in Replace mode. Clicking into an empty part of the drawing deselects all objects.
- **CTRL-ALT Click** Select the object as the primary selected object, that is, select it for editing. Does not change the selection state of other objects.
- **CTRL Click** Invert the selection state of the object without changing the selection state of any other object. Equivalent to Invert mode.
- **SHIFT Click** Select the object if it is not yet selected. Does not change the selection state of other objects. Equivalent to Add mode.

**Smart Mouse Box Selection**

When clicked on an empty region and dragged the mouse automatically makes a box selection analogous to using the Select Box selection tool in Select Replace mode. This is a general shortcut for selection. To select an object as the primary selected object for editing, CTRL-ALT click on it.

**Keyboard Modifiers with Smart Mouse Box Selection**

The following keyboard modifiers may be used with smart mouse box selection:

- **Click and drag** Click on an empty region and drag to make a box selection in Select Replace mode. Selects all objects that are entirely
within the selection box.

CTRL Click on an empty region and drag to make a box selection in Invert Selection mode.

SHIFT Use an open box selection to select all objects any part of which are within the selection box.

Selection in Tables

When we open a table that’s linked to a drawing, the table window will show selected records with a light selection color background.

For example, the four states selected in the drawing at left will have their records in the table highlighted with selection color. (The records are alphabetical sort order so Nevada and Utah are not seen in the fragment of the table shown above).

The Selections pane shows the same saved selections for both a drawing and any tables associated with that drawing. If we choose a saved selection to be previewed, the records will be highlighted in preview color in the table as well as being shown with preview color in the drawing.

For example, if we click on the Table window to move the focus to the table, the Selections pane will still have two saved selections called South West States and Mountain West. We can click on Mountain West to highlight it and press in the Preview button to preview it.

As seen in the illustration above the states in the Mountain West saved selection will be highlighted in preview color in the table. Regardless of which window has the focus, a preview involving objects that appear in both drawings and tables will preview them in blue in all the drawing and table windows in which they appear.

It is clear from the hatch patterns which objects in the drawing appear both in the current selection and are being previewed from the Selections pane. In tables, records that are both selected and are in the preview will be shown in a color midway between the selection color and the preview color. By default, the combined color is light purple.

Selecting Records
Clicking on a record handle in the table is the same as a Select Touch on that record. We can also use CTRL-click and SHIFT-click.

In the illustration above we click on the record handle for the Nevada record to select it. Selecting a record will combine it with any existing selection in accordance with the selection mode (Replace, Add and so on) currently in force.

For example, we could change the selection mode to Add and then click on the record handle for the state of Alabama and several other states to add them to the selection shown in previous illustrations. The selection will be updated both in the drawing window and in the table window.

We can select items using any combination of selection in the map via mouse-based selection tools or selection in table windows via a variety of point-and-click highlighting methods within the table. For example, we could sort the table by clicking on a "population" field and then select only those records within a particular population range. We could then save this selection in the Selections pane. At any time this saved selection could then be combined with another selection made in the drawing or in the table.

This free-form way of selecting from within tables or maps is one of Manifold’s most original and most powerful concepts. Throughout Manifold we can get exactly the selection desired by clicking in different windows under the control of selection modes, saving selections within the Selections pane and then using selection command buttons from the Selections pane to combine saved selections with the existing selection. Sometimes it is very convenient to find records in tables by sorting columns and then selecting the topmost few records in the table to also select them in the map. See the Selection in Tables topic for more.

To select a range of records, click on the first record handle and then SHIFT-click on the last record handle. This will select all records (in accordance with the selection mode set) from first to last.

Note: clicking on a cell in a table makes that cell the active cell. To select a record in a table by clicking on a cell we can CTRL-click the cell. See the Working with Tables topic.

**Showing only the Selection in Tables**

To show only selected records in a table we open the table and push in the Filter Selected button either in the main toolbar or in the View - Filter dialog.

The table will then show only selected records. Records will appear and disappear from a table window filtered with Filter Selected as they are added to or subtracted from the selection by actions in other open windows.

**SHIFT key for "Open" Mouse Selection**
The keyboard’s **SHIFT** key may be used in combination with mouse selection to “open” the mouse selection.

By default, mouse selection commands will select all those items that are **entirely within** the selection shape that’s drawn. The **SHIFT** key “opens” the selection so that it grabs all items any part of which is within the shape drawn with the mouse. For pixels in images, or points in drawings “open” mode is the same as the default. For lines or areas in drawings “open” mode is a way of selecting all objects that touch or are within the mouse box.

Drawing the above box over the US_Main map selects only those states that are entirely within the box.

In this case, just one state.

If we hold down the **SHIFT** key while making the same selection…

…we select all states that touch or are within the box.

**SHIFT** Touch Selection in Images
Just like using the **SHIFT** key causes a more inclusive selection in drawings, there is also an analogous **SHIFT** key function for touch selection in images.

Using touch selection to click on a white pixel in the image at the left will select all pixels within the tolerance threshold that are contiguous (i.e., adjacent to each other). In this case, white pixels between the legs are selected but not those on other sides of the legs.

Using **SHIFT - touch** selection to click at the same spot will select all pixels within the tolerance threshold throughout the entire image no matter where they are located. In this case, all of the white pixels within the tolerance level have been selected throughout the image.

**Tip:** Using **SHIFT - touch** selection is a good way to select pixels to replace a color throughout the entire image. Select the color throughout the entire image and then use either Hue / Saturation to change the color or the Paint Bucket tool with the **SHIFT** key to pour a different color into the selection throughout the entire image.

### Speed of Select Touch in Images

Determining whether or not pixels are within a contiguously connect region requires many spatial computations, so **SHIFT-touch** selection frequently will operate much faster than touch selection.

### CTRL Key and Select Touch in Images

Holding down the **CTRL** key while using Touch Select with images will select only that pixel that is touched. **CTRL - touch** is used when zoomed far into a map to “clean up” selections pixel by pixel.

For example, the illustrations above show an image at great zoom where we wished to select only the lighter regions. The image at left shows that one of the black pixels is selected. We can deselect it by clicking it using **CTRL-touch** with selection mode set to **Subtract**. This method allows us to easily add or subtract individual pixels from the selection.

### Autoscroll and Selection

When making freeform selections, Manifold will autoscroll the window to allow us to move the window even in the middle of a selection command. Autoscroll may be turned off or configured in Tools - Options.
**Touch Selection Accuracy**

Touch selection will select objects and pixels within a 4 screen-pixel radius of the actual screen pixel touched. This setting makes it possible to "touch" objects reliably without frustration even on higher resolution monitors. If touch selection chooses unwanted objects or pixels that are very close to the location touched, zoom in to provide greater spacing and touch again. At greater and greater zoom levels, individual pixels within images will enlarge until they take up many screen pixels as seen in the illustrations above.

**Touch Selection Tolerance Setting**

Touch selection will select all pixels whose color is within a given tolerance range of the pixel touched by the mouse. For RGB or RGBA images, tolerance is computed only on those channels that are made visible in the layers pane. For palette images, tolerance is computed based on the R, G and B values of the palette color as compared to other palette colors. Change the tolerance setting as desired in the Tool Properties pane to increase or restrict the range of pixel color values that are selected when using touch selection.

In the illustrations above we have increased tolerance from a low level to a much higher level and then clicked on the blue sky just above the head of the monument. As tolerance is increased a greater number of pixels are selected in colors that are more and more different from the blue hue of the touched pixel. At high tolerance settings pixels with colors very different from the touched pixel will be selected.

**Selections are Shown in their Map Layer**

Selections are shown in all of the image or drawing layers in which they occur. If a selection is made only in a lower layer, upper layers might cover it.
Suppose we have one RGBA image based on our sample *bronze* image that consists of regions of visible, partially transparent pixels as well as invisible pixels. We can use **Select Circle** in the image window to select only that part of the circle that is over visible pixels. It selects all visible pixels, even those with low opacity specified using RGBA pixel transparency.

Suppose we open another image window showing our standard *schloss* image. We can make a **Select Box** rectangular selection in the schloss image window.

We can display both images together in a map window. The selections made in each image window will appear in the layer associated with their image. Seeing the two selections together in the map window shows both selections have been made independently.
Suppose now we click on the bronze image window and deselect the selection made in the bronze image and change the Selection Style to use a border style. The illustration above shows the resultant map window view. Because the bronze image is above the schloss image in the map layer stack, the head of the bronze image covers not only the schloss image pixels but also the selection indication. Since the bronze image is an RGBA image that is partially transparent even near the head, if we look carefully we can see a hint of red selection border peeking through the bronze image.

Note that selections are properties of the individual components, not of a map overall. A "map" is just a stack of layers of components like images and drawings. Clicking on a layer's tab to make it active directs the focus of what we do to that layer. Any selections we make by default will be for that layer.

The above examples clicked open image windows for the bronze and the schloss image so that selections could be made in those image windows. Selections can also be made in the map window, in which case they apply to the active layer if it is visible. By default, using a selection tool in an active layer if that layer is not visible has no effect. Selection tools apply to all visible layers when the ALT key is pressed even if the active layer is not visible. Had we made the rectangular selection in the map while pressing the ALT key, we would have selected those pixels both in the bronze image as well as in the schloss image that fell within the selection box.

Selection in Maps / ALT Key in Maps

Selection and Clipboard (Cut, Copy, etc) operations in maps work on the active layer by default. To extend the action of these operations to all visible layers, press the ALT key. For example, drawing a selection box in a map will only select objects in the active layer. Holding the ALT key while drawing a selection box will select objects from all visible layers. Pressing Delete deletes selected objects in the active layer only. Pressing ALT-Delete deletes selected objects in all visible layers. Think of ALT as a mnemonic for "All."

Menu items that appear when a map window has the focus will apply only to the active layer. For example, Edit - Select All, Select None and Select Inverse apply to the active layer only, as does Edit - Copy. Menu commands cannot be extended to include all layers. The ALT key works only with mouse selection methods and keyboard commands. It does not modify menu commands (such as Edit - Copy) which always work on the active layer.

To apply selection commands to all visible layers, use the ALT key together with a mouse-based selection command such as Select Box or with a keyboard short cut such as CTRL- A or with a keyboard shortcut such as CTRL-A. For example, and ALT-Select Box used with Invert selection mode will create an inverse selection over all visible layers. ALT-CTRL-A will select all objects from all visible layers. If all objects in all layers are selected, ALT-CTRL-I ("select inverse" applied to all objects) will deselect all objects.

See the Layers and Commands topic for an example of the above.

**Image and Surface Selection Commands**
Certain selection commands are available only in images and surfaces. See the Selection using Masks and Modifying Selections topics.

**Menu Selection Commands**

Don’t forget about the selection commands available under the *Edit* menu (See also the Edit - Select All / None / Inverse topic for handy menu based selection commands):

- **Select All**: Select all objects or pixels in the component.
- **Select None**: Deselect all objects or pixels in the component.
- **Select Inverse**: Invert the selection. Those items that were not selected will become selected, while those that were selected will be deselected.

*Select All* and *Select None* are obvious in action, as seen above using an image as an example.

*Select Inverse* is a very useful command, because sometimes when making a selection it is easier to pick out those things we do not want to select. For example, if we ultimately would like to select the land area of South America in the images above, it is easier to first use *Touch Select* to select ocean areas and to then use *Edit - Select Inverse* to get the land areas. The ocean regions are very even in color and can be selected with a single click. The land areas contain many different colors and would take many clicks when using a reasonable tolerance setting with *Touch Select.*
These commands also work with drawing layers. In the sequence above, we would like to retain a circular region of lines in a drawing layer while deleting all other lines. We do this by selecting the circular region, choosing Select Inverse and then deleting the new selection (all the lines except the ones we want).

These commands also work with tables and even forms.

For example, if one control in a form is selected, using Select Inverse will select the other controls.

**Transferring a Selection between Components**

The Transfer Selection command can transfer a selection from one component to another when the two components are used together as layers in a map. For example, we can use it to select all pixels in an image that are within selected areas in a drawing. See the Transfer Selection topic for more.

**Keyboard Zoom Commands during Selection and Editing**

When making selections or editing objects (such as inserting areas using the Autocomplete feature) we will often want to zoom in or out in the middle of a selection or editing command. Use the + and - keys on the keyboard to do so. Usually the + and - keys in the numeric keypad are used.

- **“Plus” key:** Zoom in at the current tool position.
- **“Minus” key:** Zoom out at the current tool position.

The current tool position is the position of the mouse at the time the + or - key is pressed. When editing, using these keys allows us to easily zoom into a desired location, make a few precise clicks and then zoom back out and proceed at the usual scale.

**Status Bar Selection Readout**

The leftmost portion of the status bar has multiple uses. It normally is used to show extended messages that accompany tool tips when the mouse cursor hovers over a command button.

2135.9333 x 1996.6333 m

For some commands, like selection commands, the leftmost portion of the status bar will be used to show the dimensions of the area selected in the units used for the current projection taking into account the local scale and units settings in the Edit - Assign Projection dialog for that component. If the component is georegistered the sizes shown will be true dimensions.

Smart Mouse Selection

"Smart Mouse" selection is a shortcut, simplified way to make selections that is similar to selection methods used in editing operations with many Windows applications. Smart mouse selection ignores selection modes and selection object filters and works only if the mouse is not busy in a command mode. As such, it is particularly useful when editing controls on forms or for casual editing of drawings, when the mouse is not usually engaged in a command. Visual Studio users will recognize the similarity between smart mouse selection with Manifold forms and forms editing in Visual Studio.

Pressing the ESC key will escape from any tool mode, such as zoom tool or selection tool and will restore default smart mouse selection. Pressing ESC is therefore a handy way of quickly exiting from some tool mode and getting back into default smart mouse selection.

In Manifold, commands involving the mouse are normally controlled by whatever toolbar button is engaged. To use Select Box for example, we push the Select Box button in and then use the mouse in this command. If the mouse is engaged in a different command mode (such as Zoom In or Zoom Out) the mouse works within whatever command has been chosen. Sometimes we would like fast and simple selection when the mouse is not engaged in any other command. For example, when moving objects around in maps we often want to select only one object and then drag it to another position. In such cases it is faster to do selection in a "modeless" way. Smart mouse selection provides a fast, simple and modeless way of doing selection in such circumstances.

Smart mouse selection is used to select items for editing in drawings, forms, labels, and layouts. An object selected with a CTRL-ALT click will appear with edit handles that can be used to move or reshape the object. An object chosen for editing is also called the primary selected object.

This topic is written using drawings and drawing objects as examples. The same moves will work with items in layouts, labels or controls in forms as well. See the Editing Forms topic for examples of using smart mouse selection with forms.

Smart mouse selection is intended for fast, casual selections during editing operations. Smart mouse selection does not use selection modes. To make selections using selection modes, use the selection tools described in the Selection topic.

Smart Mouse Touch Selection

The simplest form of smart mouse selection is to click on an object to select it. This is a smart mouse version of Select Touch. For example, clicking on an area object in a drawing will select it. CTRL-ALT-clicking on an object will select it for editing, as seen above.

To deselect an object from editing, CTRL-click on it. This toggles it to unselected mode.

See the Editing Objects topic for examples and more information on interactive editing with smart mouse selection.

Keyboard Modifiers with Smart Mouse Touch Selection

Because a selection may already exist in the drawing when we wish to select an object for editing, smart mouse selection uses keyboard modifiers to allow a richer set of commands.

Click   Equivalent to Select Touch in Replace mode.

Clicking into an empty part of the drawing deselects all objects.
CTRL-ALT Click  Select an object for editing, making it the primary selected object. Does not change the selection state of other objects.

CTRL Click  Invert the selection state of the object without changing the selection state of any other object. Equivalent to Invert mode.

SHIFT Click  Select the object if it is not yet selected. Does not change the selection state of other objects. Equivalent to Add mode.

Smart Mouse Box Selection

When clicked on an empty region and dragged the mouse automatically makes a box selection analogous to using the Select Box selection tool in Select Replace mode. This is a general shortcut for selection. To select an object as the primary selected object for editing, CTRL-ALT click on it.

Keyboard Modifiers with Smart Mouse Box Selection

The following keyboard modifiers may be used with smart mouse box selection:

- **Click and drag** Click on an empty region and drag to make a box selection in Select Replace mode. Selects all objects that are entirely within the selection box.
- **CTRL** Click on an empty region and drag to make a box selection in Invert Selection mode.
- **SHIFT** Use an open box selection to select all objects any part of which are within the selection box.

Use within Layouts Components and Forms

Although we can always use the regular, dedicated selection commands covered in the Selection topic, for some components smart mouse selection is the most typical way of making selections. For example, smart mouse selection will be used by most users as their primary means of making selections.

Notes

Why is it called "smart mouse" selection? This is based on the idea that to support this type of selection the mouse cursor in its default mode must understand a lot about its environment. For example, it must be able to keep track of and know when it is clicked on a drawing object (and, for that matter, when the object is in the active layer if the mouse hovers in a map window) and much more. This requires considerably more thought for the cursor than merely being a default Windows cursor, so it is said to be a "smart mouse" cursor.

Note that the default action of the mouse in "smart mouse" moves depends on the context of where it is clicked and how it is moved. For example, clicking on an empty region and dragging creates a box selection mouse move. Clicking on an object and dragging is a drag-n-drop operation.

Inconsistency in Selection Methods

Advanced Manifold users will notice that there is a slight inconsistency in how selection operates in different settings, in particular how selection works in drawings when using smart mouse mode and how selection works in tables.

The general idea in Manifold is to have selection governed by both the selection mode desired (replace, add, subtract, invert, intersect) as well as by the operation of whatever selection tool has been put into play (Select touch, Select box, etc.). This general idea is modified in two cases, smart mouse selection in drawings and selection in tables, to allow simplified operation in smart mouse selection and to conform to user habits fostered by other Windows software in the case of tables.

Smart mouse mode uses neither selection tools nor selection modes. It provides a simplified, default way of selecting objects. In drawings, if a selection tool such as Select touch or Select box is used the selection mode
is always honored. Default smart mouse mode, which is available when some other tool is not in play, does not use the current selection mode. The advantage of such a difference between regular selection tools and smart mouse mode is that smart mouse mode can be a simple, default way of selecting objects. The disadvantage of this difference is that it is a difference and thus something that must be remembered.

Selection in tables will honor selection modes, but the visual selection tools used with drawings are not used in tables, as we can see by jumping ahead to the Selection in Tables topic. Because operations with tables are common in many Windows applications, in the case of tables Manifold adheres to the common Windows practice of selecting records in a table by clicking on a dedicated "handle" column. Clicking on a record handle in a table window always uses the current selection mode.

Formatting

Formatting is the application of style, color and size to objects in drawings or themes or to text in labels components. Because drawings usually appear as layers in maps, we will often think of formatting as formatting layers in maps. We use the Format toolbar to specify formatting that is to be used with objects in drawings and labels in text layers.

Formatting is not necessary in images because the appearance of images is controlled exclusively by the colors of the pixels that comprise the image. The Format toolbar is used in images to set the color and style applied by various painting tools.

A Familiar Concept

Formatting in a GIS context is directly analogous to formatting in a word processor such as Microsoft Word. When we format text in a word processor we apply display attributes such as font style, font size and color to the text.

The quick brown fox

The quick brown fox

Changing the font size, style and color can result in dramatic changes in the appearance of the text but the actual words stay the same. Just so, changing the formatting of objects in drawings can change dramatically their appearance even though the actual objects within the drawing stay the same.

The first illustration above shows default formatting for areas, lines and points. The second illustration shows those same objects with garish formatting applied as seen in a map with multiple layers (each layer having a different format). For example, one point is shown using a point style showing a yellow bus instead of the default small round circle style. Note that the lower horizontal line really consists of three lines, one of which was formatted as a thick red line while the other two were formatted using a dotted line style. In addition, layer opacity was used for the layer containing the checkerboard triangle.

Changing the format does not change the objects in the map. Using a bus symbol to show the point doesn’t turn the point into a large, bus-shaped area object. It simply uses a different icon instead of a small round circle to show where the point is located.

Formatting Requires Some Effort

Drawings will often be imported into Manifold from file formats that do not retain any information about the desired display attributes of the objects. This is analogous to importing a document into Microsoft Word from a plain .txt file. In Word, the entire document will initially appear in Courier New or some other default font. Depending on the source of the document it might not have margins or paragraph marks correctly set and so on. Converting
such a plain, .txt file into a beautifully formatted Microsoft Word .doc file will require some effort and good taste in the choice of fonts and other formatting details.

In Manifold System, we will often import complex maps from formats that do not retain information about visual appearance. In such cases, Manifold will initially show the drawing using default formatting. Specifying formatting to create a pretty map from such raw drawings will require some work and good taste.

Both illustrations above show the same map that consists of several drawings: the illustration on left uses default formatting for the drawings. The illustration at right has had formatting applied to the drawings so that land areas are colored green and ocean areas blue with population points shown as yellow icons instead of small round circles. Note how the application of sensible formatting makes the image on the right more comprehensible.

Manifold has many tools to help format complex maps with great efficiency. Also, many basic maps are provided on the Manifold downloads site have already been formatted. These maps may be used “as is” or may be easily reformatted to suite any taste.

The Formatting Drawings topic covers formatting in detail. It should be read together with the other drawings topics, beginning with the main Drawings topic.

**Thematic Formatting**

Thematic formatting is the process of automatically coloring objects in drawings or themes based on the value of their data attribute fields in tables associated with the drawing. For example, we might change the color of states by the value of their populations or increase or decrease the size of points representing cities based on the value of their population fields. The greater the population, the larger the point.

The illustration above shows cities in Texas where each city has a population field in the associated table. The point sizes of the cities have been thematically formatted by the value of the population field. The above illustration also has had the background color of points thematically formatted by the population field, so that the color changes as well.

See the Thematic Formatting topic for details on thematic formatting.

**Customization**

Palettes used in thematic formats may be customized, and new palettes may be added to Manifold. See the Customization topic.
New point styles may be added to Manifold by including True Type font symbols or images in .bmp, .jpg or other graphics files as point styles. For example, the bus style used in the illustration above comes from a popular Windows font. See the Custom Point Styles topic for more.

**Themes and Drawings**

It’s frequently the case that we would like to format the same drawing in several different ways. Manifold allows us to create **themes** to show the same drawing using different formatting characteristics. Themes require no extra storage because they do not duplicate the drawing, they simply show the same drawing using different formatting, such as different background or foreground colors. See the Themes topic for details.
Adding Text Labels

Text labels are added using **Labels** components. A labels component is like a drawing that contains only text items called **labels**.

There are two different types of labels components, **bound** and **unbound**, for which text labels are created in two different ways.

- **An unbound** labels component begins as a blank labels component that contains no labels. To create labels within an unbound labels component, we must use the **Insert Label** tools from the tools toolbar for labels to manually click at each spot where we want a label and enter the label text.

- **In a bound** labels component the positions of labels and their text can be automatically taken from objects in a **parent** drawing. Creating a bound labels component automatically creates all the labels in it as well. For example, suppose we want to automatically create text labels for every province in a drawing of a country. We could create a labels component bound to that drawing where the name of each province is taken from a "**Place Name**" field in the drawing's table. When the labels component is created, it will have a label for each province centered on the province that takes its text from the **Place Name** field. If a new province were added to the parent drawing, a new label would be created for it automatically in the labels component, since a bound labels component is always automatically synchronized to its parent drawing.

There are two types of labels components because sometimes we would like labels to be automatically created and sometimes we would like to create labels manually. For example, when using Manifold's **Internet Map Server** capability we don't know what view or zoom level visitors to the web site might select, so it would be useful in this case if Manifold would automatically create and place labels for us. On the other hand, we may spend considerable effort manually creating and positioning labels on a map for printed publication where there is only one view and zoom level.

At times we may want to combine both automatic and manual methods. For example, we might want to create labels at manually-specified positions but have Manifold populate the label text automatically from a data attribute. As will be seen in the detailed labels topics in this documentation, that is possible as well.

A labels component that creates bound labels is said to be **bound** to the drawing the table of which it uses. In the project pane it will be shown indented under the drawing at the same level as the drawing's table. An unbound labels component is not related to any drawing and is shown as a standalone component in the project pane hierarchy.

![Unbound Labels Component](image)

Labels within an unbound labels component appear as text within an otherwise transparent window, as seen above. Just like in drawings, the Layers pane can be used to turn the background on and off. When working with unbound labels components, it usually makes sense to work with the labels component as a layer in a map where other layers, such as a drawing, can provide some visual context for the position of the labels.
Labels that are bound to a drawing will be displayed with the parent drawing shown in a grayed-out schematic view in the background. This provides a visual context for the labels.

**Creating Labels Manually**

Labels can be created manually only within an unbound labels component. Because it is difficult to see the exact placement of labels without using a drawing or image as a guide, manually created labels are almost always created using a map where the labels layer is above the drawing or image layer.

**Adding Labels to a Map Manually**

1. Create a map using the desired drawing.
2. Right click on a layer tab and choose **Add - New Labels**
3. In the **Create Labels** dialog that pops up, do **not** choose any components in the **Parent** pane. Click **OK**.
4. Click the **Insert Label** button. In the labels component, click wherever a label is desired. In the popup **Text** dialog, enter the text for the label and press **OK**. [Pressing **Enter** starts a new line, since Manifold labels can be multi-line labels.]
5. When all desired labels have been entered, click out the **Insert Label** button.
6. Format labels in the labels layer as desired using the Format toolbar.
7. If you would like to have different styles or colors of labels, repeat the above process with another labels layer to create new labels in that layer. Each layer can have a different format. Alternately, if the appearance of labels is to be controlled by a data field in the drawing, use thematic formatting to specify the size, style, foreground color, background color or rotation of the labels based upon the field.

The **Insert Label** command is used to insert a label. Click to indicate the spot where the label is to appear and then provide the desired label text within the dialog window that appears. Click **OK** to accept the text. Note that labels can have multiple lines, so an **Enter** key starts a new line.

The Format toolbar is used to specify the text formatting (font, font size, etc.) throughout the entire layers component, although individual labels may be formatted differently by selecting the label first and changing its format.
Changes are immediately applied.

Labels components are usually used within maps so that other layers can provide a visual context for the location and scale of the labels. We can stack up as many labels components within a map as we like, using a different format for each labels layer to utilize many different text label formats within the map.

Manifold can also use the value of a field to specify the size, style, foreground color, background color or rotation of the labels. See the Thematic Formatting and Labels topic for details.

Creating Labels from Fields

By using bound labels Manifold can automatically create labels using information from fields. Suppose we have a drawing of Europe showing each country as an area, for example, and for each area we have data fields such as the country's name, population and other fields. We can create a labels component that takes the text for its labels for each country from one or more desired fields. See the Creating Labels from Fields topic for detailed instructions.

See Also

Labels have many more options than are discussed in this brief introductory topic. See the main Labels topic and other topics in the Labels chapter for more on labels. For example, see the Aligning Labels topic for alignment options.

Note

In addition to using Add - New Labels from map's layer tab context menu, we can create new labels components at any time using File - Create - Labels. Because maps (even maps created with default settings) use geographic projections, beginners are strongly advised have the focus on the map window when creating labels components that will be used in the map. This guarantees that the labels component will be automatically created within a geographic projection that matches the map.

Tech Tip

By default, Manifold will autoclip labels (not show some labels) to prevent the display from being too crowded with labels. If you add labels and they disappear or some other labels disappear, they are being autoclipped by the overlap resolution algorithm. To turn off autoclipping open the labels component in its own window, choose View - Display Options and uncheck the Resolve overlaps box.
Adding Legends

A Legend is a small display that provides captions, summarizes formats or otherwise explains what is seen in a window or in a print layout. Legends appear to float over the window and are always on top of other items in the window.

Legends may use simple, default styles or they may consist of complex and sophisticated items. Legends will often show object formats for drawings, surface colors by height for surfaces, thematic formats for labels (if one is present), and colors in images.

Although legends are part of a component like a drawing, they are an accessory item like a north arrow or scale bar associated with that component and are not the same as the actual contents of the component like the points, lines and areas that make up a drawing. Legends are not edited using tools such as painting tools for an image or the various editing tools available for drawings. Instead, legends are edited using settings in the Legend dialog.

Except for layouts, each component has one legend. A component remembers the settings for its legend as part of the properties of that component. Print layouts may contain multiple legends, including even multiple copies of the legend for each component that appears as an element in the layout.

An entire legend or any part of a legend may be composed for us automatically by the system or we can manually specify all or any part of a legend. Automatically-created legend items may be dynamically updated if the information they show, such as thematic formatting, changes. Dynamic and static parts of legends may be mixed, so that part of a legend (such as a title) may be manually specified while other parts, such as the colors and values for thematic formatting, may be dynamically generated by the system.

To add a legend:

1. Open the component.
2. Choose View - Legend to open the Legend dialog.
3. Check the Show Legend box and change the settings as desired. Press OK.

The default alignment is to place the legend in the right bottom corner of the window. If the window is resized or the view panned or zoomed the legend will stay in place in the right bottom corner of the window. To place the legend in any position, choose None in the Align box of the Legend dialog. The legend may then be dragged with the mouse to any desired position in the window, where it will stay no matter how the drawing or map is panned or zoomed.

By default, legends will be created showing elements for all types of objects using a simple style. Legends for maps will show elements for all components in the map.

To change a legend:

1. Double click the legend, or right click on the legend and choose Properties, or choose View - Legend.
2. Adjust the settings in the Legend dialog as desired and press OK.

In addition to Properties, the context menu that appears when right clicking on a legend also allows us to Hide the legend or to choose Align for different alignment.

Legend Styles
Manifold legends use a simple style that provides two main options:

- **Caption or no Caption** - Entering text into the Caption box adds a main caption, that is, title, to the top of the legend using inverted foreground / background colors to set it apart. When caption text is added Manifold will automatically add an additional panel to the top of the legend.

- **Standard style or Transparent** - Using a transparent style replaces the usual background color with no color.

Except for the above two adjustments to overall style, legends use a single style that consists of a series of elements, which are one or more lines of items in the legend. Although elements are by default stacked vertically...

...the clever use of vertical separator elements can force legends to have a more horizontal appearance, as seen below.

Within the legend the appearance of each item will be controlled by first, the choice of what type of element is used and second, by the various options specified for that type of element. Different types of elements have different options, in some cases rather extensive and elaborate options.

For example, text elements can have their fonts, size and attributes (such as boldfacing) controlled, while elements that show a sample of area formatting can be either manually controlled or automatically derived from the thematic formatting of a drawing. There are many different types of elements that may appear in a Manifold legend as well as many different display options within various types of elements.

**Example**

The following examples show different combinations of use of caption together with use of standard or transparent style. To the right of each legend is a screenshot of the Legend dialog used to create it (only the relevant part of the Legend dialog is shown).
The default setting is no text in the Caption box so no caption appears. The default setting is Standard in the Style box so the legend appears as a rectangle of background color within a border of foreground color.

If we enter some text into the Caption box the caption appears in an inversely-colored section of the legend.

If we switch to Transparent in the Style box the background color and surrounding box disappear.

Removing text from the Caption box removes the caption portion of the legend. Although there are many cases when transparent style is useful, as can be seen from this example it is probably not a good idea to use transparent style for legends that consist of fine text appearing against a busy background.

Example

We will add a simple legend to the Mexico sample drawing and then modify it.
We open the Mexico drawing in a drawing window. To add a legend we choose View - Legend from the main menu.

In the Legend dialog we check the Show legend box. The dialog appears with default legend elements. Thinking ahead a bit, we change the Align box to None so that later we will be able to move the legend about as desired by dragging it to whatever position we want in the drawing window.

Press OK. (To save space, the entire dialog is not shown in the illustrations for this example.)
A legend with no alignment specified initially appears in the upper left corner of the drawing window.

We can move it in an instant to a new position by clicking and dragging it to whatever location we desire.

This assumes, of course, that the mouse is not occupied by being in the middle of some other command.

To change the legend, we can choose View - Legend again from the main menu or we could right-click on it and choose Properties to launch the Legend dialog...
...or we can simply double click on the legend as a shortcut to launching the Legend dialog.

Within the Legend dialog we can check the Customize Legend box to enable editing of legend elements. With this box checked we can now select individual legend elements and change them as we see fit.

For example, we can click on the Mexico Drawing text element at the top of the dialog to select it for editing. The colored background bar shows which element is selected for editing.
Pressing the **Delete Element** button in the toolbar will delete this element.

This simplifies the legend to only one element, an element that shows an area sample that has **Areas** as the text.

The text for this item is generated using an **escape sequence**, an expression in [] brackets for which the system automatically generates the relevant text. In this case, the default text is element is the escape sequence **[Type / Column]** which the system will fill in with the type of object, **Areas** in this case, as well as the column used for formatting if thematic formatting is in play. Since this drawing does not use thematic formatting there is no mention of a column in the automatically generated legend text.

Suppose we would rather have the text be **Provinces** - we can make that change by clicking into the **Text** box to change the text.
We enter the text **Provinces** and then we press **OK**.

The result is a simplified legend positioned where we want containing the text we want.

The art of creating legends in Manifold is simply the above procedure, at times greatly elaborated to create whatever legend we want. We learn to use the **Legend** dialog to add and delete elements to legends as desired. We can have some elements created for us by Manifold or we can add elements manually using a very wide range of options or we can combine automatically-created elements with manually-added elements in the same legend. Different types of components, such as images or drawings, will have different options enabled in the **Legend** dialog. Individual types of elements will also have different options available, such as a range of display styles for color wells or a wide range of font controls for text elements.

We can pick and choose from different legends by copying and pasting elements between legends. We can have Manifold automatically assemble legends for complex components like maps and then flatten those legend elements into individual, non-automatic elements we can customize as we like. We can use escape sequences to insert text that the system automatically generates for us in a wide range of circumstances. The result of combining all of these options is the ability to create legends of great flexibility while retaining the convenience of having the system create simple legends for us automatically.

**Legends**

**Legend Text Escape Sequences**
Editing

Manifold includes a wide variety of methods for creating and editing images, drawings, tables and other components. Some methods, such as standard Windows Clipboard methods will work in almost all windows, while other editing methods are specific to the type of data (drawing, image, table, etc) being edited. Many editing operations (Cut or Copy, for example) will begin with making a selection. Other editing operations will automatically work on just the selection if one is present and otherwise will work on the entire layer or table.

Copy and Paste

Virtually anything within Manifold can be moved about using Windows Clipboard commands such as Edit - Copy and Edit - Paste. When used in drawings and images, such commands apply to objects and pixels that have been selected.

Interactive Editing

Interactive editing uses a different collection of toolbar buttons depending on whether we are editing drawings, images or other components. For example, we use the Tools toolbar to draw lines or areas in drawings. See the Editing Drawings topic for more.

Different components will also have different collections of editing instruments. For example, the Tools toolbar is not enabled for tables.

Smart Mouse Editing

When the mouse cursor is not occupied with a command mode, default "smart mouse" selection and editing applies. See the Editing Drawings topic.

Transform toolbar

The Transform toolbar is used to make global changes that potentially apply to many items at once. The user interface and usage style is the same for all components for which the Transform toolbar is enabled, but the specific functions within the toolbar will change to suit the type of component involved.

We use the transform toolbar for many routine commands, such as cropping an image. When editing drawings or images it is one of the most frequently used controls in Manifold.

Image, Drawing and Other Menu Commands

Each component has menu commands available that can alter the component. See Editing Drawings, Editing Images, Tables, Editing Surfaces and similar topics. There are literally hundreds of editing capabilities within nearly all parts of Manifold.

SQL

SQL queries may be used not only to show data or select it in different ways, they can also be used to update tables by changing the data they contain.

Scripts

We can write programs using Visual Basic scripting or JavaScript that can alter objects, recolor pixels in images and otherwise edit components.

Moving Objects by Editing Tables

To move points or other objects by editing their coordinates in tables, make sure to read the Editing Data in Tables topic, the Intrinsic Fields topic and the Editing Intrinsic Fields in Tables topic.
We can add, delete or move points or lines in Linked Drawings by editing the geocoded tables used to create the linked drawing.

**The Object Coordinates Dialog**

Right clicking on an object and choosing Coordinates launches the Object Coordinates dialog to allow direct editing of the coordinates that comprise the object. Right clicking onto an edit handle and choosing Coordinates will launch the Object Coordinates dialog with that particular edit handle coordinate highlighted.

**The Object Fields Dialog**

Double-clicking an object in a drawing launches the Object Fields dialog that shows any table fields associated with this object. Fields may be edited within the Object Fields dialog.

**The Info Pane**

An object shown in the Info Pane can have its fields edited.

**Notes**

By default Manifold uses progressive rendering to fill in the contents of display windows, allowing users to continue work while redisplay occurs in windows that show large data that might take more than a few seconds to render. Lengthy operations such as transforms automatically suspend progressive rendering and resume it upon completion, so that the system does not lose time rendering what might be obsolete data.

**Editing Objects**
Dialog Mode and Visual Tools

Manifold provides a wide range of mouse-based, visual tools. These include various tools used for editing and selection in drawings and images, painting tools in images as well as other commands that work with the mouse such as the tracker tool used to measure distance, the grabber panning tool and others.

While it is very useful to be able to visually click and drag and otherwise choose the range of action of tools using the mouse, sometimes we need to guide the operation of such tools using exact parameters. For example, we might want to draw a line from one exact location to a second exact location where we would like to specify the locations using numeric parameters such as latitude and longitude locations and not try to approximate the locations using mouse motions. Or, as is often done in COGO applications, we might want to draw a line from a starting location to another location where we would like to enter numeric values for the bearing and distance of the line to the new location.

**Dialog mode** allows us to work with a wide variety of commands using a dialog interface to enter specific values. We launch the visual tool desired, and then click at least once to start the tool and then while the tool is still in action press the **Insert** key on our keyboard to launch dialog mode. While in dialog mode the action is controlled by the values we enter into dialog's parameter boxes and the dialog commands we use.

With many mouse-based commands we can go back and forth between visual, mouse mode and dialog mode to take advantage of dialog assistance when we want it and otherwise continue using mouse tools in the usual visual way.

Because dialog mode uses the actual coordinates employed by whatever component we are working with, for most purposes it requires a clear understanding by the user of what coordinate system (projection) is in use, what units it uses and how coordinates must be specified in that projection to exactly identify a location.

Depending on the tool with which we use dialog mode and our objective we will probably use only part of the dialog while ignoring other parts, and we may want to combine the use of visual mouse tools, dialog mode and other Manifold features such as snap mode for the easiest and most effective work flow.

**Note:** This topic uses concepts that beginners may find challenging. New users will find it profitable to read this topic and then to read it a second time after practical experience with editing and other techniques. Nonetheless, this topic appears in the **Introduction** because dialog mode pops up so often (pun intended) as a very useful method in many Manifold operations.

**Ellipses and Circles**

Pressing **Insert** when using a visual ellipse or circle tool when editing, painting or selecting will pop up the **Ellipse** dialog. The dialog allows entering the coordinates of the center of the ellipse or circle and the height and width dimension. The **Ellipse** dialog is used for both ellipses and circles since a circle is just a special case of an ellipse that is as tall as it is wide.

We operate the dialog by entering the parameters we would like and pressing **Apply** or by pressing **Continue** to return to visual mouse mode.

We can specify the ellipse of action either by providing the left, right, upper and lower bounds and pressing **Apply** or by providing the location of the center and the width and the height and pressing **Apply**.
Bounds  Use this section to specify the ellipse of action by providing the coordinates of the bounding box of the ellipse.

L  Left - The X coordinate of the left edge of the ellipse.
R  Right - The X coordinate of the right edge of the ellipse.
T  Top - The Y coordinate of the top edge of the ellipse.
B  Bottom - The Y coordinate of the bottom edge of the ellipse.

Center / size  Use this section to specify the ellipse of action by providing the coordinates of the center of the ellipse and its width and height.

X  The X coordinate of the center of the ellipse.
Y  The Y coordinate of the center of the ellipse.
W  Width - The width of the ellipse in units employed by the coordinate system of the component.
H  Height - The height of the ellipse in units employed by the coordinate system of the component.

Apply  Apply either the Bounds settings or the Center / size settings to specify the ellipse in dialog mode.

Continue  Abandon this dialog and return to visual mode.

Parameter boxes in the dialog will be loaded with whatever coordinates are implied by the position of the mouse at the time the Insert key was pressed to launch dialog mode. For example, an "insert on center" form of an insert circle command for drawings will have the location of the central point clicked already loaded into the X and Y boxes.

Example

We will use dialog mode to create a circular area exactly 1500 meters in radius from a given point.
We begin with a map that has three drawing layers: a layer with roads, a layer with points of interest shown with green dots and a third layer in which we will draw a circular area. The third area has already been formatted with partial opacity so we will be able to draw areas and still see the roads “through” those areas.

The drawings and map all use Orthographic projection, which uses a coordinate system defined in meters.

To make it easier to click exactly on points, we will turn on Snap to Points mode.

Next, we will use the Insert Circle on Center tool to create a circle that's centered about the initial point clicked.

As we move the mouse cursor (a cross showing we are in the inserting circle tool) near the point the graticule jumps to the point because snap to points mode is on.

We click and hold the click. The cursor jumps directly to the point. While holding the click we press the Insert key on our keyboard to launch dialog mode.
The **Ellipse** dialog pops up. Since we are already happy with the center position clicked for the new circle, all we need do is specify the **Width** and **Height** of the circle, using **3000** in both boxes. Since the drawing is in **Orthographic** projection that uses meters we are specifying a circle (since both width and height are the same) with a radius (one half of the width) of **1500** meters. We press **Apply**.

Instantly, a circle is created of exactly the width and height (and thus, the radius) we wanted.

This example shows a useful combination of several Manifold capabilities. We began by choosing a visual tool that makes obvious sense how to use (click a point and drag to create a circle). We used **snap** mode to click exactly on a central point of interest and then we shifted gears, pressing the **Insert** key to launch dialog mode. In dialog mode we specified exactly the size of circle desired.

There is actually one more technique in use that an experience user would apply when setting up this task, and that is the decision to project the drawings in use to **Orthographic** projection so that the units of measure available for specifying the circle's size would be meters.

If we had wanted to specify the size of the circle in feet we could have used a projection that used feet as the linear measure in the projection's coordinate system. Or, if we had wanted to specify a circle or ellipse using left, right, upper and lower bounds that were latitude and longitude degrees we could have used latitude / longitude projection for which the coordinate system units are geographic degrees.

**Rectangles**
Pressing **Insert** when using a visual rectangle tool when editing, painting or selecting will pop up the **Rectangle** dialog. The dialog allows entering the coordinates of the center of the rectangle and the dimensions.

We operate the dialog by entering the parameters we would like and pressing **Apply** or by pressing **Continue** to return to visual mouse mode.

We can specify the rectangle of action either by providing the left, right, upper and lower bounds and pressing **Apply** or by providing the location of the center and the width and the height and pressing **Apply**.

---

### Rectangle

**Bounds**

- **L**: The X coordinate of the left edge of the rectangle.
- **R**: The X coordinate of the right edge of the rectangle.
- **T**: The Y coordinate of the top edge of the rectangle.
- **B**: The Y coordinate of the bottom edge of the rectangle.

**Center / size**

- **X**: The X coordinate of the center of the rectangle.
- **Y**: The Y coordinate of the center of the rectangle.
- **W**: The width of the rectangle in units employed by the coordinate system of the component.
- **H**: The height of the rectangle in units employed by the coordinate system of the component.

**Apply**

Apply either the **Bounds** settings or the **Center / size** settings to specify the rectangle in dialog mode.

**Continue**

Abandon this dialog and return to visual mode.
Parameter boxes in the dialog will be loaded with whatever coordinates are implied by the position of the mouse at the time the Insert key was pressed to launch dialog mode. For example, an "insert on center" form of an insert rectangle command for drawings will have the location of the central point clicked already loaded into the X and Y boxes.

**Lines and Areas**

Pressing Insert when using a visual tool when editing, painting or selecting will pop up the Coordinate dialog. This dialog also works in dialog mode with the Tracker distance measurement tool and the grabber panning tool. All of these tools in visual mode depend upon a series of mouse clicks to specify a series of coordinates that make up the line, define the area or specify locations clicked for the tracker or grabber.

The dialog allows entering the next coordinate desired in a variety of ways. It can be used to specify the next coordinate through direct entry of desired X,Y coordinates, as a difference in X,Y from the current position, as an angle and distance from the current location, or as a difference in angle and distance from the angle and distance of the last segment created.

We operate the dialog by entering the parameters we would like and pressing Add to add the coordinate and continue, by pressing Continue to return to visual mouse mode, by pressing Undo to undo the last coordinate added or by pressing Finish to add the coordinate and complete the overall tool action.

**Coordinate**

<table>
<thead>
<tr>
<th>X / Y</th>
</tr>
</thead>
<tbody>
<tr>
<td>X: 60631.59594</td>
</tr>
<tr>
<td>Y: 49903.80004</td>
</tr>
</tbody>
</table>

**Delta X / Y**

| X: -26.2952604 |
| Y: 26.2952604 |

**Angle / distance**

| A: -45.00 |
| D: 37.1671140 |

**Delta angle / distance**

| A: -45.00 |
| D: 37.1671140 |

| Add |
| Continue |
| Undo |
| Finish |

X / Y: Use this section to specify the coordinate by providing its X and Y coordinates.

X: The X coordinate of the coordinate.
Y The Y coordinate of the coordinate.

**Delta X / Y** Use this section to specify the coordinate by providing the change in X and Y directions from the previously specified coordinate.

X The change in X direction from the previous coordinate.

Y The change in Y direction from the previous coordinate.

**Angle / Distance** Use this section to specify the coordinate by providing the angle and distance to the new coordinate from the previous coordinate.

A Angle - Angle in degrees to the next coordinate.

D Distance - Distance in units employed by the coordinate system of the component to the next coordinate.

**Delta Angle / Distance** Use this section to specify the coordinate by providing the difference in angle and distance to the new coordinate from the angle and distance used to define the previous coordinate.

A Angle - Difference in angle in degrees to the next coordinate.

D Distance - Difference in distance in units employed by the coordinate system of the component to the next coordinate.

Add Add this next coordinate using the settings in the X / Y, Delta X / Y, Angle / distance or Delta angle / distance boxes.

Continue Abandon this dialog and return to visual mode.

Undo Undo the creation of the previous coordinate and reset the dialog to the values that prevailed just before its creation.

Finish Complete the tool without adding the current coordinate. Used, for example, to complete the creation of a new line when the last coordinate has been added.

Parameter boxes in the dialog will be loaded with whatever coordinates are implied by the position of the mouse at the time the **Insert** key was pressed to launch dialog mode. Since the visual mouse tool must be clicked at least once to start the tool the starting position, that is, the first coordinate, is already known so that the “delta” boxes and angle / distance boxes can be used.

**Example**

In this example we will create a line using dialog mode. We will be using a drawing in Orthographic projection so that units of measure will be meters.

We begin by choosing the **Insert Line** tool. This tool is used interactively to draw lines by using the mouse to click a series of clicks for each coordinate of the line followed by a right click to end and create the line.

We click into the drawing at the starting point of the line and then press the **Insert** key on the keyboard.
This pops up the **Coordinate** dialog, which is pre-loaded with the X and Y starting position at which we clicked. The drawing is projected so the starting X, Y coordinates are in linear measures and not in latitude / longitude degrees.
We will define the next coordinate for the line using the **Angle / distance** parameters to specify a bearing of **45** degrees and a distance of **250**. Because this drawing is in **Orthographic** projection the distance of **250** means 250 meters. :Press **Add** to add the coordinate implied by that bearing and distance.

![Coordinate input](image)

This extends the proposed line to the coordinate that is 250 meters away from the starting point at an absolute bearing (angle) of 45 degrees.

We will now continue the line using a slightly different technique.
For the next coordinate we will use a relative angle and distance using the Delta angle / dist boxes. We provide a relative angle of 45 and a distance of 0. We are telling the system to draw the next coordinate at a relative angle to the previous segment of plus 45 degrees at a distance that has zero change over the previous distance used.

The result is that the next segment is the same distance as the previous segment, 250 meters, and is drawn at a 45 degree angle to the previous segment. We could have achieved the same effect using the Angle / distance boxes with an angle of 90 (the absolute bearing of the desired line) and a distance of 250.

The difference between Angle / distance and Delta angle / dist is like the difference between walking a path following absolute compass directions and following relative directions.

- **Angle / distance** is like following instructions phrased like "On a compass bearing of 45 degrees walk 250 meters. Next, on a compass bearing of 90 degrees walk 250 meters. Next, on a bearing of 135 degrees walk 250 meters.
- **Delta angle / dist** is like following directions phrased like "Walk 250 meters in the direction you are headed. Turn clockwise 45 degrees and walk the same distance. Turn clockwise again another 45 degrees and walk the same distance again."

In the first case above which way you head for each segment does not depend upon what happened before. In the second case the direction you head depends upon the direction you were heading the previous segment.
We will continue extending the line by pressing the **Apply** button for **Delta angle / dist** to place the next coordinate using relative angle and direction.

The next coordinate for the proposed line is thus placed at a distance of 250 meters at an angle of 45 degrees to the previous segment.

We can continue pressing the **Apply** button for the same **Delta angle / dist** setting of 45 degrees and zero change in distance to create a series of segments 250 meters long that are at 45 degree angles to each previous segment. It may come as a surprise that doing so creates an octagonal shape like a stop sign.

To finish drawing a line we can click **Continue** to drop back into visual mouse mode and continue editing from there, or we can click **Finish**.
Clicking **Finish** ends the session with the equivalent of a right click on the mouse.

The result is that we have created a line that begins and ends at the same spot. Note that this is not an area, but we could have just as easily created an area using the same technique.

**Control Points**

Pressing **Insert** when inserting a control point will pop up the **Coordinate** dialog for control points.

<table>
<thead>
<tr>
<th>Coordinate</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>X / Y</strong></td>
<td></td>
</tr>
<tr>
<td><strong>X</strong></td>
<td>103.3102E</td>
</tr>
<tr>
<td><strong>Y</strong></td>
<td>19.908262Z</td>
</tr>
<tr>
<td><strong>Apply</strong></td>
<td>Add this next control point using the settings in the <strong>X</strong> and <strong>Y</strong> boxes.</td>
</tr>
<tr>
<td><strong>Continue</strong></td>
<td>Abandon this dialog and return to visual mode.</td>
</tr>
</tbody>
</table>

**Status Bar Reports**

When moving the mouse in creating a vector shape using visual tools such as the insert line tool, the status bar reports the length and angular bearing of the current segment as well as the location of the mouse cursor. Pressing **CTRL** will convert the report to use of alternate units (English or Metric) and will also enable use of ellipsoidal trigonometric calculations for the report.
For example, when creating a line as seen above...

\[-122.4364 \ 37.5500 \ L: 75.1393 \ m \ A: 43.88\]

...the status bar will report the mouse cursor location followed by L: length and A: angular bearing. The mouse cursor is located 75.1393 meters from the beginning of the segment at an angle of 43.88 degrees. The mouse cursor is also located at the latitude and longitude indicated.

**Tech Tip**

Using the backspace key when in dialog mode is equivalent to pressing an **Undo** button and undoes the last coordinate.

Drawings and Databases

One of the most important things about drawings is that the objects they contain, that is, every point, line or area in the drawing, can be tied to database information. This is done in a very simple way: every drawing has a table associated with it. Every object in the drawing is tied to one record, that is, one row, in the table. Even if there is no data associated with a given object, it still has a row in the table, an empty row if there is no data.

When a drawing is imported or created, a table will be created for it automatically. This table will appear under the drawing in the project pane in a hierarchical view.

Because every object in a drawing is associated with a record in a database table we can use visual methods in drawings to grab data from the table, and we can use tabular / database methods within tables to grab objects in the drawing.

Clicking on objects in a drawing is often a much easier way to find data than sifting through a text table. For example, it is much easier to select a group of Western states by clicking on them in a map than to search through a text table to find entries for "California", "Arizona", "Utah" and "Nevada."

Conversely, there are times when it is much easier to select items by clicking on their records in a table. We might sort a table by a population field and then select the top three or four states by population. We could then see them highlighted in red selection color on our map.

At times we may combine both methods, perhaps making a selection using table-oriented database methods and then refining the selection through mouse-based selection moves in the drawing.

Example

Imagine we have a drawing called Western_States that shows Western states in the US drawn as areas:

![Western States Map]

In the project pane this drawing appears with its associated table indented underneath it.

If we double click open the table for this drawing we might see that it contains four records, one for each state.
The table contains a field created and maintained by Manifold, the object ID number, plus three other fields. These other fields give the name, FIPS (Federal Information Processing Standard) code and the two letter postal abbreviation for each state.

When a drawing is created or imported Manifold automatically assigns a unique object ID number to each object. Manifold uses this object ID number to maintain the connection between each object in the map (the state areas in this case) and the corresponding row in the database table. Simple drawings might not have any data in their tables other than the object ID for each object. Drawings that are rich in data may have many fields in their database tables.

The association between objects in drawings and their record (row) in the database table is invisibly and automatically maintained for us by Manifold at all times. Whenever we select an object in the drawing we automatically select the corresponding row in the table. Whenever we select a row in the table we automatically select the corresponding object in the drawing. If we right click on the object and choose Fields in the context menu, we can see the object's fields.

If we imagine each area object as a shape cut out of cardboard, it is as though we have written the database information on the underside of each area. It is as if we could pick up the area for Utah and find written underneath the database information for that area. The association is that closely maintained.

In the example above, where do the fields come from? Our example uses a drawing originally published with many fields by the US Bureau of the Census. The drawing was imported, the drawing's table was opened and then some fields were deleted from the table to create the example shown. Most drawings used in GIS originate in some GIS data file that already has data fields created and filled in with values for the various objects in the drawing. In other cases we will use Manifold tools to merge data from databases into a drawing's table. In some cases, we will create a new field and add data by hand to each object.

Newcomers to GIS often focus on the visual presentation of maps. In contrast, experienced GIS users often feel that the most important aspect of GIS is the ability to use visual geography as a "handle" to grab and manipulate data within databases. The emphasis of much GIS work is not so much the precise drawing of cartographic features as it is amassing and utilizing rich databases of information within tables that are connected to maps. At times it is almost irrelevant how accurate or detailed is the cartography. For this reason, database skills and rich databases are extremely important in much GIS work.

Manifold includes a very fast and powerful database engine, so one can work with drawings that include many thousands of objects with many database fields per object in the drawing's table. As discussed in the Tables and Queries topics, Manifold's ability to manage database tables exceeds that of many so-called database management systems.
Manifold also has the ability to establish and exploit very rich connections with the world's premium DBMS products. Although an external DBMS product (such as Access, SQL Server or Oracle) is not required for using Manifold System, Manifold is capable of highly sophisticated usage of such DBMS products.

Except for linked drawings or relations in tables, tables that belong to drawings always exist entirely within Manifold. The data they contain is kept within the Manifold project file. Tables that are imported into a Manifold project are also managed within Manifold and their data saved within the Manifold project file. When tables are imported into the project, a copy of their data is taken from the original source and written into the project file.

Manifold can also create linked tables or linked drawings (which have their own tables that are also linked tables) in a project from external sources. When tables are linked into a project the data remains outside of Manifold in the original source. If a relation in a native table brings data into that table from a linked table, then that data also will come from the external source of data for that linked table.

Manifold has the ability to link to external tables for two main reasons. The first reason is simple space saving. At times it is more convenient not to make a copy of a table by importing it into the project. The second reason is dynamic updating by external programs. Some types of data, such as the count of customers in a particular county at exactly a certain moment, might be updated on a real time basis within a multi-user software application that keeps its data in a non-Manifold system such as SQL Server. If we link such a table into a Manifold project we can have the benefit of a table that appears in the project but which is dynamically updated by processes outside of Manifold.

**Using Relations between Tables**

A drawing's table can contain a large amount of data for objects in the drawing. However, at times it is more convenient to organize data using multiple tables instead of placing all fields in a single table. We may do this entirely within a Manifold project just to better organize our data. We could also use multiple tables because some of those tables need to be linked into the Manifold project from external sources in order to save space or to provide dynamically updated information.

A drawing's table can be used in database work just like any other table. In particular, it may be connected to other tables using relations. A relation between tables uses a key field with values common to both tables to connect the two tables so that columns from one table may appear in another table. This allows data that appears in one table to also appear in another table without having to physically duplicate the data.

To connect another table to a drawing's table, Manifold needs to know how the two tables should be related. This is done using a "key field" that contains matching values in the drawing's table and in the other table. This means that a drawing's table must have at least one field that can be used to match values with other tables.

For example, suppose our drawing of four states has only one field in the table in addition to the internal object ID field. The Abbrev column gives the two-letter US postal code abbreviation for each state:

<table>
<thead>
<tr>
<th>StatesTable</th>
</tr>
</thead>
<tbody>
<tr>
<td>ID</td>
</tr>
<tr>
<td>32761</td>
</tr>
<tr>
<td>32762</td>
</tr>
<tr>
<td>32763</td>
</tr>
<tr>
<td>32775</td>
</tr>
</tbody>
</table>

Suppose also we have a state_info table, perhaps imported from some demographic database we found on the web, that gives information for each state in the US. Suppose this table also contains the two letter postal code for each state:
In this case, we can use the state postal code abbreviation as a key field to form a relation between the two tables. We can then “borrow” fields from the state_info table and include them in our drawing’s table as if they were fields native to that table:

<table>
<thead>
<tr>
<th>Name</th>
<th>State...</th>
<th>Abbrev</th>
<th>FIPS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Minnesota</td>
<td></td>
<td>MN</td>
<td>27000</td>
</tr>
<tr>
<td>Washington</td>
<td></td>
<td>WA</td>
<td>53000</td>
</tr>
<tr>
<td>Idaho</td>
<td></td>
<td>ID</td>
<td>16000</td>
</tr>
<tr>
<td>Montana</td>
<td></td>
<td>MT</td>
<td>30000</td>
</tr>
<tr>
<td>North Dakota</td>
<td></td>
<td>ND</td>
<td>38000</td>
</tr>
<tr>
<td>Michigan</td>
<td></td>
<td>MI</td>
<td>26000</td>
</tr>
</tbody>
</table>

The illustration above shows the drawing’s table after it has had a relation formed and three additional columns included from the state_info table. We can use the data borrowed from other tables just as if the included fields were built into the drawing’s table. Whenever we select the Utah area in the drawing, it is as though that area is a handle not just to the original state abbreviation but to all of the fields.

For example, we could tell Manifold to create labels that showed the contents of various data fields for each object. These labels could grab data from the included fields as well as from the original field in the table:
The data required will automatically come out of whatever tables are connected to the drawing's table via relations. Note that to make this magic work all we need is a key field that exists in the drawing's table that can be used to match up records with a corresponding key field in the other table.

Note also that since Manifold projects can contain linked tables that use data residing in external database providers, a drawing's table can have a relation with a linked table. If the external data and hence the linked table changes, the data shown in the map will also change. This is a good way of using table data in a drawing when the data changes frequently.

For example, if we wish to display weekly sales totals in a map of sales regions we could link the sales table in our corporate SQL Server database into our project and then form a relation between that table and a drawing's table that shows sales regions. Whenever we display the map using that drawing, it will automatically include the latest sales figures as they are kept in the SQL Server database.

We can use linked tables with simpler technology than SQL Server. For example, a linked table could be created from an Excel spreadsheet that is regularly updated to incorporate the latest sales figures.

**Tables Work with Lines and Points, Too**

The above examples use areas because they are easy to illustrate as having information written on them. Any map object, including lines and points, can have database information attached. Points are often used to show the locations of facilities, customers, towns, stores and other locations. Each point could have many data fields in the table.

Lines can have data fields in tables as well. Typical uses of fields attached to lines are to maintain information on roads or to record data for streams or other waterways.

**Tech Tip: Keeping Organized**

Each object in the drawing corresponds to a record (one row) in the drawing's table. Every object in that drawing will have the database fields in that table. Not every cell in every record has to be full of data, of course, but all objects in the drawing (that is, every row in the table) will have the field structure for that table.

To keep things organized it is wise not to mix up objects in one drawing that really would be better organized in separate drawings. For example, suppose we have a drawing of states as areas with demographic information for each state. If we also have a drawing of roads with maintenance data for each road, it would make sense to keep the roads and the states in separate drawings so that the two different drawings can have different fields in their tables. We can always combine the multiple drawings in a single map if we want to see the states and the roads together in one map.

Note that there's no problem mixing lines and areas in the same drawing; however, it's usually the case that objects shown as areas (like states) tend to be associated with different types of database fields than objects that are drawn with lines (like roads). An exception to this trend is the display of water features in "hydrography" layers in maps where water features are frequently drawn using both areas (lakes) and lines (streams) in the same drawing. Drawings showing hydrography features will often use the same database table for both lakes and streams, since the same information (name, fresh or salt water, perennial or seasonal feature, etc.) fields are often used for both.
Summary

- Every drawing has a table that at least contains one field, the object ID field.
- Every object in a drawing is associated with one record in the table. A record is one row in the table.
- Each data attribute field is one column in the table.
- All objects in the drawing will have all the fields in the database table associated with that drawing.
- When objects logically should have the same data fields, group them together in a drawing.
- Use maps to show different drawings together at the same time.

For More Advanced Users

This topic discusses tables associated with drawings in an elementary way, mostly using the word “database” to mean the internal storage of tables within a Manifold project using Manifold’s own internal database capabilities. There are two more advanced notions regarding drawings and databases we will develop as we get further into Manifold.

The first notion is that the tables that appear in Manifold projects, whether they are used by themselves or joined to a drawing’s table via a relation, can be linked into the project from some DBMS server or database file outside of Manifold. The next topic, Drawings and Tables, as well as topics in the Tables chapter develop this idea.

The second notion is that Manifold can store drawings themselves (as well as tables, images and surfaces) within some external DBMS server outside of Manifold. For example, the Western States drawing used as an example could be stored not inside a Manifold project but instead might be exported into a DBMS server such as SQL Server, Oracle, DB2, PostgreSQL, MySQL or some other DBMS. Manifold users could then link that drawing into their projects so that more than one person at the same time could view and edit that drawing. This idea is more fully developed beginning with the Spatial DBMS topic in this Introduction chapter.

Drawings and Tables

Attaching Linked Tables to Drawings
Drawings and Tables

This topic gives specific examples of interacting with drawing tables, to show how the association between drawings and database tables discussed in the Drawings and Databases topic works in practice.

Recall that every drawing in Manifold has a database table tied to it. Each object in the drawing corresponds to a record (one row) in the database table. Every field in the database will be a column in the database table. A drawing’s table will have at least one field, the object ID field, which provides an identification number for each object in the drawing. The object ID is a unique number generated by Manifold when the drawing is created or imported. Tables can contain other fields as well. For example, a drawing showing cities as points could have a Name and Population field in the table that gives the name of each city and its population.

A drawing’s table can be used like any database table. For example, it can be used to form relationships with other tables, including tables that are saved outside of Manifold in external database providers.

When drawings are imported from a GIS format that saves both object and database table information the new drawing that appears in the project will automatically have a table created that is populated with data.

If we import a drawing from a format, such as AutoCAD DXF, that does not save database table information, or if we create a new, blank drawing in a project, Manifold will automatically create both the drawing and a table to go with that drawing.

Suppose we create a new drawing in the project and name it Drawing1.

By default, the minimum field in drawing’s table is an ID field that gives the object ID number of each object in the drawing. ID numbers are assigned on a unique basis for each new object created or imported into any drawing. All ID numbers are guaranteed unique.

We can open the drawing in a drawing window and also open the drawing’s table in a table window. When a new drawing is created there are no objects in the drawing or associated records in the table. To fit conveniently as screen shots within this documentation, both the drawing window and table window will be shown as relatively small windows.

Note that the ID field cells in the table are shown using the default light gray color that indicates read-only cells. The ID field in a drawing’s table may not be edited since the ID is the hard-wired connection between each object in a drawing and the record in the drawing’s table that corresponds to that object.

Drawings and their Tables are Synchronized
For drawings and their tables, any changes in one component are immediately updated in the other component. Adding or deleting an object in the drawing will add or delete the associated record in the table.

If we use the Tools toolbar to add an area to the drawing a record appears for it automatically in the table as well.

Note that the ID field cells in the table are shown using the default light gray color that indicates read-only cells. The ID field in a drawing's table may not be edited since the ID is the hard-wired connection between each object in a drawing and the record in the drawing's table that corresponds to that object.

Tables usually show more interesting data than Object IDs; however, as the simplest possible example of a drawing's table we will show just the Object ID field.

Creating another area in the drawing adds another record in the table as well.
Creating a third area adds a third record, shown with an ID of 3. [Note: It is very rare that we would ever see such low numbers in sequence as object IDs since we normally work with large, complex maps where objects are imported, deleted, created and so on in potentially large numbers. Object IDs are therefore more normally semi-random numbers and not neat, small numbers in sequence.]

The screen shot above shows our drawing and table after we have used the Tools toolbar to add several points. See the Adding Points, Lines and Areas topic for information on how to add points to a drawing.

Using the Tools toolbar we can add two lines as well. Note that two more records have appeared in the table.
Selections are Synchronized

A drawing and the drawing's table share a single selection since both the drawing and the table are just two different ways of seeing the same objects. Any changes to that selection in either the drawing or the drawing's table will immediately be updated in the other.

Any Selection made in the drawing will simultaneously appear in the table with a change in background color of the associated records. Selected records will have a faint red background color by default. The example above shows we have selected two areas, a line and a point in the lower half of the drawing.

If we change the selection by selecting two points and an area in the upper part of the drawing the selection shown in the table will immediately be updated to match.
The Selections pane shows the same set of saved selections for both drawings and their tables. The example above shows the Selections pane opened and moved into position so it can participate in our screen shots. We have selected the three areas and have saved them as a saved selection called Areas.

We can select the two lines and save them as a saved selection called Lines. [Note: there is nothing magical about our choice of the word Lines for the name of this saved selection other than the mnemonic value to remind us at a glance of what comprises that selection. We don't have to use the word Lines to name a saved selection that consists of lines. We could just as easily call it Fred or Bob or Points if we wanted to choose a confusing name.]
At any time, we can click into the Selections pane and get a Preview of any of the saved selections by pushing in the Preview button in the Selections pane. When the Preview button is pushed in the highlighted saved selection will be shown in blue preview color in both the drawing and in the table. If a record is both in the current selection and in the preview it will be shown in a color mid-way between the red selection color and the blue preview color. [Manifold will automatically interpolate between whatever selection color and preview color we specify in the Tools - Options dialog].

We can use the selection command buttons to combine a saved selection with the existing selection. In the illustration above we have pushed out the Preview button, clicked on the Areas saved selection and then pressed the Select Add button in the Selections pane toolbar. This adds the areas to the current selection for a selection that consists of both lines and areas.
Deletions are synchronized as well. Suppose we select just the areas and choose **Edit - Delete**.

The areas will be deleted in the drawing and their associated records will be deleted in the table as well.

**A Drawing’s Table Cannot Add Objects to the Drawing**

We cannot add objects to a drawing by adding records to the drawing’s table. The reason is that the information seen in the table is only part of the information that defines the object. An object in a drawing is defined by the geometric coordinates that specify its location and shape. These are not visible or part of the table: they are part of the data within the drawing itself.

Deleting an object in a drawing will delete the object’s record in the drawing’s table. Deleting a record in a drawing’s table will delete the associated object in the drawing.

**Note:** It is possible to create a linked drawing that is created based on the contents of a table, either using geocoded tables or using geometry fields in tables. In that case, the table data controls both the linked drawing and the linked drawing’s own table. If a record is added to the source table then a new point will be created in the linked drawing and a new record will appear in the linked drawing’s own table. However, even in that case we can’t add objects to the linked drawing by adding records to the linked drawing’s own table.

**Attaching External Tables to a Drawing’s Table**

So far we’ve seen that every drawing is linked to a table and that the drawing’s table is created within the project at the same time the drawing is created. All such tables exist entirely within the project. Sometimes we would like to link our drawing’s table to an external table that is linked into the project.
To do this we use relations with linked tables. See the Attaching External Tables to Drawings topic.

**The Info Pane**

A convenient way of seeing data from drawing tables one record/object at a time is to use the Info pane to step through data one object at a time.

**Tech Tip**

The illustrations above show the first object created having an **ID** of **1**. Although the first object created in a new drawing may well have an **ID** of **1**, this is not guaranteed. Object IDs are unique within a given .map file but are not guaranteed to begin with **1**. It is therefore entirely possible to create a new drawing and to then create a new object in that drawing that has an object ID of, say, **5**. Even in the case of the first drawing in a completely blank drawing it is still possible not to get an object ID of **1** for the first object created.

The Query toolbar is a fast way to select objects in drawings using the data values they contain.
Working with Tables

This introductory topic provides a brief overview of how Manifold approaches tables and databases. It is intended for readers already familiar with database concepts such as tables and queries. See the Tables topic and subsequent topics for a complete guide to working with tables. See the Working with Queries topic for an introduction to queries. See the Query toolbar topic for a fast way to select records in tables.

Tables show data organized into rows and columns. Every row in a table is a record. Every column in a table is a field. We will use the words "row" and "record" interchangeably. We will also use the words "column" and "field" interchangeably.

### Tables and Drawings

Every drawing in Manifold has a table associated with it. Each object in the drawing (that is, every point, line or area in the drawing) is linked to a row in the table. Drawings have a table even if there are no data fields saved for each object. In that case, the drawing's table is mostly empty. It has only one field, the object ID field, for each row. The object ID field is used to link each row to its associated object and cannot be edited.

Deleting an object in a drawing will delete the object's record in the drawing's table. Deleting a record in a drawing's table will delete the associated object in the drawing.

### Other Tables

Tables may also be database tables having nothing to do with drawings that are imported into a Manifold project or linked into the project from an external database source. New tables may also be created with Manifold.

Tables may be native tables (also called local tables) that have at least one column that exists entirely within the project, or they may be linked tables that are created from other tables. Linked tables are created from other tables, which could be within the same project or which could come from data sources outside of Manifold. Native tables can also use data from other tables if they include relations with other tables.

Tables may be imported or linked into projects from almost any database, even from those that have nothing to do with drawings or maps. We can import or link tables from a vast range of different types of data files and data sources, from ordinary text files such as CSV files, from applications files such as Excel XLS files that contain data, and from a very wide range of database connections and database providers such as Access, SQL Server, Oracle, IBM DB2, MySQL and the like. It's actually very difficult to find a source of data that a knowledgeable Manifold user cannot utilize.

We will often work with tables that have no geographic context. We may wish to prepare data for later use together with drawings and maps, or we might simply wish to use Manifold as a general-purpose means of viewing, analyzing, exploring and managing databases.
The illustration above, for example, shows a project with tables imported from the Microsoft Northwind Traders example database shipped with Microsoft Access.

If we open the Customers table we see the same data familiar to many Access users who have worked with this sample database.

There are two types of sources for database tables that may be imported or linked into a Manifold project:

- Tables from files and file types that may be opened directly by Manifold's own database engines and so require no other database software. These include .mdb, .dbf, .udl, .wkX, .xls, .db, and .html files as well as ASCII or text database files organized as comma separated value (.csv) form. Such file-based data storage options appear directly within the Files of type box in dialogs when importing or linking.
- Tables from data sources that are provided by external database engines via OLE DB, ODBC, ADO .NET, Oracle Call Interface (in the case of Manifold Enterprise Edition) or similar connections to database providers. Some such sources may require external database software. The default Manifold installation process will include a default set of standard Windows drivers for popular databases such as SQL Server and Oracle. Such data sources are accessed using the Data Source dialog, which appears when the Data Sources () choice is used within the Files of type box in dialogs when importing or linking.

To import or link a table into a Manifold project

1. Choose File - Import - Table or File - Link - Table depending on whether you wish to import the table or to link it.
2. In the Files of type box choose the access method desired. Choose one of the standard file types, such as MDB or XLS to connect directly to common file types. Choose the Data Sources () item to connect via ODBC, OLE DB, ADO .NET or a native connection to a DBMS server.
3. Browse over to the database file and open it. See the Data Source dialog topic for examples connecting using that dialog.
4. Choose the tables to be imported. Choose more than one table if desired.
5. When linking tables, check Read Only if you wish a read-only link. Some connection technologies such as ADO .NET or some ODBC providers may allow only a read-only link.
6. Press OK.

After the initial choice of File - Import or File - Link, all dialogs are the same. The only difference is whether the data in the table is copied into the project or if it is left outside in an external file or data source.

Alternate method to import or link a table
1. Open the Tools - Database Console dialog.

2. Next to the Data source box, click on the [...] button to launch the Data Source dialog. Connect using that dialog as shown in the the Data Source dialog topic.

3. The upper pane will show the contents of that data source, including any tables and the fields they contain. Click on a table to highlight it.

4. Click on the Import button in the dialog's toolbar to import the highlighted table. Click on the Link button to link the table.

5. Press Close.

In all cases, tables that are imported or linked will appear to be part of the project like any other table. Manifold can import data from or link to a very wide range of database files and database providers.

See the Data Source dialog topic for information on using that dialog to connect to databases.

See Importing and Linking Tables for more information on using existing tables.

See Creating New Tables for information on creating new tables.

See the Database Console topic for a useful console for browsing databases and importing and linking tables.

The database console can also be used to execute SQL commands within an external database provider, such as SQL Server or Oracle.

**Table Windows**

Clicking open a table will display it in a table window, a classic row and column text database table presentation. A table may be opened in more than one window simultaneously. Opening an SQL query will also result in a table showing the results of the SQL query.

<table>
<thead>
<tr>
<th>ID</th>
<th>Place name</th>
<th>SOM</th>
<th>VIVIEN...</th>
<th>BUS...</th>
</tr>
</thead>
<tbody>
<tr>
<td>27</td>
<td>AQUASCALIENTES</td>
<td>2374.72</td>
<td>130599</td>
<td>1031</td>
</tr>
<tr>
<td>8</td>
<td>BAJA CALIFORNIA</td>
<td>29614.39</td>
<td>373476</td>
<td>2549</td>
</tr>
<tr>
<td>9</td>
<td>BAJA CALIFORNIA SUR</td>

<tr>
<td>14</td>
<td>CHIHUAHUA</td>
<td>20414.52</td>
<td>441252</td>
<td>1272</td>
</tr>
</tbody>
</table>

Table windows show many records at once. Selected records appear highlighted in red selection color. Records will be shown in selection color whether they were selected within the table window or (in the case of drawing tables) if they were selected by clicking on the corresponding objects in the drawing. Records may also be selected using the query toolbar or queries.

Table windows are controlled using a mix of menu command choices, context menus, selection and use of the transform toolbar. Try right clicking onto a column head, a record handle, and a cell to see the different context menus that appear with tables. See the Tables - Context Menus topic for a summary guide to context menus in tables.

By default, table windows do not use horizontal or vertical gridlines between rows and columns. Gridlines may be turned on in Tools - Options.

**Columns**

Columns are headed with the name of the field they show. We can reorder, show or hide columns in a table using the View - Columns command. Using the View - Columns command, we can also display intrinsic fields as columns in the table. Intrinsic fields are computed quantities, such as the length of lines, or system quantities such as the latitude and longitude position of a point. Right click onto a column head to see a context menu of many additional commands that work with columns.

The boundary lines between column heads may be moved left or right to make a column wider or narrower. If you are using Windows 2000 or Windows XP columns may be dragged and dropped into different left to right arrangements. We can also use Best Fit or Best Fit All to automatically set the width of columns.
Click on a column head to sort it in ascending (A to Z) order. SHIFT-click on a column head to sort it in descending (Z to A) order.

**Specifying Languages for Columns**

Columns in tables can have different languages specified. This allows one column to show text in one language while another shows text using a different language character set. Several different languages can be used in different columns within the same table. By default, tables use the Windows locale setting for the current user. If desired, any text column in a table can be set to a different language by right clicking on the column head and choosing **Language**.

**Rows**

![Row selection](image)

**Records** have a **record handle** at their left margin. A black triangular arrow marks the current record in its record handle.

<table>
<thead>
<tr>
<th>U 11</th>
<th>Utilities Kasedaen</th>
<th>Herrmee Maeninen</th>
<th>Owner</th>
</tr>
</thead>
<tbody>
<tr>
<td>PARIS</td>
<td>Paris specialties</td>
<td>Marie Bertrand</td>
<td>Owner</td>
</tr>
<tr>
<td>PFR</td>
<td>commercial clients</td>
<td>Guillermo Fernandez</td>
<td>Sales Rep</td>
</tr>
</tbody>
</table>

The **current record** will be specified by a current record arrow in its handle as well as by outlining the active cell.

<table>
<thead>
<tr>
<th>U 11</th>
<th>Utilities Kasedaen</th>
<th>Herrmee Maeninen</th>
<th>Owner</th>
</tr>
</thead>
<tbody>
<tr>
<td>PARIS</td>
<td>Paris specialties</td>
<td>Marie Bertrand</td>
<td>Owner</td>
</tr>
<tr>
<td>PFR</td>
<td>commercial clients</td>
<td>Guillermo Fernandez</td>
<td>Sales Rep</td>
</tr>
</tbody>
</table>

When selected, the **current** cell is highlighted by a slightly lighter shade of the red selection color.

**Selection Methods**

Selecting records in the Table window is part of many tasks in Manifold. Selection in tables, like drawings, uses selection modes to specify whether the selection command should replace, add to, subtract from, invert with or intersect any previously existing record. The default mode is **Replace**.

- Click on a cell to make it the current cell and to make that record the current record.
- Click on a record handle to select that record.
- SHIFT-click on a record handle to select the record and to also select all the records between it and another selected record. This is often used to select a series of records: click on the top record and then SHIFT-click on the bottom record and all the records in between will also be selected.
- CTRL-click on a cell to select that record.
- SHIFT-CTRL-click on a cell to select a range of records.

See the **Selection in Tables** topic for more details.

**Copy and Paste Operations with Columns**

Copy and Paste are handy commands for copying data between fields. Suppose we have a numeric field that is a **double**, and we would like to convert the field into an **integer**. We do this by first creating a new field that is an integer. A new column will appear. Next, we **Copy** the contents of the double numeric field's column and then **Paste** into the new integer field's column.

This method works between reasonably compatible types. For example, numbers like **3.1415** may be converted into text strings such as "3.1415", but it does not make sense to attempt to convert "Main Street" into a number.
We can also use the Transform toolbar to copy values from one column to another, also with automatic conversion whenever possible.

**Editing Cells**

See the topic Editing Data in Tables for details on changing values inside cells and adding new records to tables.

See the Editing Intrinsic Fields in Tables topic for a discussion of how we can move objects by editing their locations as they appear in intrinsic fields in a table.

**Bookmarks**

Bookmarks are icons in the left margin of text components such as comments, queries and scripts. They allow fast navigation within lengthy text. Bookmarks are also available within tables, comments, scripts and queries. Within tables they are very useful for marking particular records when jumping back and forth between records in a table. When tables or queries are sorted the bookmarks correctly travel with the records into the new sort order.

To set a bookmark in a table, click anywhere in the row to be marked.

Press F8 or choose **Edit - Bookmarks - Toggle** to set the bookmark. To clear the bookmark, press F8 or choose **Edit - Bookmarks - Toggle** again.

Add other bookmarks as desired. We can now use Ctrl-F8 to jump to the bookmark below the current row or Shift-Ctrl-F8 to jump to the bookmark above the current row. See the Edit - Bookmarks topic more on bookmark.

**Effect of Tools - Options Settings**

When importing tables, keep in mind that the default setting in Tools - Options is to not import empty columns. Check the **Import empty columns in tables** option to import tables with columns that do not contain any values in the originating table.

Note also the setting of **Trim strings imported from external databases** (on by default). This will delete leading and trailing whitespace characters from imported table strings.

The **Trim strings** option (just like the **Trim** table transform operators) removes characters listed in the Tool Properties pane’s list of token separators. By default, these are the “white space” characters consisting of the space character, tab, newline and carriage return. Note that adding any other characters to the separator list in Tool Properties will subject them to removal as well if they occur as leading or trailing characters.
**ViewBots** are one-line analytic instruments used to dynamically compute a statistical or comparative measure over a subset of records and are extremely useful for analyzing tables. They are one of the most popular functions in Manifold for experienced users. See the ViewBots topic.

**Transform Toolbar**

The Transform toolbar is an extremely powerful tool for managing and editing tables. It is easy to use and should be mastered by every Manifold user doing serious work with tables. New users and experts alike will experience dramatic productivity gains by learning to use the transform toolbar.

**Active Columns**

Active Columns are a way of embedding short (or long) snippets of scripts within tables to automatically accomplish calculations. The idea is similar to that of spreadsheets, but appearing in tables in a much more powerful way.

**Decision Support System**

Manifold's Decision Support System provides remarkable data mining capabilities by applying fuzzy inferences in an easy to use way.

**Primary Keys a Must with DBMS**

When working with server-based OLE DB providers such as DB2, SQL Server and Oracle, users are strongly encouraged to maintain primary keys in all tables linked into the Manifold project. A side effect of how such servers interact through OLE DB is that if the table does not have a primary key, performance will be greatly reduced.

**ODBC and .map Files**

Manifold includes an ODBC driver. This driver allows other applications to work with data in tables and queries in a Manifold .map project file. See the Using the Manifold ODBC Driver topic.

**Notes**

Tables within Manifold have many powerful capabilities within the context menus that appear when right clicking on different parts of the table. For example, one can change field types using the Change Type choice that appears when right clicking onto a column head. In another example, one can right click on a record and choose More Like This to automatically see more records like that one sorted to the top of the table. Take the time to read through the Tables topic and subsequent topics in the Tables book to learn about these and many other powerful capabilities.

Many of the illustrations for tables are screen shots made using the Nwind.mdb sample database provided by Microsoft. This is a version of the Northwind.mdb sample database distributed with Access and thus familiar to many Microsoft Office users. Nwind.mdb is provided on the Manifold System CD in the Help examples folder.
Working with Queries

Queries are components that contain statements written in the database language SQL. SQL statements are most often used to select data for viewing, but queries can also be used to alter the structure of tables or to alter the data tables contain. Queries can select data from one or more tables, filtering, grouping and ordering it as desired or otherwise managing the contents of tables that exist within a project. The simplest form of query chooses columns and records from one table and displays them as a table.

Queries are easy to create. Use File - Create - Query to create a new query and then edit it by double clicking on it to open it (or by right clicking on it and choosing Open). Enter the SQL statement you wish to use and close the query.

Run the query by highlighting it and clicking the Run button. Whenever the query is run it will execute the SQL statement. If the SQL statement in the query returns a table the query will display it in a table window. The resultant table may be used like any other.

SQL is a really easy way of phrasing queries. Don't be intimidated by experts who make SQL out to be more complex than it need be. While SQL can certainly be used to write fearsomely complex queries that no one understands, most of the time it is used by average people to write very simple, obvious queries this one:

```
SELECT [Contact Name], [Phone] FROM [Customers] WHERE [Country] = "France";
```

The table names and fields used in a query refer to whatever tables we have in our project. If we've imported the Customers table from the Nwind.mdb sample database into our project and place the above SQL statement into a query, when we open the query we will see a simple table with two columns:

<table>
<thead>
<tr>
<th>Contact Name</th>
<th>Phone</th>
</tr>
</thead>
<tbody>
<tr>
<td>Daniel Torini</td>
<td>30.59.84.10</td>
</tr>
<tr>
<td>Frédérique Côteaux</td>
<td>88.60.15.31</td>
</tr>
<tr>
<td>Martine Rancé</td>
<td>20.16.10.15</td>
</tr>
<tr>
<td>Janine Labrune</td>
<td>40.67.86.88</td>
</tr>
<tr>
<td>Arnette Roulet</td>
<td>61.77.61.10</td>
</tr>
<tr>
<td>Laurence lebihan</td>
<td>91.24.45.40</td>
</tr>
<tr>
<td>Paul Harrich</td>
<td>64.71.15.11</td>
</tr>
</tbody>
</table>

Simple SQL statements displaying data from a single table are written as follows:

```
SELECT (fields) FROM (table name) WHERE (condition)
```

SQL is not case sensitive except inside text strings used within quotes in criteria. Many SQL writers like to use CAPITAL letters for SQL key words, like the SELECT statement, in order to keep their queries better organized, but that is not necessary. We can use upper or lower case as desired. We can use parentheses to group criteria within criteria to keep our statements legible, and we can use tabs and spaces, multiple lines and indents as desired to keep things clear:

```
SELECT [Contact Name], [Phone] FROM [Customers]
WHERE [Country] = "France"
OR [Country] = "Germany"
```

As can be seen from the above, words like And and Or may be used within criteria.

A search of Internet using any good search engine looking for keywords such as "SQL", "style" and so on will produce numerous pages advocating various styles of writing SQL queries. Choose whatever writing style you like. Extra parentheses don't hurt. Use them to keep queries legible and well organized and to guarantee the order of precedence in comparison operators is what you want it to be in complex queries.

SQL is very powerful and even fun. Don't deny yourself the benefit of this easily learned tool. The nice thing about SQL is that it is easy to learn to write simple queries and it is very easy to extend one's capabilities in an
incremental way. With a little practice, you too will be spinning out intense little SQL queries as fast as your fingers can fly over the keyboard.

**Dot Nomenclature**

"Dot" nomenclature allows us to refer to exactly a desired field within a given table even when other tables in our project might use the same field name in a different way. Dot nomenclature is simply the table name followed by a period `.` and then the field name:

```
[Customers].[Contact Name]
```

The above refers to the **Contact Name** field in the **Customers** table. If we are writing simple queries that involve only one table we need not use dot nomenclature. We could simply write **Contact Name** as in the examples above. However, if we are working with more than one table we can always use dot nomenclature to clear up any ambiguities about which field is intended. Sometimes it is necessary to use dot nomenclature to resolve ambiguities.

**Field Names in Brackets**

Manifold as well as many modern database management systems allow field names to contain the space character and other non-alphanumeric characters. Such field names should be enclosed in `[]` square brackets when written in queries. Simple field names that do not contain spaces or other non-alphanumeric characters need not be enclosed in brackets.

To preserve maximum capability to export data to a wide variety of database systems we suggest the use of field names that do not contain spaces or other unusual characters.

**Bookmarks**

Bookmarks are icons in the left margin of text components such as comments, queries and scripts. They allow fast navigation within lengthy text. Bookmarks are also available within tables and queries. Within tables they are very useful for marking particular records when jumping back and forth between records in a table. When tables or queries are sorted the bookmarks correctly travel with the records into the new sort order.

To set a bookmark in a table, click anywhere in the row to be marked.

Press F8 or choose **Edit - Bookmarks - Toggle** to set the bookmark. To clear the bookmark, press F8 or choose **Edit - Bookmarks - Toggle** again.

Add other bookmarks as desired. See the **Edit - Bookmarks** topic for notes on how to jump between bookmarks or to go to the previous or next bookmark.
ODBC and .map Files

Manifold includes an ODBC driver. This driver allows other applications to work with data in tables and queries in a Manifold .map project file. See the Using the Manifold ODBC Driver topic.

Notes

See the Queries topic for more. That topic and the topics following it in the Queries book introduce various other useful SQL methods, including examples of how to create a new query table that displays data from two other tables at once. The more advanced topics also discuss “action queries” that are used to do things with the data.

This documentation uses examples drawn from the Microsoft Northwind.mdb and Nwind.mdb sample databases. The two are very similar, except that Nwind.mdb uses spaces in the names of fields for some tables.

Just about everyone in computing thinks that “SQL” is an acronym for “Structured Query Language.” That’s not true, as the ANSI standard defining SQL officially names it “Database Language SQL.” Experts will also point out that SQL is not structured, it is used for more purposes than just asking about things (the conventional meaning of the English word “query”) and it is technically not a “language” in the Turing sense of the word.

According to ANSI, “SQL” should be pronounced by saying the letters as in “ess cue ell.” However, many people prefer to pronounce the term as the English word “sequel,” especially when referring to Microsoft’s SQL Server DBMS product since “sequel server” is more alliterative and easier to say than “ess cue ell server.” It is very common to use both pronunciations, even in the same sentence, as in “This ess-cue-ell works in Sequel Server but not in Oracle.”

See Also

The Query toolbar is a fast way to select objects in drawings or records in tables using the data values they contain. For very simple queries the query toolbar is much faster than creating and running an SQL query.

See the Database Console topic for a useful console for browsing databases and importing and linking tables. The database console can also be used to execute SQL commands within an external database provider, such as SQL Server or Oracle.

See Selecting Objects with Queries for information on selecting objects within drawings or drawing layers in maps using SQL queries.

See the Geocoding Extensions and Raster Extensions and Spatial Extensions and topics for a list of extensions to SQL in Manifold that allow creation of SQL queries that make spatial comparisons or employ the geocoding engine for work with street addresses.
Finding / Replacing Data

Search and replace operations in tables are easy with the Edit - Find, Edit - Find Next and Edit - Replace dialogs. These are very similar to the analogous dialogs in Microsoft Office applications. These commands are available for table components.

To search for a value:

1. Open the table.
2. Choose Edit - Find.
3. Enter the value to be found (text, a number, or a regular expression) in the Find what box.
4. Choose optional settings, such as matching case.
5. Press Find Next to find and select for editing the next instance of the value, or choose Find All to find and select all instances of the value.
6. Searches proceed from the current position in the table towards the end of the table. To begin a search at the beginning of the table, press Restart.

Using Find in a drawing will find and select the object that has that value in its table record. Objects will be selected as the primary selected object, ready for editing. Once the Find dialog has been used, we can use the Edit - Find Next command to find the next instance of the previously found value.

Options in Find and Replace Commands

- **Find what**  The value or regular expression to be found.
- **Replace with**  Value used to replace found values.
- **Match whole word only**  Match the value only when it occurs as a whole word. With this checked, "the" will match the word the but not occurrences of these letters within words such as weather.
- **Match case**  Find and Replace are case insensitive by default. This forces a match exactly on the case given in the Find What value. Example: unchecked, "the" will match The and tHe.
- **Use regular expressions**  Regular expressions are a concise and flexible notation for finding and replacing patterns of text.
- **Search only in**  By default, Find and Replace will search all fields. Check this to restrict the search to only the field given.
- **Find Next**  Find the next instance of the search value.
- **Replace**  Replace this instance of the search value.
- **Replace All**  Replace all instances of the search value.
- **Restart**  Move the current record pointer to the beginning of the table. Searches proceed from the current record pointer only.
- **Close**  Close the dialog

Example

To find the province of Morelos in the drawing of Mexican provinces provided as a sample, we import the mexico drawing and then open the drawing's table. Choose Edit - Find to launch the Find dialog and then enter Morelos in the Find What box. Press Find Next to select this province.
We can replace values using the Edit - Replace dialog, which is the same as the Find dialog with the addition of a Replace with edit box and Replace and Replace All command buttons.

**Using Regular Expressions**

Regular expressions are a concise and flexible notation for finding and replacing patterns of text.

See the Regular expressions topic for information on using regular expressions. These are a much more sophisticated and flexible method than simply using the * and ? characters.
Copy and Paste As

The Windows clipboard Copy and Paste As commands are used throughout Manifold to copy data, to transfer data between components and to transform data from one form into another. For example, copy and paste within the project pane are used to convert components into different forms. To convert a surface into an image we Copy the surface component in the project pane and then Paste As an image component into the project pane. Subsidiary dialogs will be called on the fly as necessary with appropriate conversion options to make the desired image component out of the data in the surface.

Any standard Windows clipboard commands work for Copy and Paste As. For example, when a component is highlighted in the project pane, we can copy using Edit - Copy, by right clicking on the component and choosing Copy from the context menu or by using a CTRL- C keyboard shortcut for Copy.

There are some limitations in this process. For example, a table can be copied and pasted as a drawing only if the table is geocoded or if it contains geometry types. See the Creating Drawings from Geocoded Tables topic.

Note that we can use the Copy, Paste and Paste As buttons either from the project pane toolbar or from the main toolbar. We can also use these commands as they appear in the right-click context menus.

Cut - Copy the highlighted component to the Windows clipboard and then delete it from the project.

Copy - Copy the highlighted component to the Windows clipboard.

Paste - Paste the Windows clipboard into the project.

Paste As - Paste the Windows clipboard into the project as a given component. The down arrow pulls down a menu showing what types of components can be used for the data on the clipboard.

Example: Copy an Image and Paste As a Table

1. Open the project pane.
2. Right-click on the image component to be copied and choose Copy from the context menu.
3. Right-click anywhere in the project pane other than onto an existing component and choose Paste As... and then Table in the context menus that appear.
4. Choose the options desired in the dialog that appears for how the image data should appear in the table. For example, for each pixel we can create separate fields giving the Red, Green and Blue channel values for that pixel.
5. This creates a new table component where each record in the table is taken from one pixel in the image. The table is "geocoded" with the pixel locations of each pixel in the image together with the values of the pixels.

For more sophisticated use, it is also usually possible to Copy from within a component window and to Paste As... the data directly into a new component in the project. For example, we can select points within a drawing and then Copy those points, click into the project pane and use Paste As... a table to create a table that contains geocoded records for each copied point.

Copy and paste works for images and surfaces between Manifold and other applications. For example, one can Copy an image in PhotoShop and Paste it into the project pane as a new image in Manifold or vice versa. Surfaces will be copied as a bitmapped image using whatever display options are currently applied. Images copied from other applications are always pasted as images.

Autoscope

The "scope" of a Copy is what is copied. When copying from an open drawing, image or other window, if a selection is present only those items (image pixels, drawing objects, table records, etc) that are selected will be copied. This is an example of autoscope, where the scope of the copy is automatically restricted to the selection if one is present.
In contrast, when using **Copy** to copy components that are highlighted in the project pane the entire component will be copied whether or not there is a selection within that component.

**Typical Copy and Paste As Combinations**

- **Comment to Script**
  Copies the text of a comment and pastes it as a script.

- **Script to Comment**
  Copies the text of a script and pastes it as a comment.

- **Drawing to Table**
  Reads the coordinate locations of points and pastes them as records into a geocoded table. This is a fast way of creating a list of latitude / longitude locations for points in a map, such as a city.

- **Table to Drawing**
  Paste a geocoded table as a drawing of points.

- **Image to Table**
  Create a table where each record is a "geocoded" pixel from the image.

- **Drawing to Labels**
  Create a labels component with a label in position for each object in the drawing. When copying and pasting between the same Manifold session, can automatically create labels that are populated from the drawing's fields.

- **Labels to Table**
  Create a table where each record is the geocoded location of a text label as well as the text string in the label.

- **Table to Labels**
  Create a labels layer from a table of geocoded records where each record has the location and text string for a text label.

- **Surface to Image**
  Although surfaces are shown in a window as if they were a 2D image, this is just an optional visualization of the data. Surfaces may be copied and pasted as images to provide true images.

- **Terrain to Image**
  Create an image from a terrain where the image pixel values correspond to terrain elevations.

- **Image to Surface**
  Create a surface from an image where pixel values are used to create elevations.

- **Surface to Table**
  Create a geocoded table where each record contains an elevation or other data value for a given point in the surface.

- **Table to Surface**
  Create a surface taking elevation values for point records specified in a geocoded table.

- **Drawing to Surface**
  Create a surface taking elevation values from drawing objects.

**Pasting Drawings as Tables**

When pasting a drawing as a geocoded table, points are represented as a single geocoded record where the latitude and longitude field of the record are taken from the position of the point and the other fields in the table are taken from any data attributes associated with the point. For lines and areas, this position will be the centroid of the object.

The **Paste As Table** dialog allows a choice of which fields will be pasted. By default, all ordinary fields are checked for pasting while **intrinsic fields** are not checked for pasting. Intrinsic fields are fields that are automatically computed, such as **Area (I)**. Intrinsic fields include:

- **Type (I)**
  A lookup field for object type: area, line or point.
Branches (I)  The number of branches (indicates topologically branched objects, such as areas with holes or islands).

Coordinates (I)  The number of coordinates that define the object.

  X (I)  X coordinate of the center of the object in native coordinate system units.

  Y (I)  Y coordinate of the center of the object in native coordinate system units.

Latitude (I)  Latitude of the center of the object in degrees latitude.

Longitude (I)  Longitude of the center of the object in degrees longitude.

Length (I)  Object length (or perimeter).

Area (I)  Object area.

Bearing (I)  0 for points and areas. For lines, the bearing in degrees of a straight line segment constructed between the first and last points of the very first branch within the line. Computed using ellipsoidal trigonometry. 90 is East and 270 is West.

Selection Mask (I)  A byte giving the saved selections mask.

Selection (I)  Boolean: currently selected or not.

The Branches (I) and Coordinates (I) fields will be pasted as Int32 integers, the Type (I) field is pasted as a variable-length Unicode text field and all the other computed fields will be pasted as Float64 floating point numeric fields.

See the Intrinsic Fields topic for more information on intrinsic fields.

**Pasting Images as Tables**

Manifold can paste images as tables where every pixel in the image is pasted as one record in the table.

  Color Index (I)  An index into the palette. Appears as a choice only when pasting palette images.

  Color (I)  A decimal number representing the RGB color. The decimal representation of the six-digit hexadecimal number formed by concatenating the three, two-digit hexadecimal values for R, G and B channels.

  Red (I)  A value from 0 to 255 for the Red channel value.

  Green (I)  A value from 0 to 255 for the Green channel value.

  Blue (I)  A value from 0 to 255 for the Blue channel value.

  Alpha (I)  A value from 0 to 255 for the Alpha channel value.

  Intensity (I)  The intensity of the pixel as a value from 0 to 255.

  Hue (I)  The hue of the pixel as a value from 0 to 255.

  Lightness (I)  The lightness of the pixel as a value from 0 to 255.

  Saturation (I)  The saturation of the pixel as a value from 0 to 255.

  Selection (I)  Boolean: currently selected or not.

  Selection Mask (I)  A byte giving the saved selections mask.
Invisible (I)  Boolean: the pixel is invisible or not.

X Offset (I)  X position of the pixel. The column number of the pixel in image row and column coordinates.

Y Offset (I)  Y position of the pixel. The row number of the pixel in image row and column coordinates.

X (I)  X coordinate of the center of the pixel in native coordinate system units.

Y (I)  Y coordinate of the center of the pixel in native coordinate system units.

Latitude (I)  Latitude of the center of the pixel.

Longitude (I)  Longitude of the center of the pixel.

Color Index (I) appears as a choice only when pasting palette images; however, the RGB and Alpha values appear even if the image is not an RGB or RGBA image. In this case, they represent the R, G, B and Alpha values for the color of the pixel. Note that even though a color may be taken from a palette, it still can be described as composed of R, G and B values.

Pasting Surfaces as Tables

Manifold can paste surfaces as tables where every pixel in the image is pasted as one record in the table.

Height (I)  Height of the pixel.

Selection (I)  Boolean: currently selected or not.

Selection Mask (I)  A byte giving the saved selections mask.

Invisible (I)  Boolean: the pixel is invisible or not. Missing pixels are reported as invisible.

X Offset (I)  X position of the pixel. The column number of the pixel in image row and column coordinates.

Y Offset (I)  Y position of the pixel. The row number of the pixel in image row and column coordinates.

X (I)  X coordinate of the center of the pixel in native coordinate system units.

Y (I)  Y coordinate of the center of the pixel in native coordinate system units.

Latitude (I)  Latitude of the center of the pixel.

Longitude (I)  Longitude of the center of the pixel.

Cut and Paste

Cutting objects from one drawing and pasting them into a different drawing is the default way of moving objects between drawings in Manifold. To avoid the need to think about projections, create your blank drawings by creating one drawing and then copy that blank drawing and paste it as several additional drawings. This will guarantee that all of the drawings use exactly the same projection settings. It's then possible to copy, cut and paste objects between the drawings without worrying about projection nuances.

If you've Pasted something into a drawing and don't see it, try Zoom to Fit to make sure it is not outside the window at the current zoom and pan setting.

Copy and Paste between Applications
Some items within Manifold cannot be copied and pasted to other applications because the other applications
don't understand the objects used within Manifold. For example, Microsoft Word does not understand how to
accept vector objects containing data attributes if objects are copied from a Manifold map and pasted into Word.

Images and surfaces can be copied from Manifold and pasted to any application that understands bitmaps.
Surfaces will be pasted as a bitmap using the current display options.

Another option to transfer images or a view of drawings or maps is to use the Tools - Make Image command to
save to an image component. This captures the desired component as an image. The image can then be used
within Word or other applications.

Copying tables or table columns or records will copy data to the Clipboard both in internal Manifold format as well
as conventional Windows tab-separated text format, which is handy for pasting into Access, Excel and numerous
other Windows programs that use tables.

**Tech Tips**

At times we would like to fetch a component that's been saved in a .map project file for use in another project
file. We can import the component using File - Import - Component directly from the .map file. Another way to
do this is to open a second instance of Manifold and to open the saved .map project. We can then Copy
components from that project file, switch to our current working instance of Manifold and Paste them into our
current project.

Sometimes we would like to transform a component from one form into another, such as converting a surface
into an image, and we don't need to keep a copy of the original component around. In such cases it is faster to
Cut the original component and Paste As a new component. When using Copy Manifold must make a copy of
the data, which can take a long time in the case of very large components.

**See Also**

Don't miss the Copy and Paste: Image / Table / Drawing example for a detailed series of steps using Copy and
Paste As. Starting with an image the example creates a table and then copies that table and creates a drawing.

See the Edit - Paste / Paste Append topic for information on the Paste Objects dialog, which pops up when
copying objects from one drawing and pasting them into another drawing.

See the Download and Mosaic TerraServer Images topic for an example using Copy and Paste to assemble a
larger image out of smaller ones.
Working with Text Components

Comments, queries and scripts are called **text components** because they contain text.

In the case of comments the text contained is whatever we want it to be.

Comment example:

```
Longitude_Resolution: 0.
Geographic_Coordinate_Ur
Geodetic_Model:
  Horizontal_Datum_Name: I
  Ellipsoid_Name: GRS1980
  Semi-major_Axis: 6378137
  Denominator_of_Flattening
```

Comments are often created when importing formats such as **SDTS** that contain "readme" information, metadata or other text information along with GIS data of various sorts.

Query example:

```
SELECT States.* FROM States WHERE
  IsArea(States.ID) AND
  SELECT Max(Area(Counties.ID))
  Where Contained(States.ID, Co
```

Queries contain text that makes up SQL statements.

Script example:

```
Sub SayHello
  str = "Hello!"
MsgBox str
End Sub
Sub Main
  Call SayHello
End Sub
```

Scripts contain text that forms programs written in the scripting language in use.

All three types of windows accept standard Windows text editing shortcuts such as **CTRL-X** to Cut, **CTRL-C** to Copy, **CTRL-V** to Paste and so on. Text component windows also support Edit - Find and Edit - Replace. However, since text components only allow highlighting of one block of text at a time the **Find All** command will be disabled.

All text components support bookmarks, which are icons that can be placed in the left margin to mark a line of text, as seen in the comments component illustrated above. Place a bookmark at any line of text by pressing **F8** or by choosing **Edit - Bookmarks - Toggle** from the main menu. The Edit - Go To command can be used to jump to any bookmark.

To set a bookmark:
1. Open the component.
2. Click on the line where the bookmark is to be placed. This positions the cursor on that line.
3. Press F8 or choose Edit - Bookmarks - Toggle from the main menu.

Script components also support breakpoints, which are icons that mark a line of code at which script execution automatically stops. Breakpoints are used for debugging scripts. Place a breakpoint at any line of text by pressing F9 or by choosing Edit - Breakpoints - Toggle from the main menu. Breakpoints can temporarily disabled to allow code to flow through the breakpoint line without losing the marked position. The script component seen above shows two breakpoints. The Edit - Go To command can be used to jump to any breakpoint.

**To set a breakpoint:**

1. Open the component.
2. Click on the line where the breakpoint is to be placed. This positions the cursor on that line.
3. Press F9 or choose Edit - Breakpoints - Toggle from the main menu.

Bookmarks and breakpoints are most frequently used when writing large, complex scripts.

**Go To**

The Go To command can jump to any line number, bookmark or breakpoint. In the above example we can jump to the breakpoint set at line 7 for the line that contains the text "Call SayHello"

- Programming Manifold
Undo / Redo

Many Manifold commands can be undone using the **Undo** button. The keyboard shortcut for Undo is **CTRL-Z**.

Once undone with **Undo**, a command may be redone with **Redo**. The keyboard shortcut for **Redo** is **CTRL-Y**.

The **Undo** command will undo the last issued command. In some cases, Manifold will allow undoing more than one command, but usually it is only the last command that can be undone.

**Very important:** Not all commands and operations in Manifold may be undone. Routine image editing and drawing editing commands, transform operators, selections, copy and paste operations, renaming and other commands can in general be undone. However, some operations with tables and external tables linked into a Manifold project may or may not be undone. Even simple changes to tables if they are linked to an external data provider might not be undoable if the external provider does not support undo. Before making sweeping changes to tables, please take time to make a copy of the table data by exporting it to a file.

**Confirmations**

Some **Undo** actions require making transient copies of data to allow the action to be undone. Certain operations can involve lots of data and thus result in slower performance than desired because of the time required for copying transient data. Manifold provides two options in the Tools - Options - Confirmations page to control this behavior:

- Confirm creating undo actions larger than [50] MBytes
- Never create undo actions larger than [250] MBytes

The sizes used in the above options are user settable, with 50 and 250 MB the respective defaults.

**Note**

The **CTRL-Z** keyboard shortcut for **Undo** is frequently used with editing when operating with the mouse with one hand and commanding cut, copy and paste commands with **CTRL-X**, **CTRL-C** and **CTRL-V** keyboard shortcuts to reverse unintended keyboard commands.
Linked Views

Manifold can automatically pan the view in one window based on where we look in a different window that is the active window, a capability that is managed using the World pane. When a window is set to track the view in the active window we say that the two windows have linked views.

The World pane shows the current center point of the active window on a simplified map of the world. In addition, the World pane is used to control linked views by specifying Show Position Reticule and Track Position settings for individual windows. Open the World pane by choosing View - Panes - World or by using SHIFT-ALT-O to toggle the pane on or off. The World pane may be docked underneath the project pane when using docked panes.

The World pane is context sensitive: it shows the current Show Position Reticule and Track Position settings for the active window. The World pane announces the active window in the title bar and marks the center point of the active window with a reticule. In the example above, we have opened the Mexico sample drawing in a window. The World pane therefore announces Mexico as the active drawing and positions the reticule over Mexico in the World pane's minimap.

Show Position Reticule - Show a reticule in this window that always marks the center position of the currently active window (if it falls within the view seen in this window). Push in to activate.

Track Position - Pan this window so the center position of the currently active window is centered in this window's view. Push in to activate.

(Coordinates Readout) The bottom of the World pane reports the coordinates of the center point of the active window.

To instruct a window to show a reticule at the current position

1. Open a component in a window.
2. Open the World pane and push in Show Position Reticule.

If any other window is now opened (even a second copy of the component opened above) the center point of the current position of the active window will be shown with a reticule.

To instruct a window to track the current position

1. Open a component in a window.
2. Open the World pane and push in Track Position.

If any other window is now opened (even a second copy of the component opened above) the tracking component will be panned so that it always shows the current position of the active window centered in view.
**Example: Displaying Position**

For our first example we will use two drawings showing the same subject. The right-hand drawing will be a zoomed in view. The left-hand drawing will always show where the zoomed-in view is positioned by placing a reticule at that spot.

We begin by importing the sample *Mexico* drawing. We open the *Mexico* drawing in two windows. First we click it open in the window seen on the left and then we right click on the *Mexico* drawing in the project pane and choose **Open in New Window** to open it in another window. We've resized both windows to fit into a screen shot for this documentation and then zoomed into the window on the right. To color the drawing, we use the Color dialog and then change the color using a preset in the thematic formatting dialog to suit our taste.

Note that the focus is on the window on the left (because it has an "active window" title bar.

With the focus on the window on the left, we push in the **Show Position Reticule** button in the World pane.
A reticule appears in the center of the left-hand window. The reticule appears in the center because the active window is the same window.

Suppose we now click on the right-hand window and use **Zoom Box** to zoom into a region in that window.

With the focus on the window on the right, the reticule in the left-hand window will move to the position of the center point of the active window. Because the right-hand window view is zoomed into a location on the East coast of Mexico, the reticule moves to that position.
We can now use a command like Center Point to click in various locations within the right-hand window. As we move to different locations, the reticule in the left-hand window will move to show the current position seen in the right-hand window.

**Example: Tracking Position**

For our second example we will use the same drawings and arrange things so that as we pan the left-hand drawing the right-hand drawing will provide a zoomed-in "moving map" view.

With the focus on the right-hand pane, we press in the Track Position button in the World pane. This commands the window to move so that the center point of the active window is centered in it.

We can now click back to the left-hand window to move the focus there and use Center Point to move about in the window. As we move, the right-hand window automatically pans to follow. In the illustration above we first zoomed into the right hand window to show greater details and then we clicked on the left-hand window.
and zoomed in. We then used Center Point to move around in the left-hand window. If we click on a position on the Northern coast the right-hand window pans to show us that location in greater detail.

![Map Illustration](image1)

If we click Center Point on a spot on the Southern coast the right-hand window again moves to show us that location.

**Example: Linked Views with Maps**

Linked views can be an essential tool for navigating within very dense and detailed maps. In this example we've downloaded CD 155 of the VMAP 1 set from NIMA ([www.nima.mil](http://www.nima.mil)), showing parts of Central and South America at approximately 1:100K-scale paper map equivalent resolution. In the illustrations below, the map on the left shows boundary layers with most layers turned off. The map on the right shows elevation layers, also with most layers turned off. The map on the right is a huge map representing hundreds of megabytes of data (use a fast machine). In particular, unless it is zoomed far into the map the elevation contour lines blend into a black mass.

![Map Illustration](image2)

We click on the left-hand map to make it the active window and then we press Show Position Reticule in the World pane. We then click on the right-hand map to make it the active map and then we press Track Position in the World pane. Now, whenever we move the right-hand map (say, by scrolling with CTRL right clicks of the mouse or by using the Center Point command), the reticule in the left-hand map will show us where our right-hand view is located.
If we click on the left-hand map we can use Center Point to move the center position to any spot and see that spot greatly enlarged in the elevation contour lines map on the right.

**Example: Navigating a Terrain using a Surface as a Guide**

One of the many excellent uses for linked views is to use a surface to steer a view in a terrain. In this example we've imported a surface showing terrain elevation in the Grand Canyon area of the United States. We've opened the surface as a small window and zoomed into the surface. We've also opened the terrain in a window.

To set up the linked views we click on the terrain window and press Track Position. We then click on the surface window and press Show Position Reticule. We don't really need to press Show Position Reticule for the surface window to move the terrain window, but it is usually convenient to have the position reticule appear at the center of the surface window so we can see exactly where the terrain is positioned.
We can now use commands like Center Point to navigate in the surface window and the terrain window will automatically jump to whatever location we center in the surface window. In the views above we've clicked onto the river channel. Note that the terrain window has been rotated a bit to provide a view to the East aligned with the river.

If we click on a different location (again, on the river channel) the terrain jumps to that location as well.
Many GIS programs have some sort of "minimap" navigation pane where one can click into the pane and move the position of the main display to that location. Manifold's linked views capabilities allow us to use any window as a "minimap" control to move any other window.

Newbies will sometimes get mixed up between Show Position Reticule and Track Position. To help keep things straight:

- **Track Position** is a "moving map" command. It tells the window to move to whatever is the current position.
- **Show Position Reticule** shows a reticule at the current position. It does not move the map.

It's slightly redundant, but one can have both Show Position Reticule and Track Position pushed in at the same time. In that case, the reticule shown by Show Position Reticule will always appear at the center of the display.

Do the contents of a window disappear when it has Track Position set? If the active window shows a geographic location that is not covered by the data set in the window, Manifold will still merrily pan the window to a location far beyond the contents of the window. Check to see if the window is correctly georegistered if you think the contents should appear.

More than one window can be set to use Track Position. In that case, all windows with Track Position set will be panned to the new location whenever the active window is panned. Panning lots of windows that contain large amounts of dense data is, of course, computationally intensive and will slow system response.

It's easy to think that linked views work only between two windows. That's not so: linked views settings of Track Position and Show Position Reticule apply to *all* windows that are open and have these buttons set in the World pane.
### About Geocoding

A **geocoded** table is a table where every record has a location given in latitude and longitude, using standard decimal degrees notation for the latitudes and longitudes. Unless each record is geocoded with a latitude and longitude location Manifold cannot know where that record is located. Once a table is geocoded it may be used to create drawings.

<table>
<thead>

For example, the table above is not geocoded. It lists the names of towns in the United States but there is no way to tell from the table exactly where the towns are located. If we were to try to draw points on a paper map for each town we would not know where to place the points. If a table is not geocoded, it cannot be used to create a drawing in Manifold either, because Manifold also would not know where to put the points.

</table>

In contrast the above table is geocoded. Each record now has a latitude and longitude location given in decimal degrees notation. We could use the latitude and longitude values to draw a point for each town on a paper map of the United States. Manifold could also use this table to create a drawing.
If a table is geocoded it can be used to create a drawing, which in turn can be used in a map like the illustration above. Right away, the positions of the towns convey an immediate visual impression of their locations that one does not get in a table presentation. The display of data at the right location is part of the great power of a GIS like Manifold, so we would like our data to be geocoded so the data can immediately be displayed within a map.

The problem is that a lot of the important data sets we deal with, whether they are lists of customer addresses or lists of oil wells or lists of fire hydrants that need maintenance, are not geocoded. The central problem for many GIS users is getting their data geocoded. Depending on the contents of the table, geocoding the table can be a reasonably straightforward process or it can be very difficult or even impossible.

Let's take a look at three geocoding tasks to see what approaches to geocoding are possible in different cases. We will look at geocoding a table of towns, geocoding a table of fire hydrants and geocoding a table of street addresses.

**Geocoding a Table of Towns**

Suppose we have a table with town names like the first example above. How can we geocode it? In the simplest case we look up the latitude and longitude of each town in a reference book or atlas and we add the latitude and longitude to the table for each record by hand. A better way is to use the power of Manifold to automate the process.

If we have a table somewhere that already lists latitudes and longitudes for towns we could extract information from that table automatically. Because there are many geocoded tables of populated places that are easily obtained by free download from the Internet it is usually a straightforward matter to geocode a table of place names.

There are three techniques that are most frequently used:

- If we have another database table that contains the town name and latitude and longitude we could use SQL facilities such as Union to combine the two tables via a relation using a key field such as the name of the town.
- If we have a drawing that shows points for cities in the United States (such as a drawing of populated places) we can geocode the table using the drawing as a guide with Manifold’s spatial Match tool. See the Spatial Geocoding with Match topic for more on this tool.
- If we have the Manifold Geocoding Tools package installed, we can geocode using the town name by following the fast and simple procedures in the Street Address Geocoding topic.

**Geocoding a Table of Fire Hydrants**

Suppose our town would like to create a GIS database of all fire hydrants in the town. We plan to use the power of GIS to help keep track of the status of all fire hydrants and to help plan regular maintenance, cleaning, flushing of water systems and so on. Let’s say we have inherited a database of fire hydrants that provides an identification number for each hydrant, some status information on the hydrant and a “location” field that consist of
a text comment noting what street the hydrant is on and what is the nearest crossing street. Our task is to geocode the table with the latitude and longitude location of each hydrant.

In the United States, the simplest way to accomplish this task is to connect a portable, WAAS-enabled GPS device to a laptop loaded with Manifold, turn on the GPS Console and then drive to the location of each fire hydrant. With Instant Data turned on we would place a point at the location of each fire hydrant and write down the identification number of that hydrant. The result of this process will be a map of points where each point is the location of a single fire hydrant. In addition to the object ID field, the drawing's table will have only one data attribute field in it, the identification number of the hydrant. We can then use this drawing together with Manifold's Match tool to geocode the hydrants database table using the identification number fields as key fields.

Although recording the locations of fire hydrants in an entire town in this way requires a substantial amount of driving, the process goes very rapidly when the GPS Console and Instant Data are used. WAAS-enabled GPS devices can achieve 2-meter (about 6 feet) accuracy, which is sufficient accuracy to locate fire hydrants.

Unfortunately, WAAS is generally available within the United States only. In regions outside the United States GPS devices will provide only 15-meter (about 50 feet) accuracy by default, which many people would not consider sufficient accuracy for mapping fire hydrants. 15-meter accuracy may be fine for locating bridges, which are large structures that are easily found when one is positioned within 15 meters of them, but in the case of smaller objects such as fire hydrants, especially if they are to be placed on digital maps in relation to features such as buried pipes, one normally would like better accuracy.

One way to accomplish this geocoding task outside of the United States would be to drive the city streets and manually mark on a paper map the locations of all hydrants. We could then scan the paper map, georegister the resultant image and then use Tracing to create a drawing of points that show the location of each hydrant. We could then enter the identification number for each hydrant into a data field for each point and then once again use Match to geocode the database table using the identification number as a key field.

Another alternative might be to acquire an aerial photograph of sufficient resolution that hydrants are visible, to scan in the photograph, georegister it and then use tracing to create a drawing of hydrant points and Match to geocode based on the drawing. Although overhead photography is probably not very practical in the case of fire hydrants (which would be obscured by trees in many cities) it is a very practical way of geocoding other infrastructure items, such as bridges or electrical transmission towers. Panning and zooming within a map that contains an image layer and then clicking to create a point at various locations in an overlying drawing is a very fast process.

Note that the task of geocoding a table of fire hydrants is directly analogous to the task of geocoding a table of oil wells, a table of monitoring stations in a forest or, for that matter, any table of items whose location is not known. In all such cases we must determine the latitude and longitude location of each item by either physically measuring the latitude and longitude with a GPS, by marking the location accurately on a map or by determining the locations using an aerial photograph. If the items to be geocoded are easy to reach and a GPS is available the geocoding process might be very straightforward. If they are far away and there is no aerial photograph or other map that can be used, then it could well be impossible to find their locations and thus geocode the table.

Geocoding a Table of Street Addresses

If we had a table of street addresses like the one below we could not plot these on a map because the table is not yet geocoded. Without a latitude and longitude location for each record we would not know where to place it on a map.
The ability to find a latitude and longitude location for a given street address is called street address geocoding. Without a latitude and longitude location for a street address, no GIS package knows where that address really is.

It is easy to make the conceptual mistake of thinking of a street location as being an exactly defined location, the same as a latitude/longitude location. However, that mistake arises mainly from how people use addresses to find locations for the delivery of mail or to go to a particular restaurant or other location. Street addresses, of course, do not really convey an exact latitude and longitude for the address. They simply provide a means by which a postal carrier or someone else physically traversing the streets can find a particular address.

To find an address we have to find the street (with the help of a map if we don't know a particular town), orient ourselves to the address system used on that street and then locate the address. As anyone who has tried to find an out-of-sequence address in an unfamiliar town knows, there is a great difference between hunting down a particular street address and going directly to a latitude/longitude location.

It is one thing to be able to find a given street address by physically going there (perhaps with the help of a local street map) and it is quite another thing to plot a table of street addresses, such as the table of restaurant addresses, on a map as seen above without ever going to the actual address. To plot each restaurant shown in the table we need to know the actual latitude and longitude address at which it is located. To do that, the table must be geocoded as seen below.
In recent years the adoption of geocoding technology by consumer computer applications (at least in many First World nations) has also encouraged us to think of street addresses as being equivalent to a latitude/longitude location for the purpose of computer mapping. Internet mapping sites allow us to enter a street address, such as "525 Main Street, Central City," and instantly see a street map with the location of the address marked as if we had provided an exact latitude and longitude location. Low cost navigation systems that combine GPS technology with built in maps and street address geocoding systems allow us to specify a street address and navigate directly to that location, again, as if we had given exact latitude/longitude coordinates for our desired destination.

As a result, it is quite common for people to expect to be able to enter a street address into a web site or a map and to see a physical location for that address, a sort of "geocoding on the fly." Some applications may give the appearance of taking a list of addresses and displaying them straightaway as points in a map; however, in all cases the software will internally take the intermediate step of using the address to determine a latitude and longitude location for the record. The latitude and longitude location is then used to plot the location of the point.

Software packages use many different strategies to geocode street addresses into latitude and longitude locations. The basic approach is to maintain a large database of streets and address ranges so that the location of a particular address can be estimated from the database. Software that can perform street address geocoding may be built into a GIS package, it may be sold as separate geocoding software, or it may be provided as an Internet web service.

If we install the Manifold Geocoding Tools package, we can turn on the street address geocoding capability that is built into Manifold. The Manifold street address geocoding engine becomes functional when the Geocoding Tools package is installed and a geocoding data source is available, such as the Manifold Geocoding Database for US streets that is provided on the Manifold downloads site. If we have installed Geocoding Tools and a geocoding data source we can use Manifold to geocode a table of valid US street addresses with the approximate position of each address.

To geocode street addresses outside the US, other geocoding data sources may be used. For example, Microsoft’s MapPoint product may be used as a geocoding data source for addresses in Canada or in various European countries. See the Geocoding Data Sources topic.

**How Street Address Geocoding Works**

Any geocoding software (including Manifold) that provides street address geocoding must find the street address and an equivalent location in a database. Unfortunately, there are no global databases that provide an accurate location for each street address although it is possible through special means to create local databases that have accurate locations for street addresses.

To take the United States for example, there is no national database that specifies exactly where all addresses are located. This is mainly because addresses in the US are highly irregular, are poorly documented and change too rapidly for either private companies or government agencies to be able to keep up with perfect accuracy. Therefore, when using any street address geocoder it is important to understand that the output of the geocoder is almost certain an approximate location and not an exact location.

The closest approximations to a national database of address locations that exist in the United States are the U.S. Bureau of the Census TIGER database and the TIGER/Line data sets derived from TIGER. TIGER/Line attempts to show known roads with address ranges for each road segment. Actual addresses are not noted, but...
are represented only as a best effort at showing the address range (from lowest to highest address number) that occurs in a particular street segment. Most geocoding software in the United States, including Manifold, uses databases that are derived in some way from the TIGER/Line data sets.

Based on data sets like those created by the Census Bureau, geocoding software can be created that compares a record's address, such as 525 Main Street, Central City, Idaho, 01120 to an internal database of street segment coordinates and address ranges for each segment. For example, after zeroing in to Main Street by using State, ZIP code and City fields, the software can find the right Main Street segment that contains the address range for the address number at hand. If one particular Main Street segment has a high value of 600 and a low value of 500 for the address range on that segment, the software could then reasonably infer that 525 Main Street is located about one fourth of the way up that particular street segment. It could then assign the latitude and longitude of that interpolated spot to the record.

It is important to understand that the geocoding software has no idea where the actual address is located. It simply interpolates the location of the address by making what is hopefully a reasonable guess based on the address range recorded for a given street segment. Clever software can use a variety of strategies to make better guesses, but at the end of the day the results are usually accurate to only within a city block in urban areas and are wildly inaccurate in rural areas. Addresses of the form Rural Route 10 Box 82, for example, in a rural area might not be geocodable to within tens of miles if they are geocodable at all.

Note that the above method for creating and using geocoding databases does not store the actual locations of specific street addresses. It only says that if there are any street addresses on, say, this particular street segment of Main Street they would fall into the range between 100 and 200 Main Street. If we ask the system to geocode 150 Main Street the system doesn't question our implied assertion that there really is an address of that nature, it simply takes it on faith that if we are asking to geocode such an address we want the system to report what the computed location should be and so the system plops a point half way up that segment of Main Street.

The geocoding database does not actually know there are any addresses on that segment of Main Street or, if there are any, what those addresses might be. It simply knows that if there are any addresses on that segment of Main Street those addresses will be between 100 and 200. As far as the database is concerned there could be empty fields on that segment. Because the database is structured in this way it is not possible to reverse geocode using segment and address range data.

Reverse geocoding is the process of finding all addresses that are within a given range of a given location. Reverse geocoding can only be accomplished with any sort of accuracy if the database in use is a points of interest style database that contains not a database of segments with an address range on each segment but rather contains a database of points with the location of each point and the specific address for each point. Such databases also allow precise accuracy for each address instead of an estimated, interpolated location for geocoded addresses.

Creating geocoding software that can accurately assign an exact, non-interpolated location for each individual address requires a database of all addresses and their exact latitude and longitude locations, that is, the points of interest style of geocoding database. To support 911 service and other emergency response services, some towns are using GPS equipment to create precise databases that show the exact location of each address in their town. Manifold can use such user-provided data sets for precise address geocoding and for reverse geocoding. See the Geocoding Data Extensions topic.

For information on using Manifold's street address geocoding system, see the Street Address Geocoding topic.

Street Address Geocoding Outside the United States

Unfortunately, the United States is the only country that places large government databases of street address ranges like TIGER/Line into the public domain. In other countries, acquiring a database that shows streets and address ranges for those streets is very costly, and in many cases not possible.

As a result, there are many fewer choices for street address geocoding software outside of the United States. Because the Manifold Geocoding Database is based on public domain government data, it is possible for Manifold to provide it for no additional cost on the Manifold download site. Because there is no public domain data for streets and address ranges outside the United States, Manifold provides no geocoding databases for locations outside the United States. However, Manifold includes an option to use Microsoft's MapPoint product as a geocoding data source for addresses in Canada or in eleven European countries. See the Geocoding with MapPoint topic.

Another way to do geocoding outside of the US is to create our own point location geocoding database and then use that as a geocoding data source. A fast way of creating such a point location geocoding database is to use Manifold's GPS Console with a portable computer. Two people ride in a vehicle with one person driving and the
other person operating the computer. They drive to each address and the computer operator uses Instant Data to add a point at that location with the exact address. This can be a very fast process, so fast that an experienced, determined team of two people in a single vehicle can geocode thousands of addresses per day. A town of 50,000 addresses can usually be geocoded in well under a week’s time.

The resultant point location database can then be used for geocoding with Manifold. See the Geocoding Data Extensions topic.

**Geocoded Tables use Decimal Degree Notation**

Geocoded tables in Manifold must have valid latitude and longitude fields consisting of degrees from 0 to +/- 180 longitude and 0 to +/- 90 latitude, with partial degrees denoted as decimal fractions. A minus sign denotes West longitudes and South latitudes. This style of writing latitudes and longitudes is called **decimal degrees**.

Like all modern GIS packages, Manifold uses decimal degree notation because it is an unambiguous standard that is well suited for arithmetic operations and can be written in database tables as text fields or numeric fields. Older methods of writing latitudes and longitudes, such as the use of the letters “E”, “W”, “N” and “S” or the use of degrees, minutes and seconds notation are not well standardized and involve clumsy notation that is not very useful in computing operations. Manipulating values such as *East 32 42’ 15”* is somewhat akin to trying to do longhand multiplication using Roman numerals… not very efficient or sensible.

In modern times most databases of geocoded information use decimal degrees. However, over the years there have been many different styles used to write latitude and longitudes in database tables. Older tables might use text fields to express coordinates in the form of degrees, minutes and seconds, for example. Other tables may use degrees, minutes and decimal fractions of degrees. Some tables will denote longitudes in degrees from 0 to 360. Others might use text strings and prefix a letter, such as “N”, “S”, “E” and “W” to indicate North or South latitudes and East or West longitudes.

Manifold’s approach to dealing with such tables is to import them into Manifold where Transform toolbar operators and other tools can be used to convert coordinates into standard decimal degree notation. This allows the full power of Manifold tools to be brought to bear to adjust the table into the desired form. Clever use of token operations will allow transformation of any format into the desired decimal degrees. See, for example, the Using Tokens and Text Strings topic and the Extract Last Names using Tokens example.

If you have a table that has latitude and longitude values using some old-fashioned notation you should first translate those values into modern decimal degree notation. Only then is it safe to consider it a geocoded table.

**Note:** Although this documentation is written to require decimal degrees notation, in fact if coordinate columns in a geocoded table use degree - minute - seconds notation Manifold will try to parse the notation used to extract valid longitude and latitude values. manifold.net strongly recommends using decimal notation to avoid any possible ambiguity.

**“Generic” Geocoding Strategies**

Geocoding a table by specific addresses is often not required. Although it is easy to understand the conceptual appeal of adding an exact latitude and longitude position for each customer record by address, such geocoded tables also lay a conceptual trap for the unwary in that they are intrinsically inaccurate. Sometimes it is better to have an approximate table that does not lay claims to false accuracy. For many GIS purposes it may be enough to simply pin down a customer location to a specific ZIP code and not to a specific city block. This can be done using spatial geocoding with Manifold’s **match** command. See the Spatial Geocoding with Match topic for spatial geocoding within Manifold.

By spatially geocoding tables using key fields we can often end up with a geocoded table that combines our desired records with a latitude and longitude position for each record. The classic example is displaying customer address records using their ZIP codes. If we have a drawing that shows a point for each ZIP code centroid we can merge the customer address table into this drawing using the ZIP code as a key field. In that case, customer records will appear as a point at the ZIP code centroid for their ZIP code. [The Manifold street address geocoding engine can also geocode addresses that consist only of ZIP codes as well, by geocoding the address to the ZIP code centroid, so as a practical matter there is no need to use Match to geocode to ZIP codes in the US if we have the Geocoding Tools package installed.]

This “generic” method of geocoding is often the only possible method of geocoding for international users who do not have access to a street address geocoding data source for their locations but who do have postal code or telephone code maps or other data sets that can be used as guides for spatial geocoding based on Match.
GIS Jargon and the “Geocoding” Word

New GIS users are sometimes worried about being heard using words in an atypical way that betrays their inexperience, so let's take a moment to discuss a fine point of nomenclature.

The word geocoding as used in this topic and generally used in the GIS world is a jargon or slang word that is reserved for the specific case of adding latitude and longitude values to records in a table in order to specify the geographic location of each record. People who are new to GIS or people who use their jargon in sloppy ways will at times use the word geocoding to refer to the general way GIS drawings keep track of the locations of things. That's a mistake that denies us the usefulness of having a handy slang word that means a single, precise thing.

GIS drawings contain geometry information that describes the shape and location of the objects they contain by recording the coordinates that define the shape and location of the objects. The geometry information is called the object metric (another handy slang word). It's true that in the case of single points the coordinates that define the location of a point are indeed a single pair of latitude/longitude values just like those that might appear in a geocoded table giving a list of records that are to appear as points. However, in the case of lines or areas there are many coordinates that define those objects. We don't therefore refer to the geometry of objects in drawings as being “geocoded.”

Therefore, while a verbally-imprecise or inexpert user might say things like "I'm going to geocode those farm boundaries by tracing over an aerial photo," that's not really using the word "geocode" as it is normally expected to be used. One might say, "I'm going to geocode that table of addresses" but one would not normally talk about "geocoding" the shape of an area. Instead, one might say things like "I'm going to digitize those boundaries from a photo" or "I'm going to trace those boundaries..." or even perhaps (awkwardly) "I'm going to locate those boundaries."

Usually in drawings once the drawing is created if it needs to be cast into the correct geographic context we speak in terms of georegistering or georeferencing it (synonyms). The more subtle idea here is that it is not so much that we have chains of coordinates that correctly define the object metric but that we care about the important nuances of placing those coordinates correctly within an Earth coordinate system such as a projection and a specific location.

Our example of geocoding a table of fire hydrant locations brings us right to the edge of accepted use of the geocode word. If we speak in terms of adding latitude / longitude values to that table of locations then we can be righteous about using the term geocode to describe what we are doing. On the other hand, suppose we have a digital map with a layer of streets and we are creating points in the drawing where the hydrants are located: in that case, we would talk in terms of locating the hydrants on the map or digitizing hydrant locations. So we might say something like "I've got to digitize these hydrant locations from that scanned image so I can geocode that table."

Geocoding is normally something that is done with tables which are then used to create drawings, or something that is done with individual records so they can then be displayed in drawings. For example, a web site designer might say, "When the visitor provides a street address I need to geocode it so I can figure out what part of the map to show."

Coordinate Columns

The latitude and longitude columns used in geocoded tables are also called coordinate columns, because they give the latitude and longitude coordinates at which each record is to be located. A more general form of geocoded tables occurs if the columns are labeled X and Y or have some other column names and give coordinates other than simple latitude and longitude values.

For example, a geocoded table might have coordinate columns that give the actual X and Y coordinates that locate the record in some specific projection, that is, if some specific coordinate system other than simple Latitude / Longitude projection. We're getting ahead of the game for those readers who are going through this documentation in a straight progression of topics, because we have not yet read any of the projections topics. But for the time being, trust us on this: we can have coordinate columns other than simple latitude or longitude which give the X and Y values in some projection for each record. If so, that table also is a geocoded table.

Geocoded Tables and Geometry Columns

Geocoded tables are conceptually the easiest way for new users to understand how a table can store items that are to be displayed in a drawing. It's easy to think about: each record has a latitude and longitude location saved in some coordinate columns. Place a point at that location. The simplicity of this idea is why we introduce
geocoded tables in the Introduction chapter. It is also why most GIS products have some way of working with geocoded tables.

But Manifold can do more, much more. A more sophisticated, more powerful and ultimately higher performance way of saving items within tables is to use geometry columns, which actually save the object metric in a column using some appropriately clever technology. Tables that can save the full object metric can have each record represent not just points but also lines or areas as well, no problem.

There are many possible ways of doing this, but there are surprisingly few GIS systems that can do it in a sophisticated way or even do it at all. In fact, there are so few systems that can do it at all that there has not even evolved a standardized slang term for such tables. Everyone in GIS knows what a geocoded table is, but for those tables that use geometry columns, well, what do you call them? There is no standard term.

At manifold.net we refer to such tables as geometry tables to make clear we are talking about tables that have one or more columns containing true geometry data as opposed to the very simple case of geocoded tables. We use the term geometry table regardless of the specific technology used to implement the geometry column. For example, we use the term geometry table to describe a table that stores geometry using OGC WKB “well known binary” form as well as to describe an Oracle Spatial table storing geometry using Oracle’s high performance SDO_GEOMETRY data type.

Why should we bother to give such tables their own special name?

The reason is that the GIS world tends to divide into two classes of users and applications: those users who do relatively simple, straightforward things using geocoded tables and would like to do so as simply and in as straightforward a manner as possible, and those users who need to operate at a quantum leap higher in sophistication, typically higher end enterprise users, who do far more complex things using geometry tables and who want the full power of tools designed to work with such data.

To support users doing more simple and straightforward things Manifold provides a set of simplified dialogs and capabilities that let us work with geocoded tables in pretty much the same fashion that any simple GIS can do. These features make it convenient and easy to use geocoded tables in a wide range of applications, especially when we need to interface with our colleagues from the database world or web site design world who really don’t want to learn anything about GIS. This documentation includes topics that are dedicated to using geocoded tables without getting into more complex things.

In contrast, those users working with geometry tables can work to their heart’s content and maximum level of expertise doing all the wonderful things made possible by geometry in tables. Those users who don’t need the higher level of function provided by geometry tables can stick to using geocoded tables. We introduce the notion of geometry tables here so that users teleporting into other topics are not confused when they read about geometry in tables in addition to the simple case of geocoded tables.

Notes

The table of sushi restaurants lists sushi restaurants approximately within one mile (1.6 km) of the main USGS facility in Menlo Park. The map in the illustration shows the USGS facility as a yellow diamond and plots the restaurants as green dots. Once we get over our astonishment at the provinciality of a region that can support no more than eleven sushi restaurants per mile, we can see that the restaurants in Palo Alto in the lower right are more tightly clustered than those in Menlo Park, which tend to be spread out along a single main road.

The illustration should not be used for navigation (none of the illustrations in Help should be used for navigation!) since the nature of sushi restaurants is to come and go almost like the seasons. Even at the time of publication of this document several of the restaurants mentioned have disappeared and have been replaced by others.

Creating Drawings from Geocoded Tables

A **geocoded** table is a table where every record has a location given in latitude and longitude. In Manifold, it is easy to create a drawing from a geocoded table. We simply copy the table and paste it as a drawing.

For an example of a geocoded table consider the following table:

<table>
<thead>
<tr>
<th>Longitude</th>
<th>Latitude</th>
<th>Name</th>
<th>State</th>
</tr>
</thead>
<tbody>
<tr>
<td>-119.47</td>
<td>39.02</td>
<td>Incline Village</td>
<td>NV</td>
</tr>
<tr>
<td>-82.68</td>
<td>27.56</td>
<td>St. Petersburg</td>
<td>FL</td>
</tr>
<tr>
<td>-123.42</td>
<td>46.2</td>
<td>Lake Oswego</td>
<td>OR</td>
</tr>
<tr>
<td>-75.25</td>
<td>40.17</td>
<td>Lancaster</td>
<td>PA</td>
</tr>
<tr>
<td>-77.05</td>
<td>38.91</td>
<td>Alexandria</td>
<td>VA</td>
</tr>
<tr>
<td>-74.34</td>
<td>39.49</td>
<td>Margate</td>
<td>NJ</td>
</tr>
<tr>
<td>-70.84</td>
<td>42.5</td>
<td>Marblehead</td>
<td>MA</td>
</tr>
<tr>
<td>-88.55</td>
<td>44.02</td>
<td>Oshkosh</td>
<td>WI</td>
</tr>
<tr>
<td>-104.79</td>
<td>41.15</td>
<td>Cheyenne</td>
<td>WY</td>
</tr>
<tr>
<td>-97.67</td>
<td>30.52</td>
<td>Round Rock</td>
<td>TX</td>
</tr>
<tr>
<td>-122.11</td>
<td>47.67</td>
<td>Redmond</td>
<td>WA</td>
</tr>
<tr>
<td>-97.04</td>
<td>37.68</td>
<td>Wichita</td>
<td>KS</td>
</tr>
<tr>
<td>-122.15</td>
<td>37.45</td>
<td>Palo Alto</td>
<td>CA</td>
</tr>
</tbody>
</table>

Each record has a value in the latitude and longitude columns. The latitude and longitude of each record specify where that record is located. Note that the latitude and longitude values should be expressed in decimal degrees, the standard GIS notation for latitudes and longitudes. For an introduction to geocoding, see the About Geocoding topic.

Creating a Drawing from a Geocoded Table

Geocoded tables may be used to create drawings. Drawings created from geocoded tables contain points at the latitude and longitude positions of each record in the table.

The illustration shows a map where a drawing of points created from the geocoded table is overlaid in a layer above a drawing showing the United States. The points for each town were plotted at the latitude and longitude of that town as given in the table.
There are three ways to create a drawing from a geocoded table. The first method is to copy the table and paste it as a drawing. The second method is to import a drawing directly from an external geocoded table. The third method is to create a linked drawing from a geocoded table that is either part of the project or residing in some file or database external to Manifold.

To create a drawing from a geocoded table:

1. Import the table into a Manifold table.
2. In the project pane, use **Edit - Copy** to copy the table and then use **Edit - Paste As - Drawing** to paste it as a drawing. A new drawing will appear in the project pane.

To import a drawing from an external geocoded table:

1. Choose **File - Import - Drawing** and open the desired database file or connect to the desired data source.
2. Choose the table desired and check the desired fields. Specify the fields that contain latitude and longitude values (by default, the system will guess that any fields named "Latitude" and "Longitude" are the fields to use). Press **OK**. A new drawing will appear in the project pane.

### Pasting New Drawings and Copying Fields

Pasting a geocoded table as a drawing in the project pane will create a new drawing together with a new associated table in the project. The drawing will contain points at the location of each record.

The associated table (like the tables for all drawings) will be created with at least one field, the object ID field. During the paste process a **Paste As Drawing** dialog will appear asking if any additional fields should be pasted from the geocoded table into the new drawing table. If the **Latitude / longitude coordinates** check box in the **Paste As Drawing** dialog is checked, drawings will be created in Latitude / Longitude unprojected form.

For example, if copying the geocoded table illustrated above we might wish to paste the table into a new drawing as points without copying any of the data fields. In that case, the new table created with the drawing will be empty except for the object ID field. In another example, we might wish to copy the **Name** field as well so that each point record has an object ID field and a **Name** field containing the name of the town at that point. Depending on our desired use of the data we might import all of the fields from the original table. We might even wish to import the latitude and longitude fields as well.

**Very Important:** If we copy the latitude and longitude fields from the original table into the table associated with the drawing, it is very important to realize that these are just copies of the latitude and longitude fields that were part of the original table's records. They are not a "handle" into the geometric coordinates that define the position of the points within the drawing's internal structure. If we click open the table and change these values they will not move the points in the drawing about. See the Editing Data in Tables topic for some additional notes on this concept.

### Geocoded Data and Projected Coordinates

This section involves more advanced concepts requiring an understanding of projections. So far this topic has discussed geocoded tables where each record has valid latitude and longitude fields in decimal degrees. Geocoded tables can also have locations for each record expressed in projected coordinate measures within a certain projection. Such geocoded tables can be copied and pasted to create a new drawing, imported to create a new drawing or used to create a linked drawing.

When using a table that is geocoded using projected coordinates as a new drawing into the project pane we must uncheck the **Latitude / Longitude coordinates** box in the import or pasting dialog. Manifold will then create the new drawing using default Orthographic projection values. Once the drawing is created we can open it and change the drawing's coordinate properties into whatever projection coordinate system was being used by the coordinate values in the table. To do this, we use the **Edit - Assign Projection** dialog after the import to make any necessary adjustments. See the Import a Shapefile example topic for a simple example and the Import Drawing - SHP, Shapefiles topic for a more extensive example of using **Edit - Assign Projection** to adjust projection parameters after import.

### To paste a table geocoded with UTM coordinates
1. Import the table.
2. Copy the table and paste as a drawing.
3. In the Paste As Drawing dialog, uncheck the Latitude / longitude coordinates box.
4. Choose the fields giving UTM coordinates for X / longitude and Y / latitude and press OK.
5. Open the drawing created by the Paste As operation.
7. In the projection dialog, choose the UTM zone that was used for the table's coordinates and press OK.

Geocoded Tables Define Points by Default

When we consider a geocoded table like the examples above it is pretty obvious how each record in such a table corresponds to a single point. Each record has a single latitude/longitude location, so it makes sense to create a point at that table. GIS newbies will often ask, "Why not have a geocoded table that defines lines and areas too?"

That's actually not a bad idea and, in fact, is accomplished at a more expert level by using geometry tables. However, usually the request is to store lines in a table using coordinate columns that give lists of latitude and longitude locations, just as a geocoded table gives locations for points.

The problem that there is no obvious, single standard for defining what records in a table represent a line or an area. A line, for example, consists of a sequence of locations, each of which must be specified. What would such a table look like? Would there be one record that gives the beginning location of a line followed by a series of records that give each location in the body of the line until the last one? Where would the data attributes go? Would they be repeated for each record that gives one of the locations in a line? How would the table indicate that some records define points, some define locations in a line and some define locations in an area? How are multi-branched objects, like areas with holes or islands in them, represented?

It's fairly easy to work out a simple standard for representing points, lines and areas in tables. The problem is that everyone who has done so seems to have worked out a different standard. As a result, there is no single recognized way of encoding anything other than points within geocoded tables. Instead, people use various GIS formats, such as shapefiles or mid/mif files or other typical formats to save and exchange GIS information that contains lines and areas as well as points. If they want to use tables to exchange such information, they use a more sophisticated approach of using geometry tables, which have a "geometry" column that can for each record define the metric of areas, lines or points.

Manifold does allow one exception to the above, a method of saving coordinates in geocoded tables that allows lines to be created when a drawing is linked to that table. Although there is no standard GIS method for representing lines in geocoded tables, Manifold uses a simple convention that can be used to create lines in linked drawings from tables.

When importing or linking a drawing from a geocoded table, we may optionally specify a LineID column that will be used to identify which points will be used to draw lines. However, note that this convention applies only when creating linked drawings or importing drawings from geocoded tables and does not apply when copying a table and pasting it as a drawing. In the copy / paste operation only points are created.

Tech Tip: Changing Ordinary Fields in Tables does not Move Objects

This is a challenging idea for newcomers to GIS who may find it difficult to keep in mind the distinction between the original geocoded table used to create a drawing and the drawing's table.

Recall that every drawing in Manifold has its own table associated with the drawing. The drawing's table contains the data attributes (if any) for the objects in the drawing. If there are no data attributes, then the drawing's table will simply contain one column, the object ID, for each object.

The positions of objects in drawings are embedded within the geometry of the drawing without need to have latitude and longitude values listed in a table. Sometimes we create drawings from geocoded tables that have a latitude and longitude for each record. We might wish to have the latitudes and longitudes that were used to position the points immediately at hand in the drawing's table and so when pasting the geocoded table as a drawing we may tell Manifold to bring along the latitude and longitude fields along with the other fields.

Whatever the motive or process that was used to create a drawing, it is often the case that "latitude" and
"longitude" numbers will be copied to fields in a table as well as being embedded within the geometry of a drawing. GIS beginners often mistakenly think that the positions of items in the drawing are determined from the listings of latitude or longitude fields in the table, so that editing these fields will move the objects. That's not the case.

We can use intrinsic fields to display in a table the actual latitudes and longitudes of objects associated with records. However, intrinsic fields are special, system-generated fields and are different than "latitude" and "longitude" fields we might bring into a table that are ordinary text or numeric fields. The rest of this topic explains why this is so.

Drawings are often created in Manifold from geocoded tables. A geocoded table is a table where each record has latitude and longitude fields that specify the location of that record.

Suppose we have an Access database that contains a list of towns together with their latitude and longitude coordinates:

<table>
<thead>
<tr>
<th>Towns: Table</th>
</tr>
</thead>
<tbody>
<tr>
<td>Longitude</td>
</tr>
<tr>
<td>-----------</td>
</tr>
<tr>
<td>-119.47</td>
</tr>
<tr>
<td>-82.56</td>
</tr>
<tr>
<td>-123.42</td>
</tr>
<tr>
<td>-75.25</td>
</tr>
<tr>
<td>-77.06</td>
</tr>
<tr>
<td>-74.34</td>
</tr>
<tr>
<td>-70.34</td>
</tr>
<tr>
<td>-88.56</td>
</tr>
<tr>
<td>-104.79</td>
</tr>
<tr>
<td>-97.67</td>
</tr>
<tr>
<td>-122.11</td>
</tr>
<tr>
<td>-97.34</td>
</tr>
<tr>
<td>-122.15</td>
</tr>
</tbody>
</table>

We can import this Access table into a table in Manifold [either by importing the data or by linking to the external table].

216
To create a drawing from this table we use **Edit - Copy** to copy the table and then we use **Edit - Paste As - Drawing** in the project pane to create a new drawing based on the data in the table. Each geocoded record will appear as a point in the drawing.

<table>
<thead>
<tr>
<th>Longitude</th>
<th>Latitude</th>
<th>Name</th>
<th>State</th>
</tr>
</thead>
<tbody>
<tr>
<td>-119.47</td>
<td>39.02</td>
<td>Incline Village</td>
<td>NV</td>
</tr>
<tr>
<td>-82.68</td>
<td>27.56</td>
<td>St. Petersburg</td>
<td>FL</td>
</tr>
<tr>
<td>-123.42</td>
<td>46.2</td>
<td>Lake Oswego</td>
<td>OR</td>
</tr>
<tr>
<td>-75.25</td>
<td>40.17</td>
<td>Lancaster</td>
<td>PA</td>
</tr>
<tr>
<td>-77.05</td>
<td>38.91</td>
<td>Alexandria</td>
<td>WA</td>
</tr>
<tr>
<td>-74.34</td>
<td>39.49</td>
<td>Moraga</td>
<td>NJ</td>
</tr>
<tr>
<td>-70.64</td>
<td>42.5</td>
<td>Marblehead</td>
<td>MA</td>
</tr>
<tr>
<td>-88.55</td>
<td>44.02</td>
<td>Oshkosh</td>
<td>WI</td>
</tr>
<tr>
<td>-104.79</td>
<td>41.15</td>
<td>Cheyenne</td>
<td>WY</td>
</tr>
<tr>
<td>-97.67</td>
<td>30.52</td>
<td>Round Rock</td>
<td>TX</td>
</tr>
<tr>
<td>-122.11</td>
<td>47.67</td>
<td>Redmond</td>
<td>WA</td>
</tr>
<tr>
<td>-97.34</td>
<td>37.69</td>
<td>Wichita</td>
<td>KS</td>
</tr>
<tr>
<td>-122.15</td>
<td>37.45</td>
<td>Palo Alto</td>
<td>CA</td>
</tr>
</tbody>
</table>

When we use the **Edit - Paste As - Drawing** command to create a new drawing, Manifold will automatically create the associated data attribute table for that drawing. By default, that new table will have at least one field, the object ID field. During the **Paste As** operation Manifold will give us the option of copying additional fields from the original table into the new data attribute table for the drawing. The dialog presents a list of check boxes for each field in the original table. We can copy any of the fields we desire.

For example, if our geocoded table is a list of customer records containing fields such as name, address, city, state, and so forth together with a latitude and longitude for each record, we might wish to copy the name, address and other informational fields. There is no particular technical reason to copy the latitude and longitude fields (these fields in the original table will be used automatically to position the points in the drawing for each record) but we can do so if for some reason we want to have this information in the table.

If we do copy the latitude and longitude fields into a table associated with the drawing, we will see them in the table window when the table is opened. It is very important to realize that these are just table fields that were copied from the original table. They are not a “handle” into the geometric coordinates that define the position of the points within the drawing’s internal structure. Altering the values will not move the points, nor are the fields even necessary to keep the points “positioned” at the right spots.
For example, in the Table window we could delete the "Longitude" field. We could delete the "Latitude" field as well. If we do so the points do not magically disappear from the drawing. They will still be there. All that we have done is delete a field from the data table associated with the drawing. The points in the drawing have already been created when Manifold read the original database. Changing the text data in the table (either the original one or the new table created with the drawing) changes nothing about those points and does not alter the coordinate numbers inside the drawing.

The above discussion may seem obvious to experienced GIS users; however, for new users it is easy to look at a drawing's table that is full of records with latitude and longitudes values for each and to forget that changing the values in the table does not actually move the points about.

How then can we change the actual location of points in a drawing? There are four main ways:

- We can show the Latitude (I) and Longitude (I) intrinsic fields and then change their values. See Editing Intrinsic Fields in Tables. This is the best method when points must be moved to given coordinates.
- We can right click on individual points in the drawing and use the Object - Coordinates dialog to change the location of the geometric coordinates that define the points. This is a seriously tedious approach.
- We can use any one of a wide variety of interactive editing tools in a map or drawing window to move the points by selecting them and dragging them to a new location.
- If the drawing is a linked drawing created from a geocoded table we can directly edit the latitude and longitude values in the external table and then use View - Refresh Data to update the drawing and move the points.
Note that neither of the above options will change the contents of any "latitude" or "longitude" text fields we might see in a drawing's table.

Remember that this discussion so far is about latitude/longitude values that might be copied into a drawing's table when that table is created. The situation with a table that controls a linked drawing created from a geocoded table is different. Linked drawings created from geocoded tables are drawings of points that are automatically created from and controlled by an external geocoded table using the latitude and longitude values in the table for each record. In addition to the external table that controls them, linked drawings (like all drawings) have their own tables as well.

Attempting to change **Latitude (I)** and **Longitude (I)** values in a linked drawing's own table won't move the points about in the drawing because these fields are read-only when a linked drawing is created from a geocoded table (the other, non-intrinsic fields usually will be read/write). However, changing values in the external table that controls the linked drawing and doing a **Refresh Data** will move points about.

A final subtlety: keep in mind that a linked drawing can be created from a geometry column in external tables. In such cases, the **Latitude (I)** and **Longitude (I)** values in the drawing's table will usually be read/write and may be edited to move the points about.

**Note**

The **Skip zero latitude / longitude records** option is checked by default in the **Paste As Drawing** dialog. If checked, any records in the table that have a zero value in the latitude and longitude fields will not have an object created in the drawing. This is a safety measure so that when pasting geocoded tables that have zero values for latitude and longitude (and thus, are not really geocoded) spurious points will not be created for the zero valued records.

**Creating Linked Drawings from Geocoded Tables**

A geocoded table is a table where every record includes latitude and longitude values in decimal degrees notation that give the position of that record. A **geocoded linked drawing** is a drawing that is created from the data in a geocoded table and intermediate query. Geocoded linked drawings are read-only drawings that by default contain points and optionally may be configured to include lines as well. The location of each point in a geocoded linked drawing is taken from the geocoded table via an intermediate query.

**To create a linked drawing from a geocoded table:**

1. Choose **File - Link - Drawing** and open the desired file or connect to the desired data source.
2. Choose the table desired and check the desired fields. Specify the fields that contain latitude and longitude values (by default, the system will guess that any fields named "Latitude" and "Longitude" are the fields to use. Press OK.

Four new components will appear in the project:

- **A linked table** - This linked table is a way of linking the table data from the geocoded table that will provide the data for the linked drawing.
- **A query** - This query transforms the ordinary, geocoded data in the coordinate columns into geometry data from which the linked drawing will be created.
- **A linked drawing and the linked drawing's table** - The linked drawing is like any drawing, except it is created dynamically from the data within the geocoded table.

Why the intermediate query? It is there to make life easier for inexperienced or casual users - the query makes it possible for Manifold to use very powerful, general purpose spatial technology for linked drawings while still retaining a simplified ability for less experienced or more casual users to easily create linked drawings from geocoded tables.
Geocoded tables are a great convenience for simple applications, but for big-time GIS work they are too limiting. A more powerful way of working is to use **geometry tables**, which save information about the objects they define in a geometry column. In fact, this is such a more powerful technology that all Manifold linked drawings are created from geometry data.

However, to save users from having to create geometry tables when they want to do something so simple it can be accomplished with geocoded tables, Manifold has special internal capabilities to allow us to create linked drawings from geocoded tables. When we attempt to create a linked drawing from a geocoded table, Manifold can tell what we are using is not a geometry table. In that case, it automatically writes a query that converts the geocoded table data on-the-fly into geometry data and then links the drawing from that query.

This retains the simplicity of a geocoded table while allowing all linked drawings to use a common internal technical framework. The chain of action from the original geocoded table into the geocoded linked table in the project through the query into the linked drawing is perfectly dynamic: changing a latitude or longitude in the original geocoded table will dynamically move the point associated with that record in the drawing. Adding a record to that geocoded table will create a new point in the drawing, and deleting a record will delete the corresponding point.

**Example**

Let us see how this all works in a specific example.

<table>
<thead>
<tr>
<th>Towns : Table</th>
</tr>
</thead>
<tbody>
<tr>
<td>Longitude</td>
</tr>
<tr>
<td>119.47</td>
</tr>
<tr>
<td>-62.68</td>
</tr>
<tr>
<td>-123.42</td>
</tr>
<tr>
<td>-76.25</td>
</tr>
<tr>
<td>-77.05</td>
</tr>
<tr>
<td>-74.34</td>
</tr>
<tr>
<td>-70.84</td>
</tr>
<tr>
<td>-66.55</td>
</tr>
<tr>
<td>-104.79</td>
</tr>
<tr>
<td>-97.67</td>
</tr>
<tr>
<td>-122.11</td>
</tr>
</tbody>
</table>

Suppose we use **Access** to create an .mdb file with a geocoded table called **Towns** as seen above in a screenshot of an Access session. Each record has a latitude and longitude value as well as other information of interest for each town.

In Manifold, we choose **File - Link - Drawing** and then choose .mdb in the **Files of Type** box to open our Access .mdb file.
Manifold knows what we have is a geocoded table so it opens the Link MDB File dialog with appropriate options. Since we named our coordinate columns Latitude and Longitude Manifold can guess these are the ones we intend to use for our X / longitude and Y / latitude values so it will preload those column names into those boxes. We press OK.

The new components are created in the project pane.
If we pop open the linked table called **Towns** we see that Manifold simply linked a table into the project from the external Access .mdb table. There actually isn’t any data saved within the project file for this table: the data is brought dynamically into Manifold from the Access .mdb. If we changed something in the external Access .mdb, such as the name of a town, that change would also appear in the linked table as well.

![Linked Table Diagram](image)

This linked table in the project is what creates the linked drawing, using the **Towns Points** query as a dynamic translator.

If all we want to do is utilize the linked drawing we don’t need to understand how the query works or what it does. All we need know is that it transforms the simple geocoding style of data from the linked table into the more powerful geometry data form used by linked drawings.

However, for those who have a taste for spatial SQL and are curious about what that query does, we can pop it open in a query window and take a look.

```sql
OPTIONS CoordSys("Latitude / Longitude");
SELECT [Towns].*, AssignCoordSys(NewPoint([Longitude], [Latitude]), CoordSys("latitude / longitude")) [GeoData] FROM [TOWNS];
```

Setting aside for a moment the query telling itself it’s going to be doing things in **Latitude / Longitude** projection, we see the guts of the query use the **NewPoint** spatial SQL function to create a point from Latitude and Longitude coordinates. As is mentioned in the Spatial Extensions topic, the **NewPoint(x, y)** function "Returns a point with given XY coordinates in default coordinate system."

One very cool thing about linked drawings is that they can be created on-the-fly not just from tables, but also from queries. The query grabs the lat/lon data from the table and creates points from that data that are expressed as geometry data.

![Linked Drawing](image)
The linked drawing created from that query knows what to do with that geometry data. It makes points in the right positions, complete with all the other data that was in each record.

We can display the new Town Points Drawing in a map with our example US_Main drawing and see that the points are in the right place. Redmond is indeed up there in the rainy Northwest and Round Rock (the home of Dell Computer) is still in Texas.

Read Only Locations with Read / Write Data

One downside of linked drawings when they are created from geocoded tables is that they are basically read-only as regards position of the points. We can’t drag points around in the linked drawing and expect the latitude and longitude values to change in the originating Access .mdb file. If we change the latitude and longitude values in the originating geocoded table the points will move in the drawing, but we cannot move the points in the drawing and cause the values in the table to change.

However, and this is totally cool, linked drawings are read / write for all other fields in their originating geocoded table. If we pop open the linked drawing’s table in the Manifold project and change Round Rock to Red Rock, if we also pop open the Access .mdb file in Access, we will see that change in Access as well. If we change a value in the Access file we see the change in Manifold. Amazing!

Note: Changes will be displayed in Manifold whenever we trigger a refresh in an open window. This happens when a window opens or closes, pans or zooms or when we issue a View - Refresh command or, if we are using IMS if the web site has been told to refresh on some interval.

In fact, this is so much fun we recommend all Manifold users cobble up a geocoded table in Access, if only with three or four records in it, and then create a linked drawing from it in Manifold. Open Manifold in one window on your computer and open the linked drawing's table and also open the Access table in Access. Watch what happens as you change values in Manifold or in Access: the corresponding value will also change in the other window.
The screenshot above shows a Microsoft Access session opened with the *Towns* table from the *towns.mdb* file. Behind it is a Manifold session with a red arrow inserted into the illustration to indicate the point associated with the Round Rock, Texas, record. The Access table has that record highlighted.

If we delete that record in Access, we can see (after refreshing the view) that the point has disappeared from the Manifold drawing.

**Uses for Drawings Linked from Geocoded Data**

The intent of all this, of course, is not to have fun manipulating tables in one window while points move about or disappear from other windows. The great power we get from using drawings linked from geocoded tables is that we can keep data centralized within databases such as Access or SQL Server or even just tables in simple Excel spreadsheets and then use that data in GIS displays.

The beauty of this idea is that people or applications who know nothing whatsoever about GIS can continue to work with Access, Excel or our favorite DBMS program in their usual way, and automatically any changes they make to the data will be updated in our GIS display in Manifold.

Consider an example: Suppose we have a vehicle tracking application. Each truck in our fleet of trucks has a GPS device and a cell transmitter that reports the location of the truck. We would like to display the location of each truck in a web site that shows points at the location of each truck. When our truck equipment vendor sold us this system we also got some software that listens to the location reports and puts them into a table in our database.

To connect this table data to GIS and to the web we don't need to find a programmer who knows all about the truck hardware and all about databases and GIS and web programming as well.
Instead, we can divide the application into two parts using the common database table:

- **Acquire truck locations** - Just about everyone in the business of selling GPS/location devices for trucks provides software that will update an Access table or some other database table with a record for each truck and the current latitude / longitude location of that truck. That's easy to do and we probably have plenty of people on our staff who know how to do anything we want with the database software we've been using all these years. They might not know GIS, but they know their DBMS.

- **Display truck locations** - The Manifold part of the task is easy: create a linked drawing from the geocoded table that holds the truck locations and then do an IMS website that shows that drawing. The database and truck equipment people don't need to know anything about GIS, and our Manifold people don't need to learn how it is that the truck hardware communicates latitude / longitude locations into the database table. All they need know is the name of the table, the database it is in and the names of the columns that contain the latitude and longitude values.

The above approach is a great way of working with data from geocoded tables for many different types of applications. Whether we are keeping track of trucks, noting the locations of dealers in our retail network, grabbing the locations of recent earthquakes from a web site, marking the positions of favorite sushi restaurants or showing the sites of active fishing spots we can use the same method.

Some standard process with which we have long familiarity creates geocoded tables in our favorite database, which all our organization knows and loves. Without harassing anyone with GIS stuff, we use Manifold to create drawings linked from those geocoded tables. We can then work with those drawings in Manifold projects like any other, we can publish them in IMS web sites, we can serve them out as images using OGC WMS or a Manifold Image server, or we can use them to create things like PDFs from a print layout for publication. In all cases, whenever we use that linked drawing it will show the current data in the table at the moment of its use.

### Exchanging Files

If we would like to exchange data with other users we should employ linked drawings with care if the linked drawing is linked from a table outside the Manifold project. If the table controlling a linked drawing is outside of Manifold it will not stored within the Manifold .map project file. Sending a colleague a copy of our .map file will not also send them the database table from which the linked drawing is created.

Using Projections

Projections are used within GIS and mapping for three main reasons:

- To provide a more natural looking map,
- To enable measurements of areas and lengths in printed maps,
- To enable easy measurement in linear units such as meters or feet when performing analyses.

Manifold System has a very flexible approach to projections. In particular, the "native" projection in which the data of a particular component is kept can be different from the projection used to show that component within a map. Any projected component can be re-projected into a different projection at will.

Using projections does not require much thought or study if one uses projections in a simple way. However, it does require some reading of this documentation. After reading this topic, make sure to read the Projections topic and the Projecting a Map topic.

Projections and Maps

Maps can use any projection desired no matter what projections are used by the components within them. The view of the components within the map will be re-projected on the fly to suit the projection requested of the map. This works well so long as the components within the map are not too large.

To change the projection used by a map:

1. Open the map.
2. Launch the Edit - Assign Projection dialog.
3. Choose the projection to be used (see tips in the Projections topics).
4. Choose sensible parameters for that projection if parameters are required. Use the Suggest button to automatically enter reasonable parameters.
5. Press OK.

The above procedure changes only the view used by the map. It does not re-project the data in the components within the map.

Since dynamic re-projection requires processing time, as the components get larger it can take so long to re-project them on the fly that maps may become slow to display. A map can display faster if it uses the same projection as the components that make up the layers of the map. If one component is very large (such as an image) it may be helpful to use the same projection for the map as well as for that large component layer.

To use a layer's projection as the map's projection:

1. Open the map.
2. Right click on the layer tab for the component whose projection is to be used for the map.
3. Choose Use Projection.

The above procedure instructs the map to use the same projection as a particular component in the map.

Projections and Components

At times we may want to change the projection used by a component. For example, suppose we have a map that includes a compressed image layer that uses a very large linked image and it also has a drawing layer that uses a very large drawing. The map will use the same projection as the image because otherwise the linked image could not be displayed in the map (linked images cannot normally be re-projected). For speed, we might therefore want to change the native projection used by the drawing to be the same projection as used by the map.

Note: Before re-projecting a component into a new projection Manifold will ask us to verify that the starting projection was correctly assigned. See the Verifying Projections section below.
To re-project a layer to use the map's projection:

1. Open the map.
2. Right click on the layer tab for the component whose projection is to be used for the map.
3. Choose Project to Map.

At any time, we can change the projection of a component whether or not it is part of a map. For example, we may have a drawing using some UTM projection that we would like to re-project into Latitude / Longitude to allow export into some legacy drawing format. We can do so using the Edit - Change Projection dialog.

To re-project a component:

1. Open the component.
2. Launch the Edit - Change Projection dialog.
3. Choose the projection to be used (see tips in the Projections topics).
4. Choose sensible parameters for that projection if parameters are required. Use the Suggest button to automatically enter reasonable parameters.
5. Press OK.

The above procedure changes the constituent data within the component into the new coordinate system and units of measure used by the new projection. When re-projecting an image or a surface, the Suggest button will automatically suggest equal values for the X and Y local scale parameters, thus resulting in geographically "square" pixels.

Using the Suggest button will result in "reasonable" values for local scale, which will prevent the newbie error of commanding Manifold to re-project an image using pixel scales that result in a very large number of pixels being used to represent the image. Depending on exactly what the user specified, such an error could cause Manifold to re-project an image so that it requires many gigabytes of storage space, possibly exceeding the amount of free space available on disk. If you do not understand the meaning and proper use of scale and other parameters, it is easy to avoid such errors by using the Suggest button when re-projecting an image.

At times we would like to use a particular projection in a map and for faster performance would like to re-project the components that make up the layers of the map into that same projection. To do so, open the map and note the projection parameters used in the Edit - Assign Projection dialog. Next, open the component in its own window by double clicking on it and then use Edit - Change Projection to change the component's projection into the same projection and parameters used by the map.

**Very Important:** To re-project a component, use the Edit - Change Projection command. Do NOT use the Edit - Assign Projection command. This latter command is used to specify the projection to be used by a map window or to manually correct the projection of a component imported from a format that is unable to provide projection information.

**Verifying Projections**

Once a component has been correctly imported into Manifold, the system will automatically manage projections from then on. The catch is getting a drawing or image or other component correctly imported into Manifold in the first place if it must be imported from a format that does not reliably capture projection information. Surprisingly many formats for drawings and images used in GIS work are very old formats that do not reliably capture projection information.

It is so important to make sure that a projection has been correctly assigned that Manifold tries to ascertain when a component is imported from a format that does not store projection information. In such cases, Manifold will take special measures to ask us to verify the projection assigned. The first time such a new component is opened, Manifold will overlay an info bar onto the window telling us that the projection used by the component has not yet been verified, and inviting us to click on the info bar to verify the projection.

Clicking on the info bar will launch the Edit - Assign Projection dialog. We should take a moment to review the settings shown by that dialog to verify that the projection is indeed what it should be. If it is, we can click OK and thereafter Manifold will not nag us about verifying the projection. If the projection is not what it should be, we can specify the desired projection. Once we verify the projection assigned, we can open the component without Manifold nagging us to verify the projection.
We can get rid of the info bar without launching the Assign Projection dialog by clicking the X sign at the right side of the info bar; however, Manifold will know that we’ve not yet verified the projection of this component and the info bar will appear again the next time the component is opened in a window.

If we do not want to verify projections of new components, once we acquire enough expertise not to want to verify projections anymore unless it is absolutely necessary, we can get rid of the info bar by changing the Prompt to verify projections of new components option in the Tools - Options dialog.

Conversely, if we would like Manifold to remind us to verify the projection of all new components, even those imported from formats that correctly store projection information, we can uncheck the Suppress prompt for non-default projections option in the Tools - Options dialog.

**Note:** The rule of thumb used by Manifold to decide if a component has been imported from a format that does not store projection information is to simply raise the info bar whenever a new component's projection is Orthographic, the default used for imports from formats that do not provide coordinate information, or if the component has been imported in Latitude / Longitude with coordinate locations outside the expected range (+/- 90 latitude and +/- 180 longitude).

That leads to some unnecessary use of the info bar as occasionally we will import a component from a perfectly expert GIS format where the component just happens to have truly been stored in Orthographic projection, but for a short hand rule of thumb it works surprisingly well.

More worrisome is that the rule of thumb will miss occasions when formats have some projection information but not complete projection information. The classic case is shapefiles using incomplete .prj accessory files or some image formats accompanied by “world” files. In that case, there may be enough information to cause a projection other than Orthographic to be used, so that the rule of thumb does not cause the info bar to be raised, but not sufficient information from the format to have all projection parameters correctly assigned. In that case, we have be alert enough as users to manually launch the Assign Projection dialog to verify the projection and to accurately specify all parameters if needed.

Beginning GIS users working with formats such as shapefiles or graphics formats using "world" files may want to uncheck the Suppress prompt for non-default projections option in the Tools - Options dialog so that they are reminded by Manifold to always verify projections on all new components.

**XML Files Created upon Export and Used on Import**

Not all formats to which Manifold can export have the ability to correctly save projection information. As a safety measure to ensure that projection information is never lost, Manifold always writes an accompanying .xml file when exporting drawings, images, labels, maps or surface components to a file. The accompanying .xml file contains coordinate system information and some other metadata. The XML file is created for all formats, even those that correctly save coordinate system information.

When Manifold imports drawings, images, labels or surfaces, the system will check for an accompanying .xml file that might have been written by Manifold. If such an .xml file exists, Manifold will read it and use the information it contains to load a correct coordinate system.

In addition to the .xml file that is automatically created, Manifold projections dialogs such as the Edit - Change Projection dialog provide toolbar commands to manually write or read projection information from accessory files using generic XML, ERDAS AUX, Golden Software GSR or ESRI PRJ files.

**Automatic use of Custom Datum Transformations**

Manifold uses high accuracy coordinate transformation mathematics when re-projecting data from one coordinate system to another. In certain parts of the world, custom transformation formulae are routinely used (and, at times mandated by law for certain uses) to convert datums during re-projection. If the Use custom datum transformations option is checked in the Tools - Options - Miscellaneous pane (checked by default) Manifold will use such custom datum transformations when available.

Currently, NADCON formulae are used to convert between NAD27 and NAD83 in North America and NTv2 formulae are used to convert Canadian, Australian and New Zealand datums supported by NTv2.

If a converted location is outside of the conversion domain supported by such custom methods, no datum conversion is done.
**Datum Pairs supported by Custom Transformations**

<table>

</tbody>
</table>

Custom datum transformations will be invoked **only** when converting between the above pairs in either direction. For example, they will be used when converting NAD27 to NAD83, or when converting from NAD83 to NAD27. Pairs shown above are listed using their full names as they appear in the datum box in Manifold projection dialogs, not using the abbreviated form commonly used. For example, **North American 1983 (mean for CONUS)** is referred to as **NAD83** in abbreviated form.

The **names** of the above datums are significant, not the parameters used. For example, if we convert **GRS80** (the parameters of which are identical to NAD83 so it is the same datum) to NAD27 (mean for Canada), Manifold will **not** use the custom NADCON conversion formulae. This is done on purpose, so we can use NAD83 as the name of the datum for conversion-sensitive North American data (so that the custom transformation will be used) and GRS80 as the name of the datum for all other data where we would like to use the general purpose routines.

**Custom Datum Pairs for NTv2**

Additional datum pairs may be added to those supported by Manifold for use in NTv2 transformations through customization. See the Custom Datum Grids for NTv2 topic for details.

**A Note on Orthographic Projection**

Manifold uses the Orthographic projection by default for components imported from formats that do not provide any projection information. Although the Orthographic projection is the classic “view from space” projection and thus widely used, one limitation of Orthographic is that the projection is defined only for the sphere datum. If other datums are to be used, an alternative “view from space” projection is the Stereographic projection.

Projections and Imported Components

Manifold can import drawings, images, terrains and tables from a very wide range of formats. Some formats such as SDTS are very modern formats that are easy to import with little user intervention. Other formats are very primitive formats that are poorly suited for data interchange. Some formats well suited for CAD programs are less well suited for GIS. Primitive formats or those formats not originally designed for GIS can require a lot of user intervention to import into a GIS program like Manifold.

When working with modern formats the import process is normally easy and automatic in all respects. For example, Manifold can easily import drawings from MapInfo mid / mif format in almost all cases without any need for user intervention. In such cases we import the drawing, pop it open, verify the projection by launching Assign Projection and clicking OK and we're done.

When working with archaic GIS formats such as ESRI.shp or with formats optimized for CAD work such as AutoCAD.dxf user intervention often will be required. In that case, we may not get away with just verifying the projection by pushing OK in the Assign Projection dialog. Instead, we will have to actually understand what the projection parameters are supposed to be and to change them to the right parameters if necessary. That requires a lot more thought than simply pressing OK.

The most frequent class of technical support questions when using Manifold arise from confusion over importing projected maps from old GIS formats such as ESRI.shp or non-GIS formats such as AutoCAD.dxf. Because such formats require a lot of user involvement when used with projected maps, they require a much greater degree of user understanding for correct import. That's a drag, because it requires the novice user to learn much more about projections than seems fair for a beginner. On the plus side, we don't have to learn very much in order to take advantage of the very large amount of free GIS data available in legacy formats.

This topic is an overview for reasonably experienced users. If you are completely unfamiliar with projections and coordinates you should also read the Projections book topics, beginning with the Projections topic. If importing shapefiles, see also the Import a Shapefile example.

Projections and Older Formats

Problems with old formats usually arise if the data they contain is intended to represent a projected map. If the data represents an unprojected map we can breathe a sigh of relief. Even very old formats can usually be imported quickly if the data they contain is not projected data. However, when old formats are used to save projected maps we will almost always have to participate in the import process by specifying projection parameters manually using the Assign Projection dialog. This is especially true of non-GIS formats such as .dxf that were designed to save CAD drawings. Regardless of how convenient they are for CAD usage, such formats will require extra steps to import into GIS.

Modern GIS formats are "smart" and automatically save the projection parameters in use together with the data. During import, Manifold will fetch all necessary parameters from such modern formats automatically and will load the coordinates properties for that drawing with the correct parameters necessary to use the data.

CAD formats such as AutoCAD.dxf and older GIS formats such as ESRI.shp, do not save the projection parameters in use. While one is tempted to refer to such formats as "dumb" formats in contrast to the "smart" encoding of projection information within modern GIS formats, we suggest the term "legacy" format. After all, such formats work perfectly well when used as originally designed for their intended purpose (usually a more limited purpose than expected of modern GIS applications) and should not be blamed if someone uses them inappropriately.

Importing data from legacy GIS formats causes so much trouble for beginners in GIS that Manifold tries to protect us from newbie errors by reminding users to verify the projection in use when a new component is first opened if Manifold thinks there is a good chance the component has been imported from a format that does not save projection information. Manifold raises an info bar to ask us to verify the projection if the component has been imported in Orthographic projection or if it has been imported in Latitude / Longitude with coordinate locations outside the expected range (+/- 90 latitude and +/- 180 longitude).

The classic error is that someone imports projected data from a legacy format like shapefiles and then when they see it looks OK visually they assume it imported OK as well when in fact the correct projection still needs to be assigned. When an info bar pops up reminding us to verify the projection it is more difficult to skip over that necessary step.

When legacy formats are used to save projected maps they require users to keep track manually of the projections used in the file. This is usually done with a readme.txt file, a "metadata" information text file or other
documentation that accompanies the data files and specifies what projection parameters should be used with those files. Users must read the documentation to know what parameters to use. If we download the data files and neglect to fetch the documentation that says how to use them we will find ourselves in trouble. Of course, we will also be in trouble if the authors of the data files neglected to provide any accompanying documentation for us to read.

Because the above is such an obvious hassle most sensible people will refrain from using CAD formats or older GIS formats to save projected data. GIS data in such formats therefore is usually unprojected data that may be imported into Manifold with no special user action required except to specify which datum should be used (as shown in the Import a Shapefile example).

On those occasions when we encounter a projected map that is saved in an older format we will have to specify projection parameters after the import. We can do this using the Assign Projection dialog when we verify the projection to be used.

However, there may be no warning that the data contained in the file is projected and so must be interpreted in a way known only to its author. When acquiring data in older formats we should always keep in mind the possibility that the files contain projected data. If we suspect projected data is involved, we should keep an eye out for documentation that explains what projection parameters are to be used with the file. We may have to search long and hard for this information.

To import from a format that does not save projection information:

1. Import the drawing or image using File - Import. Use default settings.
2. Open the drawing or image.
3. Click verification info bar to use the Edit - Assign Projection dialog to specify the projection information that should be used.

Note that complete information on all projection parameters is required. If a projected drawing is supposed to use Lambert Conformal Conic projection then simply saying that it uses Lambert Conformal Conic projection is not enough: all of the various parameters used within that Lambert Conformal Conic projection (such as datum, latitude / longitude center of the projection, standard and any optional parallels used) must be known as well and specified in the Assign Projection dialog.

Users should be careful to get the best information they can on the projections supposedly used by a given drawing or image. Be skeptical and be thorough: publishers of projected data using legacy formats may not realize that the information they provide is inaccurate or insufficient. For example, if one imports projected files in .shp format that show Wisconsin, it is not enough to say the files are in "Wisconsin State Coordinate System (NAD27)." If the files are in the State Plane Coordinate System using NAD27 we need to know whether they are in the Wisconsin North, Central or South zone.

Another issue is that a projected drawing imported from a legacy format may appear to have imported well at first glance. There is not much visual difference between projections and "unprojected" Latitude / Longitude coordinates in many parts of the Earth when small regions are in view. If we don't use the imported drawing together with other drawings it could take us a while to realize that someone fooled us by providing a projected data set in a legacy format.

It is also quite possible that a Latitude / Longitude unprojected drawing imported from .shp will look absolutely perfect and even will align well with other drawings. However, the datum used might be different than the default datum of WGS84 used in most modern GIS settings, such as GPS devices and Manifold. For example, many drawings in .shp format published by USGS will use the NAD27 datum. If we forget to change the datum after import we could introduce a small but possibly significant error into the data.

The message from the above is that when we verify the projection used by a new component we should not just launch the Assign Projection dialog and then blindly, credulously click the OK button without taking a moment to carefully review the dialog.

**Manually Specifying Projection Information**

Assuming we can lay our hands on the necessary projection information, we can import projected drawings or images from legacy formats. We first import using default settings for that format and then change the projection parameters from their default settings into the correct projection parameters to be used with that data. This is done on a one-time basis using the Edit - Assign Projection dialog.
To do this, click on the new drawing to highlight it in the project pane, and then open the Edit - Assign Projection dialog (or, open the drawing and then click on the verification info bar to open the dialog). This will display the (wrong) parameters used during default import. Enter the correct parameters intended to be used with that data. We only need do this once and then forever more Manifold will keep track of all projection parameters for us automatically.

Once a drawing or image is imported, the projection parameters in use for that component may be seen at any time by opening the Edit - Assign Projection dialog for that component. We can also reach this dialog by viewing the component’s coordinate properties using View - Properties.

Changing the projection assigned to a drawing simply changes how Manifold interprets the internal coordinate numbers that comprise the actual data set. The only time we would do this manually is if we import a projected map from a legacy format and need to tell Manifold (manually) what parameters are supposed to be used. When importing a projected map from a legacy format, the internal coordinate numbers are already correct but there is nothing in the format that says how these numbers should be interpreted. We can tell Manifold how those numbers should be interpreted by entering them into the Assign Projection dialog on a one-time basis.

**Importing Images**

Regarding projections, most images fall into one of several classes:

- Simple overhead photographs created without any projection intended.
- Unprojected images intended for geographic usage.
- Projected images saved in smart geographic image formats.
- Projected images saved in legacy formats.
- Linked images served by an image server or linked from a data source.

Most images one encounters are simple photographic images in .jpg or other photo image formats. They usually show overhead aerial photographs of small geographic areas and are frequently oriented “north up.” They are not intended as “projected” data sets, although most such images can often be handled as if they are projected in the Orthographic projection.

The Orthographic projection shows geographic data as a "view from space.” When a map of the world or a hemisphere is shown in this projection, one sees the Earth as it would be seen from space. Zooming far into the center of such a projection provides a simulated ride towards the planet from space to a location directly overhead a particular location.

For all practical purposes, an aerial photograph shot from directly overhead a particular spot that covers only a few kilometers or miles may be treated as an image in Orthographic projection. By default, unless something about the format used tells Manifold to assign a specific projection, Manifold imports all images as if they are in Orthographic projection and automatically georeferences their lower left corner to the intersection of the Equator and the Prime Meridian (that is, zero latitude and zero longitude).

**Note:** Although the Orthographic projection is the classic "view from space" projection and thus widely used, one limitation of Orthographic is that the projection is defined only for the sphere datum. If other datums are to be used, an alternative "view from space" projection is the Stereographic projection.

To use North-up overhead images as part of a geographic map, we could use the Edit - Assign Projection dialog to "move" them to the right location. We could do this by moving the center of their projection (the lower
left corner, in the case of images) as necessary to the right location and by adjusting the scale of the image. An easier way to accomplish the same thing is to use Manifold’s georegistration tools to easily move, scale and warp the image as necessary from its default location. This is a lot easier than editing the coordinates properties by hand using the **Assign Projection** dialog.

Some images intended for geographic use cover very large areas of the Earth and are presented in "unprojected" **Latitude / Longitude** form. Using such images in Manifold is easy: we import them using default settings for images and then change the projection assigned in the **Edit - Assign Projection** dialog for that image to **Latitude / Longitude**. We will also have to set the scale factor in use. The scale factor can usually be determined from documentation or by computation (divide the number of degrees covered by the image by the number of pixels in the image to see how big each pixel is supposed to be). If desired, we can use the georegistration tools in Manifold or simply use trial and error to adjust the scale factor to be a good match to a known vector map.

Projected images that are saved in smart geographic formats are also easy to use. Manifold will import them with all necessary parameters with no user intervention required. All we need do is verify the projection used and we’re done.

Projected images that are saved in legacy formats will waste more time than all the above cases put together. Such images usually fall into two subclasses:

- Images that are close to, but are not quite, overhead views and so must be adjusted.
- Sophisticated projected images saved in legacy formats that do not reliably capture projection information.

The first case is easy to deal with. We ignore the published projection information (if any) and assume the image is in Orthographic projection and then we force it into a shape that matches a known vector map by using Manifold tools to warp the image. When done in a sophisticated way, this is known as **orthorectification**. Many Landsat images, for example are very close to perfect overhead views. Even though such images are technically in Space Oblique Mercator projection, it is often much easier to treat them as Orthographic projection and to warp them slightly using Manifold georegistration tools than it is to track down the exact projection parameters that must be used.

The second case is more difficult to deal with and is directly analogous to encountering a projected drawing saved in a legacy GIS format. We need to find the projection parameters used in the projected image. We can then enter them into the **Edit - Assign Projection** dialog for this image. The problem here is that few GIS packages can handle projected images so often webmasters or librarians or other people who are involved in distributing such images realize that that projected images should be accompanied by projection parameters. Most folks will just treat a Landsat image, for example, as a simple photograph. When we ask for a Landsat image of a given area they simply give us a **.jpg** and don’t realize that without the accompanying projection information it is not very useful in a GIS.

We can open such images in Manifold, but if we don’t have the projection information we will not be able to re-project the image or otherwise use it in a sophisticated way. In the case of Landsat images, if we can track down the original copy of the image in the Landsat database we have a good chance of finding the projection parameters that must be used to use this image as a projected image within Space Oblique Projection.

**Changing Projections**
Once a drawing or image is correctly imported into Manifold and the projection has been verified we can change the projection into whatever projection we like. To re-project a drawing into a new coordinate system we use the Edit - Change Projection dialog.

The dialog opens with the projection parameters currently in use. These are taken from the coordinates properties of the drawing. If the drawing was imported correctly (with manual updating of coordinate properties if need be using the Assign Projection dialog), these parameters will be the correct parameters required for the coordinates in the drawing to make sense.

When we use the Edit - Change Projection dialog to cast the drawing into a new projection, Manifold will re-compute the coordinates within the drawing to the equivalent numbers required by the new projection. Manifold will also change the coordinates properties to the new parameters now required to make sense of the new numbers. All of this happens automatically. Henceforth, when we open either the coordinates properties dialog or the Assign Projections dialog we will see new parameters to match the new coordinate numbers. Re-projecting a drawing in this way permanently changes the internal coordinates used to define the drawing.

Because drawings are often seen through a map window within maps, it is not always necessary to re-project them if we want to see the drawing in a different projection. We can leave the drawing in whatever projection it was in on import and view it using a map that has been assigned a different projection. The map will re-compute the view on the fly to present the drawing as it would appear in that different projection.

Specifying the projection used by a map does not change any data inside the drawings - it simply changes the way the data is seen by computing on the fly how the drawing should look in the projection requested of that map. Even if several different drawings using different native projections participate in a map Manifold can re-compute them all on the fly to display them correctly in the projection desired for that map. As long as the drawings are not so large that our computer slows down too much during the re-computation process, this works well.

If we are working with large drawings and they must appear within a map using a different projection the process of displaying them in the map may be too slow for our taste. In that case, we can either change the projection of the map to be the same as the drawing, or we can re-project the drawing into the projection used by the map. A map window can work faster if the drawings and images they contain use the same projection requested of the map. This is especially true if many large drawings and images are used in the map.

As explained in detail in the Images topic, images may also be re-projected Images that are used within maps will often be re-projected to match the projection requested of the map. This is because images tend to involve much more data than drawings (each pixel in an image is like an object in a drawing) and re-projecting them on the fly is slower than re-projecting drawings.

**A Projections Strategy**

For most interactive editing and map preparation work in middle latitudes a good strategy is to keep all drawings in Latitude / Longitude form and to work with them in maps using the Latitude / Longitude projection. This is the name given to the "unprojection" that uses simple latitude and longitude degrees instead of any other projection. Most GIS data is published in this form, so it's likely that this will be the native "projection" used by most drawings on import. Latitude / Longitude projection is also used to publish most images that cover the entire Earth, such as the globe.bmp sample image shown above.

When working within smaller regions or individual cities, working in Orthographic projection centered on the region of interest is often a good choice. This is the default projection used for image and non-geographic drawing import, so it is fast even if images are involved. It is also the closest match to an overhead view as would be seen from an airplane flying over the region.

Of course, if you have a fast system or are working with smaller maps you can simply keep drawings and images in whatever projection they were in when imported and use whatever projection you like in maps.

**Very Important:** To re-project a component, use the Edit - Change Projection command. Do NOT use the Edit - Assign Projection dialog. This latter command is used to manually correct the projection of a component imported from a format that is unable to provide projection information.

**Notes**
Introduction

As discussed in the Coordinates topics, CAD drawings coming into a map from non-geographic contexts will have to be georeferenced the way images must be georeferenced. Like images, CAD drawings also use the Orthographic projection by default and are georeferenced in the same way.

Recent extensions to ESRI .shp format will save partial projection information within a .prj auxiliary file; however, most .shp data predates the availability of this latest hack so it does not help much.

Although the georeferencing tools are a lot easier to use than editing an image's coordinates properties by hand, every expert user of Manifold should experiment with hand-editing coordinates properties to better learn how coordinates work.

We must apologize for such a large, dense topic so early in the Introduction. However, it is made necessary by the prevalence of legacy GIS formats. Working in smart GIS formats is easy and requires much less expertise in projections.

How to Print

Manifold provides two paths to printing:

- The contents of any component window may be printed in a default way with File - Print. The visible contents of the window will be printed using a simple dialog.
- More sophisticated layouts may be composed using a Print Layout which may then be opened and printed using File - Print. The layout will be based on whatever settings (paper size, orientation, etc.) are specified in the File - Page Setup dialog.

To Print using a Print Layout

1. Click in the project pane and create a new layout with File - Create - Layout. The Create Layout dialog will pop open. If the layout is to be based on a particular component (often the case when we create a layout for a single component), choose the component to be used in the Create Layout dialog.
2. Open the new layout.
3. Verify paper size and other overall options are correctly specified in File - Page Setup.
4. From the project pane, drag and drop into the layout any other components that are to appear as elements of the layout. Create any new layout elements, such as text entries, using layout tools.
5. Edit the elements in the layout to change size, position, views to be printed, etc. Clicking on an element selects it so that it may be formatted using the formatting toolbar. Right clicking on an element allows choosing the Properties dialog to change the views and other display characteristics. CTRL-ALT clicking on an element will select it for editing so that it may be moved or resized.
6. When satisfied with the appearance of the layout, use File - Print to print the layout.

Note that printing items with a layout is a three-step process: create the layout, adjust the elements of the layout to taste, and then print the layout.

Example

In this example we create a new layout from a drawing.

We begin with a drawing of Mexico. We would like to print this drawing using a layout.
In the project pane toolbar we click on the Create button down arrow for a pull-down menu of project pane components that may be created.

We choose a Layout. This will pop open the Create Layout dialog.

The Create Layout dialog displays a list of all components in the project. This project only has one component, the Mexico drawing. We click on Mexico Drawing to highlight it and then press OK. If we wanted our new layout to be named something other than "Layout" we could have specified a new name as well.

In the project pane a new layout is created underneath the parent Mexico Drawing component. To open the layout, we double-click on it.
The default layout will show the entire component on whatever is the default page size and orientation defined for our printer. Since most people use Letter or A4 sized paper in a portrait orientation it is quite likely the layout will look like that above. The light gray lines bordering the drawing show the extent of page margins that have been set for this printer.

Given the East - West extent of Mexico, our drawing would look better if printed on the paper in landscape orientation.

To change the paper orientation we choose File - Page Setup and click on Landscape, then we press OK.
The layout will be redisplayed using landscape orientation for the paper. If we like, we can print the layout now with File - Print. However, to continue this example we will add a text element to the layout.

We can insert text into the layout using the Insert Text button.

Click on the Insert Text button and then draw a box in the layout where the text is to appear.
In the **Insert Text** dialog enter the text desired and press **OK**. In this case, we will simply enter the word "Mexico". If we later change our mind about the text we can always edit it by double-clicking the text element. This will reopen the **Insert Text** dialog for editing. See the **Layouts** topic for information on other parts of the **Insert Text** dialog.

The new text appears in the layout using the default Tahoma 9pt font, which is too small to be legible in the illustration of the layout shown above. In any case, we would like to make the font larger. To do so we will select the new text element and change the font size using the formatting toolbar.

Before changing the font size we will first change the selection style used. Manifold can show selections in different styles, with the **Dense Dots** style being the default. It may be more convenient to show selections in layouts using the **Border** style.

To change the selection style we click on the down arrow of the **Selection Style** button in the selection toolbar.
We then choose **Border**.

To select the text element that was entered we click on it.

It immediately appears within a red selection box that shows the extent of the text element box we drew with the mouse.
To change the font size, we click on the font size button in the formatting toolbar and choose a new size. We can change the font to a 40 point size, the font to **Verdana** and push in the **Bold** button to boldface the font.

The result is a text element exactly the way we want it. To turn off selection we can simply press the **Select None** button or just click in the layout window outside of any layout element.
To print the layout we choose **File - Print**.

### Exporting to a File

To save the layout to a file, we choose **File - Export - Image**.

![Export dialog](image)

In the **Export** dialog we choose the file name to which to save and the file type. In this example we will save to a **.pdf** file.

![Export PDF File dialog](image)

In the **Export PDF File** dialog that follows choose the resolution to use for the output file. **Pixel resolution** specifies the resolution with which images and surfaces that are in the layout will be saved. **Vector resolution** specifies resolution used to save drawings and labels as well as layout elements such as text or horizontal and vertical lines. If saving to PDF for subsequent work in some other program before printing choose a **Vector resolution** setting that is the same as the resolution of the printer that will be used. If printing to a 600 DPI printer, for example, use 600 DPI. **Pixel** and **Vector resolution** must be at least 1 DPI and cannot exceed 7200 DPI.

The **Ignore styles** checkbox is an advanced option that forces Manifold to export the image using default point, line, area and label styles. This can be useful when exporting for later use in vector-style graphics editors such
as Illustrator because the default styles produce a relatively small number of simple vector objects per Manifold entity. In contrast, more complex styles available in Manifold can produce five to ten relatively complex vector objects per point. If the Illustrator operator prefers to work with simple objects check this box.

See the Export Layout - PDF topic for details on other options in the Export PDF File dialog.

The .pdf file can then be used in other programs. For example, it can be viewed in Adobe Acrobat Reader as shown above or imported into Adobe Photoshop.

Note: Although .pdf and .ps formats are often thought of as "universal" formats that can capture exact renderings of data for use in other programs, they do have numerous limitations. For example, neither .pdf nor .ps can render opacity. If a layout includes a map that shows a drawing below an image that has 50% opacity in the map, the .pdf created by exporting the layout to a .pdf file will show the image with 100% opacity. .emf exports do support opacity for images and surfaces but not for drawings.

Moving Elements

Elements can be moved by selecting them for editing with a CTRL-ALT-click and then dragging them into the desired position.
To move the text element, hold down the **CTRL** and **ALT** keys while clicking on it. Edit handles will appear on the element. The mouse will automatically change to a move or resize cursor when positioned over the text element or over an edit handle.

To move the element click on it and drag to a new position.
Note that text elements have transparent background color by default, as seen in the background color box in the formatting toolbar.

The transparent background color allows text to be positioned over other layout elements with the text "floating" above the other elements. If desired, the background color for the text element can be changed to some other color, to fill in the rectangular area of the text element with background color.

**Visual Perception**

Printed layouts may look slightly different (especially if varying opacities are used in maps) in terms of brightness, opacity or contrast than they appear on screen. This effect arises from the wildly different nature of the media used, a computer monitor versus a printed page. After all, images created by emitted light, like those shown on a computer monitor, are very different from those created by absorbed or reflected light, like those shown on a printed page.

For that matter, even using different types of paper will change the appearance of a printed page at times. Using photo quality paper in inkjet printers can result in dramatically brighter and more vivid images that have better contrast than images obtained with non-photo quality paper.

**Notes**

Why bother changing the selection style to **Border**?

Some users feel that the **Border** selection style is less visually intrusive when formatting text and other elements in layouts. At left above is the **Border** selection style while at right above is the default **Dense Dots** selection style. Either way is fine according to the taste of the user.

**Tech Tip**
In the Tools - Options dialog check the Adjust display scale for monitor resolution box. That will match the scale used in Manifold to what is literally shown on the monitor given monitor size, DPI and other factors.

When working with layouts we can then choose View - Zoom to and choose a zoom of 1:1 so that the layout is shown exactly real size. If we have a large enough monitor we can then see the layout exactly as it will be printed with, for example, an A4 sized paper layout being displayed as a full-sized A4 sheet of paper on the monitor.

Printing to Files or Images

Maps created in Manifold will often include combinations of drawings, images, labels, surfaces and other components. For export to other programs (such as PhotoShop or Illustrator) we may wish to save a given map as an image with higher resolution than that visible on screen.

To do so, begin by creating a layout for the component. There are then two choices for creating an image from a layout:

- Use the Tools - Make Image command to save the layout as an image in the project. When called from a layout, Make Image allows specification of the desired size of the image in pixels. This command can be used to save a drawing or other component as an image (a process often called “rasterization” in some software) or it can be used to save a complete map as an image.
- Use the File - Export - Image command to save the layout to an image file. Use this command to save a layout as a .pdf or other file format.

To save a map or other component as an image in the project:

1. Create a print layout for the component.
2. Open the layout and choose Tools - Make Image.
3. In the Make Image dialog, choose a name for the image, a description if desired and the resolution desired. Press OK.

Note: We can also right click onto a component in the project pane and choose Make Image or Export. Use Export - Image to export to Adobe .ai (Illustrator), .ps (PostScript, as used by PhotoShop or Illustrator) or .pdf (Acrobat reader) files.

Make Image Options

- Name: Name of the image to be created.
- Description: Optional description to be entered into the image component's Description property.
- Resolution: Desired resolution in DPI. Appears only when making an image from a layout.
- Size: A status report at the bottom of the dialog gives the size of the image to be created in megabytes given current DPI settings.

To save a map or other component as an image file:

1. Create a print layout for the component.
2. Open the layout and choose File - Export - Image.
3. In the Export dialog, choose a name for the saved file and the type of file to be created. Press Save.
4. Some file types (such as .ai, .pdf or .ps) will raise dialogs to allow choice of Pixel resolution or Vector resolution and other options. Choose the options desired and press OK.

About Pixel and Vector resolution

Layouts can consist of many different types of elements. They can contain components such as images, surfaces, drawings, labels and other components, system-created items such as North arrows and legends, and elements created in the layout dialog such as text and horizontal and vertical lines. When a layout is exported to an image format all of these different types of elements must be converted into a common form that will be understood by the destination file format.

In the case of image formats, even quasi-vector formats such as .pdf, the various different elements must be rasterized into some specific level of detail or resolution. The Pixel and Vector resolution settings control how
this is done. **Pixel resolution** is used to convert for export any images and surfaces that are in the layout. **Vector resolution** is used to save drawings and labels as well as layout elements such as text or horizontal and vertical lines.

There is no resolution gain in using a higher pixel resolution than the native resolution of any images. If an image was scanned at 150 DPI there is no point in exporting it at 600 DPI since the higher resolution will simply use 16 small, 600 DPI dots to duplicate a single, larger 150 DPI dot. It may be convenient to save an image at higher resolution simply to accommodate later work in a program like PhotoShop.

If saving to a file for subsequent work in some other program before printing choose a vector resolution setting that is the same as the resolution of the printer that will be used. If printing to a 600 DPI printer, for example, use 600 DPI.

Working with GPS Receivers

The Global Positioning System (GPS) provides a low cost and high accuracy means of finding the exact location and altitude of any place on Earth using inexpensive, hand-held GPS receivers. GPS receivers costing well under $200 can provide 15-meter accuracy and GPS receivers enhanced with WAAS capability that cost slightly more can provide better than 3-meter accuracy. Connecting a GPS receiver to a laptop running Manifold provides a high quality means of automatically acquiring position and other GPS data at a very low cost.

Manifold’s GPS Console provides direct interaction with a GPS (Global Positioning System) device connected to the computer via a serial port or USB connection. The GPS Console allows setting moving map mode or automatically fetching position and other data from the GPS device.

The Manifold GPS console works with any GPS receiver or other device that can communicate with a PC using non-proprietary, standard NMEA version 2 protocol using the sentences enumerated at the end of this topic, or with Garmin devices using either Garmin protocol or NMEA protocol. See the notes below under the heading Choosing a GPS Device for more information.

To acquire data from a GPS receiver:

1. Attach an NMEA compatible or Garmin protocol GPS receiver to a serial port or USB port on the computer. If a serial port connection is used, note which serial port (COM1, COM2, etc) is used. If you are using an NMEA compatible device, make sure it is set to NMEA version 2.
2. Launch Manifold. Open the project into which the GPS Console will save objects. Create a drawing if one does not yet exist. We must have at least one drawing in the project to accept data from the GPS device to use Track commands.
3. Open the GPS pane with a SHIFT-ALT-G or with a View - Panes - GPS Console command from the main menu.
4. In the GPS Console, choose the Drawing into which objects will be saved. The drawing cannot be a read-only drawing (such as a read-only drawing on an Enterprise server in Enterprise Edition).
5. Press Properties in the GPS Console toolbar. If a serial port is used, choose the serial port and the serial port properties for the GPS device. Most GPS devices use the default baud rate of 4800 and other default settings. If a USB port is used, choose either the Garmin USB connection or the generic USB Human Interface connection if a non-Garmin USB GPS is in use. Press OK.
6. Press in the Connect / Disconnect button to connect to the GPS device.
7. Press in the Track option buttons for the GPS tracking actions desired, typically the Track Points or Track Line button as well as the Track Columns button. If Track Columns is used, choose the destination fields within the drawing’s table for the various data fields acquired from the GPS receiver.
8. Press Track to manually acquire one reading of data from the GPS receiver as set forth by the Track options.
9. To automatically acquire repeated readings of data, choose the Refresh interval and press the Track Sequence button.
10. Manifold will acquire readings of data as set forth by the Track options until the Track Sequence button is pushed out again.

Note that the GPS Console can write to a drawing even if it is not opened. Once GPS tracking is started by pushing in Track Sequence, tracking will continue until the Track Sequence button is pushed out even if the GPS Console pane is hidden.

The Track action buttons work independently of each other, except that Track Columns requires Track Points to be enabled. If the Track Points button is engaged the system will create points whether or not the Track Center or Track Line buttons are engaged. Push in the Track Line button and the system will begin growing a line to follow changes in position as well as creating points. Push out the Track Line button and the system will stop growing the line but will continue to create points. Push the Track Center button in or out at any time to start or stop "moving map" mode where the drawing is centered to the current GPS position.

Most people working with the GPS Console will work with a map that shows some sort of base map drawing in one layer with a blank drawing into which GPS points or lines are written as a second layer. The base map layer provides orientation for the user while the new drawing layer keeps the data created by the GPS conveniently organized in a second layer.

Controls
Connect / Disconnect - Press IN to connect to the GPS device using serial port parameters specified in the GPS properties dialog. The GPS dialog cannot fetch data from the GPS device until it is connected. Connecting to the GPS also serves as a test of the connection.

Track Center - “Moving map” mode: with each reading of data from the GPS receiver move the drawing so that the acquired position of the GPS is always in the center of the currently active window. When Track Center is engaged and either a Track or Track Sequence command is issued the active window will be panned to center on the location reported by the GPS.

Track Line - With each reading of data from the GPS receiver extend a line to the current position. This option creates a line object that shows the sequence of tracked positions.

Track Points - With each reading of data from the GPS receiver create a point at the current position. This option creates a series of points that show the sequence of tracked positions.

Track Columns - Used to choose which names will be used for destination fields of downloaded data. Otherwise, has no effect unless Track Points is selected. Raises a dialog allowing choice of the destination fields within the drawing’s table for the various data fields acquired from the GPS receiver. Choose a blank destination in the Save To column to not import a given GPS field. When selected, Track Columns will write the selected data fields into the specified destination fields in the drawing’s table with each reading of data from the GPS receiver.

Track - Press to fetch data from the GPS. Each press of this button commands one acquisition of data and the creation of objects or moving map action as specified by the Track Center/Line/Points/Fields buttons.

Track Sequence - Start / Stop acquiring data from the GPS receiver repeatedly using the given time interval between readings. When this button is pressed in, each specified time interval repeatedly commands data acquisition and the creation of objects or moving map action as specified by the Track Center/Line/Points/Fields buttons.

Download Waypoints - Enabled only when connected to a Garmin device using Garmin protocol or when an NMEA device is detected as sending waypoints. Press to download waypoints. Press again to cancel downloading. When pressed, the system will begin downloading waypoints from the GPS receiver, arranging them in order and creating a point object for each waypoint. A line object will be created for a route. To cancel the download process without creating any objects, click the Download / Waypoints button again before the download is complete.

See the Waypoints and Projections paragraph below for important notes on projections.

Upload Waypoints - Enabled only when connected to a Garmin device using Garmin protocol. Press to upload waypoints. Press again to cancel uploading.

Properties - Set up the serial port connection to the GPS receiver by specifying either a USB connection or the serial port used and the serial protocol options required by the GPS receiver.

Drawing Choose the drawing into which objects and data acquired
from the GPS will be placed.

**Refresh** Specify the time interval and time units (minutes, milliseconds or seconds) between automatic data acquisition when tracking.

**Datum** Datum used by the GPS receiver. The datum setting dialog is resizable.

**Altitude** Value reported by the GPS receiver for the height of the GPS antenna. Although handheld GPS receivers integrate the antenna into the instrument case, remember when using an external antenna the GPS device reports the position of the antenna.

**Bearing** True heading computed by the GPS receiver for its motion based on differences between recent positions measured. The true heading is the magnetic heading corrected for magnetic variation reported for the current position by the GPS device.

**Mag bearing** Magnetic bearing.

**Mag variation** Magnetic variation.

**Latitude** Current position latitude.

**Longitude** Current position longitude.

**Quality** Circular error probability computed by the GPS receiver for the position it is reporting.

**Speed** Speed in centimeters per hour computed by the GPS receiver for its motion based on differences between recent positions measured.

**Satellites** The number of GPS satellites in view of the GPS receiver.

**(status bar)**

### Properties Dialog

**Device** Serial port or USB device to which the GPS receiver is connected. Most computers support COM1 and COM2 with connectors on the chassis. Manifold will automatically search the first 1000 possible COM port configurations and allow use of any COM port that appears to be working. If a USB port is used choose either the Garmin USB connection or the generic USB Human Interface connection if a non-Garmin USB GPS is in use. USB choices will not be available if a USB GPS device is not detected.

**Baud rate** Speed of the serial connection. Use 4800 for most GPS receivers.

**Data bits** Number of data bits in the serial protocol. Use 8 for most GPS receivers.

**Stop bits** Number of stop bits in the serial protocol. Use 1 for most GPS receivers.

**Parity** Parity setting for the serial protocol. Use None for most GPS receivers.

**Test** Test connection to the GPS receiver. Instructs Manifold to listen for valid NMEA sentences.
Consult your GPS receiver’s user manual for information on what settings to use for the \textit{Properties} dialog when using a serial port connection. The \textit{Properties} dialog will fail to launch if there are no available COM ports or USB devices available. Unplugging a USB GPS device will automatically disconnect the GPS Console.

Pressing the \textit{Test} button in the \textit{Properties} dialog commands Manifold to try connecting to the GPS to see if it is alive and well and to report, if possible, what protocol the GPS recognizes. If a GPS is found, a message box will pop open to report whether it is using NMEA or GARMIN protocol.

If the GPS uses NMEA protocol, Manifold will report the NMEA tags recognized.

If the GPS uses GARMIN protocol Manifold will report a list of recognized GARMIN subprotocols recognized as well as the version of each subprotocol. If a GPS device switches from GARMIN to NMEA protocol, Manifold will automatically detect the change.

\textbf{GPS Columns Dialog}

The \textbf{GPS Columns} dialog allows specification of NMEA data that will be downloaded from the GPS, if available. Note that not all GPS devices will transmit all of the following fields. For example, only a depth sounder that repeats GPS location information while transmitting depth information as an NMEA repeater will provide \textbf{GPS Depth} information. The complete list of fields in the \textbf{GPS Columns} dialog is taken from all NMEA sentences that the Manifold GPS Console NMEA parser recognizes.
To capture a given field, double click into the Save To cell for that field and choose either the name of an existing column or to create a new column for that field choose [New Column].

**Select All** - Capture all fields.

**Select None** - Capture no fields.

**Select Inverse** - Uncapture all captured fields and capture all uncaptured fields. A fast way to use all but one field: click Select None, capture the one field not desired and then click Select Inverse.

**GPS Air Temperature**  
Air temperature.

**GPS Altitude**  
Altitude.

**GPS Bearing**  
True bearing.

**GPS Depth**  
Depth from the sounding transducer to the sea floor. Note that transducers are normally mounted some distance below the water line of a vessel, so that to compute the depth of water we may need to add the distance between the vessel’s water line and the transducer to the reported GPS Depth figure. Some depth sounders reporting depth in an NMEA stream have a configuration option which allows adding a fixed distance between the water line and the transducer so that the GPS Depth reported will be the distance from the water line and not from the transducer.

**GPS Dew Point**  
Dew point.

**GPS Humidity**  
Humidity.

**GPS Humidity, Relative**  
Relative humidity.

**GPS Latitude**  
Latitude of current position.

**GPS Longitude**  
Longitude of current position.

**GPS Magnetic Bearing**  
Magnetic bearing (computed from true bearing using variation).

**GPS Magnetic Variation**  
Variation used by the GPS for this position and

The availability of numerous additional columns, such as GPS Depth, opens the door to numerous applications if we have the equipment that can provide such NMEA information. For example, suppose our boat has a depth sounder that can read GPS latitude / longitude information from a GPS device (either external or built-in) and can then repeat it on an NMEA serial connection as an NMEA "talker" along with depth information generated by the sounder.

We can then automatically map depths for a water body by simply connecting the NMEA serial cable to a laptop running Manifold and then set the GPS console to record GPS Depth as well as GPS Latitude and GPS Longitude. We set Track Columns and Track Points on and then cruise around the body of water for all regions where we want to capture depths. We could use the resulting depths to create a surface that shows the bathymetry of the water body, or we could create labels from the depth values to create a chart with traditional depth sounding values in the chart. If we need to make any adjustments to the depth values captured, such as, for example, a correction for the distance between the water line and the transducer we could use the transform toolbar for tables to add a fixed value to all of the depths.

**Protocol Requirements for Downloading and Uploading Waypoints**

The Upload Waypoints command works only with Garmin devices connected using Garmin protocol that, further, support the relevant Garmin subprotocol. Some older Garmin devices do not support Garmin uploading protocol.
Although the **Download Waypoints** command works when either NMEA or Garmin protocols are used for connection, as a practical matter it is easiest to use with Garmin protocol. When used with Garmin devices in Garmin protocol, the **Download Waypoints** button is enabled upon connecting to the GPS device and one simply presses the button to download whatever waypoints are stored in the GPS device.

When using NMEA protocol, the **Download Waypoints** command will stay disabled until the GPS device actually transmits some waypoints. Many units using NMEA protocol do not transmit waypoints unless specifically instructed to do so via the devices user interface. For example, the device may only be able to send waypoints for download if they are part of a route and that route has been made “active.”

It is such a hassle to decode the user documentation for most GPS devices to figure out what must be done to send waypoints down the pipe for download, and such an annoyance to fumble with thumb-based menus that most people who want to download waypoints from a GPS will simply buy an inexpensive Garmin device and use that with Garmin protocol.

Note that as in the case for uploading waypoints, when using a Garmin device it must be a reasonably modern device that supports the required Garmin download subprotocol.

**Downloading Waypoints, Routes and Tracks**

Most GPS devices can store **waypoints**, which are point locations noted by the GPS. Most GPS devices make it easy to mark a waypoint at a desired location. In addition, most GPS devices also allow designation of **routes** and acquisition of **tracks**. A route is usually a list of waypoints. A **track** is a series of positions recorded by a GPS device and is imported into Manifold as a line. While routes are formed from waypoints, tracks are entities independent of waypoints. Manifold can import waypoints, routes and tracks.

Download of waypoints, routes and tracks and upload of waypoints in Manifold works only with Garmin protocol, which means we must be using a GPS device manufactured by Garmin. Garmin units implement two different protocols for downloading routes and tracks, so Manifold provides two separate checkboxes, one for downloading routes and the other for downloading tracks. If a particular Garmin unit does not implement either the route or track download protocol, the relevant checkbox will be disabled.

**To acquire waypoints from a GPS device:**

1. Attach a Garmin protocol GPS receiver to a serial port or USB port on the computer. Note which serial port (COM1, COM2, etc) is used.
2. Launch Manifold. Open the project into which the GPS Console will save objects. Create a drawing and verify the projection of that drawing using **Assign Projection** if a drawing does not yet exist. Using **Edit - Change Projection**, change the projection of the drawing to **Latitude / Longitude**.
3. Open the GPS pane with a **SHIFT-ALT-G** or with a **View - Panes - GPS Console** command from the main menu.
4. In the GPS Console, choose the drawing into which objects will be saved. The drawing cannot be a read-only drawing (such as a read-only drawing on an Enterprise server in Enterprise Edition) and it must be in **Latitude / Longitude** projection.
5. Press **Properties** in the GPS Console toolbar. If a serial port is used, choose the serial port and the serial port properties for the GPS device. Most GPS devices use the default baud rate of **4800** and other default settings. If a USB port is used, choose either the Garmin USB connection or the generic USB Human Interface connection if a non-Garmin USB GPS is in use. Press **OK**.
6. Press the **Download Waypoints** button in the GPS console toolbar.
7. In the resultant **Download Waypoints** dialog, choose options desired such as whether to download waypoints, routes and tracks, which data fields should be downloaded and into which columns should they be imported. Press **OK**.
The **Download Waypoints** dialog provides the following controls:

- **Download waypoints** Check to download waypoints.
- **Download routes** Check to download routes.
- **Download tracks** Check to download tracks.
- **Reuse downloaded data** Recycle already downloaded data instead of fetching it again from the GPS device. Used to save already downloaded data into different drawings.
- **Create new drawing** Create a new drawing, called **GPS Data** by default.
  - **Choose all** - Download all columns.
  - **Choose none** - Download no columns.
  - **Choose inverse** - Reverse values in **Save To** column so that those columns currently marked for download are now downloaded and vice versa.

**Column** Columns available for download.

**Save To** Columns into which downloaded data should be placed. Click into the **Save To** cells to choose from pull down menus of columns in the destination drawing's table. Choose [New Column] to create a new column in the drawing to accept the data.

Waypoints in a GPS normally have a latitude, longitude and altitude for each waypoint. In addition, each waypoint has a name and a symbol used to represent that point in the GPS. Some waypoints may also have a comment in the form of a short text string.

Once download occurs, the GPS Console will report the results of the download in the status bar at the bottom of the display.
Note that because GPS connections can be very slow the download of tracks can take a long time. Manifold will provide progress indications during the download process.

Due to the slow interface used by GPS devices the waypoint download process can be very slow at times, with only a few waypoints per second being downloaded. Tracks especially can take a long time. Manifold will provide progress indications during the download process.

When creating a new drawing using the Create new drawing option the new drawing will be created using Latitude / Longitude instead of the usual default Orthographic projection.

**Reusing Downloaded Data**

The GPS Console will cache downloaded data so that unnecessary downloads can be avoided if possible. The Reuse downloaded data option tells the GPS Console to recycle any data already downloaded instead of freshly downloading it. This option will be enabled only if there is some data available to reuse.

Use this option if you have downloaded data from a GPS device and there have not been any changes made to the data in the device, for example, no new waypoints added. If we have just downloaded data into a drawing and we would also like to download those points into a different drawing we can use this option to avoid the slow download process.

It is true that we could simply copy the downloaded points from the first drawing into the second, but it could be that the drawing into which the waypoints were first downloaded already had many points in it and that it is easier for us to simply download the waypoints again into a second drawing than it is to figure out which of the many points in the first drawing are the recently downloaded waypoints that should be copied.

To reuse downloaded data:

1. Connect to a GPS unit using Garmin protocol.
2. Select a target drawing in the Drawing box.
3. Download data using the Download Waypoints toolbar button.
4. Select another target drawing in the Drawing box.
5. Press the Download Waypoints button again.
6. Check the Reuse downloaded data option and click OK.

**Waypoints and Projections**

Downloaded waypoints will not be created if doing so would create an object outside the region that the projection in use can show. This prevents the addition of data that is impossible to show in the projection in use.
For example, the Orthographic projection used by default for new, blank drawings can only show one hemisphere of the Earth at a time. Waypoints that would appear in the hidden hemisphere of the default Orthographic projection will not be created. For this reasons, drawings created automatically when downloading waypoints will be created in Latitude / Longitude so waypoints will always be created no matter where they are located on Earth.

To avoid needing to think about projections the simplest approach to deal with the above is to create a new drawing that will accept the waypoints and then to immediately use Edit - Change Projection to change the projection of the drawing from the default Orthographic into Latitude / Longitude. There are no hidden hemispheres or disallowed locations in Latitude / Longitude so waypoints will always be created no matter where they are located on Earth.

Users who have confidence in their ability to use projections correctly can create a new drawing that uses a projection appropriate to their area of interest in which the waypoints will appear. The easiest way to do this is to create a map based upon a drawing that shows reasonable background features (such as roads or cities) for the area of interest and to then add a new drawing to the map by right clicking a layer tab in the map and choosing Add - New Drawing. The new drawing will automatically be created in the projection used by the map, which, if the map shows the area of interest correctly, will of course be a reasonable projection to use.

Adding a new drawing to an existing map to accept waypoints is also a good idea because seeing the waypoints appear against a background map that provides visual context is a good check against errors. For example, if we are working with a Garmin device and downloaded waypoints appear in the expected places we know we’ve chosen the correct route’s waypoints (if there is more than one route full of waypoints stored on the GPS device) for download.

### Uploading Waypoints

Many GPS device can receive uploaded points and store them as waypoints for later use. Such waypoints usually may be displayed in the GPS device’s built-in maps (if any) and used for navigational purposes.

Manifold can upload points from a drawing into a GPS device as waypoints if the following conditions are observed:

- Uploads require a Garmin device connected using Garmin protocol.
- The drawing from which uploads occur can only contain points.
- The drawing must be in Latitude / Longitude projection.
- The drawing’s table must contain a column that contains a unique, short name for each point.
- The GPS device must be capable of accepting uploads of waypoints. Note that some Garmin devices, such as the “hockey puck” simplified receivers like the GPS18 and later such devices, cannot store waypoints within the device nor accept uploads of waypoints.

To upload waypoints into a GPS device:

1. Attach a Garmin protocol GPS device capable of accepting waypoints to a serial port or USB port on the computer. Note which serial port (COM1, COM2, etc) is used.
2. Launch Manifold. Open the project into which the GPS Console will save objects. Make sure the drawing from which points will be uploaded is in Latitude / Longitude.
3. Open the GPS pane with a SHIFT-ALT-G or with a View - Panes - GPS Console command from the main menu.
4. In the GPS Console, choose the drawing from which points will be uploaded.
5. Press Properties in the GPS Console toolbar. If a serial port is used, choose the serial port and the serial port properties for the GPS device. Most GPS devices use the default baud rate of 4800 and other default settings. If a USB port is used, choose either the Garmin USB connection or the generic USB Human Interface connection if a non-Garmin USB GPS is in use. Press OK.
6. Press the Upload Waypoints button in the GPS console toolbar.
7. In the resultant Upload Waypoints dialog, choose the column that will be used to provide the GPS Waypoint Name value for each point and, optionally, the columns that will provide the GPS Waypoint Symbol and GPS Waypoint Comment values if such are desired. Press OK.

### Upload Waypoints Dialog
The Upload Waypoints dialog provides the following controls:

<table>
<thead>
<tr>
<th>Column</th>
<th>Load From</th>
</tr>
</thead>
<tbody>
<tr>
<td>[GPS Waypoint Comment]</td>
<td>Comments</td>
</tr>
<tr>
<td>[GPS Waypoint Name]</td>
<td>Name</td>
</tr>
<tr>
<td>[GPS Waypoint Symbol]</td>
<td>Symbol</td>
</tr>
</tbody>
</table>

Note that each point's name should be unique in whatever column is used to provide the GPS Waypoint Name. Using the same name for a subsequent point will simply overwrite any previous waypoint by that name.

Examples

The following examples assume the GPS receiver has been correctly connected to the computer and the GPS Console has been set up.

To connect the GPS receiver and set up the GPS Console:

1. Attach an NMEA or Garmin compatible GPS receiver to a serial port or a USB port on the computer. Note which serial port (COM1, COM2, etc) is used.
2. Launch Manifold. Open the project into which the GPS Console will save objects.
3. Open the GPS pane with a SHIFT-ALT-G or with a View - Panes - GPS Console command from the main menu.
4. Press Properties in the GPS Console toolbar. Configure USB port or serial port properties for the GPS device. Press OK.
5. Press Connect / Disconnect in to connect to the GPS device.

When working with GPS devices we will often travel from position to position. We would like to use our current position as reported by the GPS to move a map so that our position is always at the center of the map.

Move a map to show GPS location at the center:

1. Open the map desired.
2. Choose a drawing in the map as the Drawing choice in the GPS Console. Connect to the GPS device by pushing in the Connect / Disconnect button.
3. Choose a reasonable refresh interval, such as every 5 or 10 seconds. What is reasonable depends on the travel speed and the scale of the map. There is no point in refreshing the display every second if one's travel speed is so slow or the scale of the map so big that it takes minutes for any change in position to be noticeable.
4. Choose (push in) Track Center in the GPS Console toolbar.
5. Press IN Track Sequence in the GPS Console toolbar.

We might want to show a reticule at the center of the map when in Track Center, "moving map," mode. Reticules are controlled from the World pane.
Show a reticule at the center of the map:

1. Open the subject map.
2. Open the World pane.

A very common use of GPS Console is to create maps by driving the periphery of ranches or over roads in a vehicle equipped with a GPS receiver and a laptop running Manifold. The GPS Console is set up to record position by creating points over a regular time interval.

To create a series of points at a given time interval:

1. Open the subject map or drawing in which points will be created.
2. Choose the drawing as the Drawing choice in the GPS Console. Connect to the GPS device by pushing in the Connect / Disconnect button.
3. Choose a reasonable refresh interval, such as every 5 or 10 seconds. What is reasonable depends on the travel speed, the scale of the map and the desired accuracy.
5. [Optional] In the Track Columns dialog, choose [New Column] as the Save To method or all fields to be imported. Choose a blank value in the Save To method to not import a field. If mapping a parcel of land using higher accuracy GPS receivers many people would import GPS Altitude.
6. Choose (push in) Track Points in the GPS Console toolbar.
7. Press IN Track Sequence in the GPS Console toolbar. The system will begin creating points.
8. Press OUT Track Sequence in the GPS Console toolbar to stop creating points.

Note that the act of creating a point in a drawing from a GPS position automatically captures the latitude and longitude of that point. Even if we do not import the GPS Latitude and GPS Longitude fields from the GPS device at that instant using the Track Columns option, we always can see the latitude and longitude of that point by showing the Latitude (I) and Longitude (I) intrinsic fields in the drawing’s table.

As an option we may wish to capture fields from the GPS that are not implied by the location of the points created. For example, we may wish to capture GPS Altitude so that each point has a data field giving the altitude of that point.

Example Scenario

We work for a rural township and would like to create a precise map of all addresses on rural routes. We dispatch a vehicle with a driver and a person to operate a laptop computer connected to a GPS device. They will capture a point for each address as follows:

1. Configure Manifold using a drawing that shows streets in the township. In the map, add a blank drawing called Points to receive GPS-generated points.
2. Click open the table associated with the Points drawing and create an Address field that is a variable length text field.
3. Configure the GPS console to save points to the Points drawing. Press in Track Center and Track Points and configure Track Columns to save Latitude and Longitude. Connect to the GPS device by pushing in the Connect / Disconnect button.
4. Enable Edit - Instant Data .
5. Drive to each address, pausing at the address.
6. At each address, press the Track Once button. This will pan the map to that location, save a point at that location and will raise the Instant Data dialog.
7. In the Instant Data dialog, select Address as the field and enter the street address.
8. Continue in this fashion for all addresses, driving to each and pressing the Track Once button. With each future address Instant Data will automatically position the cursor for data entry for the Address field.

When adding points it is helpful to see the results of a data entry as points appear. We can add a labels component to the map so that each point is labeled with the Address field as it is created. To do so, copy the
drawing and paste it as a labels component using the Address field. Drag and drop the new labels component into the map. As each point is created the address for the label will appear.

The result of the above scenario will be a drawing with a point for each address. Each point will have a latitude, longitude and address field. This same process can be used to locate all bridges, fire hydrants, manhole access points, transformers or any other facility. For locations in urban areas, use an WAAS-enabled GPS receiver to achieve accuracy of 3 meters or better.

**Accuracy**

Typical GPS accuracy is approximately 15 meters worldwide. For many years, the U.S. military deliberately damaged the accuracy of signals sent out by satellites to civilian GPS devices so that their accuracy averaged only 100 meters. The signal sabotage program was called “Selective Availability” (SA). SA was turned off by Presidential order in the year 2000 to allow all GPS devices whether military or civilian to operate at full GPS accuracy of 15 meters. Because most GPS devices use chip sets produced by a limited number of vendors, even the cheapest handheld GPS device delivers about the same default accuracy as the most expensive.

An easy way to see the accuracy of a GPS device is to connect it to a laptop computer and then start recording points without moving the GPS device. As points are collected the actual location for each point will vary slightly due to transient changes in what the GPS computes to be its location.

The above plot shows approximately 750 points collected with a Garmin GPS18 USB device at a stationary location. After collecting the points using Track Points we added an Order field to the drawing and then used the transform toolbar to add an arithmetic series to the Order column beginning with 1. This is just a simple way of numbering each point in order from 1 to 750. We then used thematic formatting to color the background color of the points with a spectrum of colors from purple to red so that there is a visual indication of the order in which points were acquired.

The width of the scattered points is about 6 meters (18 feet) and the height about 4 meters (12 feet). The points were acquired with six satellites in view, but given that the Garmin GPS18 uses WAAS it is not spectacularly good accuracy. Presumably, if more satellites were in view (the GPS18 has 12 channels to handle up to 12 satellites at once) or if WAAS reception were better at the test location then accuracy would be improved.

**Enhanced Accuracy**

Two enhancement systems provide GPS accuracy better the default 15-meter GPS accuracy:

- **Differential GPS (DGPS)** - An older technology that requires additional receiving circuitry usually implemented as an external black box. Provides 3-meter to 5-meter accuracy.
- **Wide Area Augmentation System (WAAS)** - A newer system functioning throughout North America that can be implemented using almost the same receiving circuitry already designed for regular GPS.
function. Provides better than 3-meter accuracy 95% of the time. Europe and Japan are developing similar systems.

Many low cost handheld devices now include WAAS functionality built in for just slightly increased prices over non-WAAS products. At this writing it is possible to buy a WAAS-enabled GPS device for just over $100 that can connect to a laptop computer.

When mapping land parcels with GPS, in North America one should use a WAAS enabled GPS receiver if possible to achieve accuracy better than 3 meters over 95% of the time. WAAS also provides this same accuracy in altitude measurements. An accuracy of better than 3 meters is roughly equivalent to the accuracy of TIGER/Line and USGS 1:100,000-scale SDTS/DLG drawings, so it is a good match for much GIS work.

WAAS-enhanced GPS is also a good match for mapping civic infrastructure such as the locations of fire hydrants, 911 addressing, rural geocoding and many other applications.

**Bearings, Magnetic Bearings and Variation**

**Bearings** are radial measurements describing directional movement on the Earth where travel directly towards the North Pole is assigned a value of $0^\circ$, directly East is $90^\circ$ degrees, South is $180^\circ$ degrees and due West is $270^\circ$ degrees. **True** bearings are given based on this system that uses the bearing toward the North Pole as the zero value. The North Pole, in turn, is defined by the spin axis of the Earth. Bearings are also referred to as "headings".

Magnetic compasses do not point towards the North Pole of the Earth. Instead, they point approximately at the North Pole of the Earth's magnetic field, which is usually located hundreds of miles away from the North Pole defined by the spin axis, approximately 700 miles (1140 kilometers) away. In addition, due to fluctuations in the Earth's magnetic field the magnetic North Pole will move over a period of years relative to the true North Pole.

Because the magnetic North Pole is located hundreds of miles from the true North Pole the bearing shown by a compass will not the same as the true bearing. Instead, the compass shows **magnetic** bearing (also known as "compass" bearing). The difference between the magnetic bearing shown by a correctly compensated compass and the true bearing is called **variation**. Variation is different at different locations on Earth because different locations have a different geometric relationship between the location and the placement of the true North Pole and the magnetic North Pole. Other factors, such as magnetic anomalies in a particular region, can greatly influence variation as well.

Variation can be substantial. For example, the variation in the San Francisco Bay region is approximately $15.6^\circ$ degrees. That means to head directly North one must follow a magnetic bearing of approximately $344^\circ$ degrees as indicated by a compass or as indicated by a GPS device set to display magnetic bearings. Variation can change surprisingly fast in some regions of the Earth. In far north regions or in locations near magnetic anomalies positions that are only a mile (1.6 km) apart can have an entire degree difference in variation.

Variation also changes over time as the Earth's magnetic field drifts to slightly different locations relative to the Earth's spin axis. The changes are quite rapid compared to most geophysical processes; there are locations on Earth where significant (greater than 1%) changes in variation will occur within a few years.

Consumer GPS devices are intended to assist navigation in settings such as boating or hiking where magnetic compasses will also be used. Such GPS devices are often setup by default to display magnetic bearings even though the GPS computation within the unit provides a true bearing. Most GPS devices calculate the magnetic bearing they display by consulting a look-up table within the unit that contains an approximate variation for various locations on Earth. Since the unit knows its location and the current date, it can find the current variation for that location in the table (interpolating if need be) and adjust the true bearing to the magnetic bearing that is displayed.

Garmin, for example, at the present writing uses an internal lookup table based on the IGRF 90 international standard Earth magnetic field model to estimate the variation at any given location. The model as used by Garmin provides +/- 2% accuracy for more than 95% of the Earth's surface through the year 2010. Because variation changes more rapidly in some locations (such as northern Canada) where there is a high variation to begin with and a high annual rate of change in variation, in some locations the internal lookup table will result in accuracy worse than 2% by the year 2010. To deal with such cases Garmin provides the ability to manually specify the variation to be used.

Most units will normally report true bearings via their NMEA interface. They will also report the variation used for that location at the time of the measurement. When capturing data from a GPS it is best to capture the true bearings. The true bearing is an invariant quantity that is linked to the spin axis of the Earth. For tactical
navigation purposes it is convenient to use magnetic bearings with GPS devices so that the bearing reported (and captured within Manifold) is the same as that seen on a compass. However, for archival purposes it is risky to use magnetic bearings because the actual direction indicated by a magnetic bearing depends upon variation, which in turn depends upon the location, the geophysical model employed and the date of the measurement. To maintain archival integrity over the years it is best to capture variation together with magnetic bearings if magnetic bearings will be used.

**Note:** A more precise term for variation is magnetic **declination**. "Variation" is a less technical term employed in marine and air navigation. We use the term **variation** because it is widely understood by lay audiences to be the difference between true bearings and magnetic bearings. A further desire is to avoid confusion with the meaning of "declination" in celestial navigation and astronomy where together with right ascension it is used to describe the position of a star.

**Datums**

The default datum used by almost all GPS devices is WGS84. Manifold assumes data coming in from the GPS receiver is in latitude / longitude coordinates using the WGS84 datum. When GPS information is added to a drawing, the GPS coordinates will be converted on the fly from latitude / longitude coordinates and WGS84 into whatever coordinate system (projection) and datum are used by the drawing.

If your GPS receiver is set to use some other coordinate system (projection) or some other datum, then Manifold's interpretation of the data it receives from the GPS receiver will not be correct. The easiest way to avoid such problems is to make sure your GPS receiver is set to use WGS84 and latitude / longitude coordinates. If your GPS receiver is set to use other coordinates or a different datum, the easiest path is to use the setup menu in your GPS receiver (see the documentation for your GPS receiver) to change it to use latitude / longitude and WGS84.

**Troubleshooting**

If your system is unable to read data from the GPS receiver check the following (using a log file if necessary):

- Is your GPS turned on and transmitting location data? Some GPS devices do not transmit location data until they have acquired a signal.
- Is your GPS a serial port interface device or a USB interface device?
- Is the GPS device plugged into your computer's serial port, or, if it is a USB device is it plugged into the USB port?
- Is your GPS interface set to NMEA version 2? Most modern GPS receivers when set to "NMEA" for their interface will automatically use version 2. Some GPS devices, such as Garmin, may come with their own proprietary interface protocol selected by default. Although Manifold can communicate with Garmin devices in Garmin protocol, for other proprietary formats you will have to change the interface protocol to NMEA version 2 in the GPS receiver's setup menu. If you experience any difficulty acquiring fields when working with Garmin protocol, set the device to use NMEA protocol.
- Is your serial port or USB port on your computer functioning correctly?
- Have you chosen the correct serial port in the **Properties** dialog? If using a USB port have you specified a USB connection?
- If you are using a manufacturer's cable to connect a serial port GPS device to a USB connection and that manufacturer provided custom USB drivers, did you install the USB drivers successfully?
- When using a serial port connection, do the baud rate and other serial port settings in use for the computer match the settings used by the GPS device?
- Some GPS devices will not begin transmitting until an active route is specified or some other setup procedure is followed. If this is the case with your device have you correctly set up the GPS?
- Use HyperTerminal to manually check the GPS interface as described below.
- When downloading waypoints from some Garmin devices, the route containing the waypoints must be set as the **active** route. See your GPS device user manual for information on how to designate a particular route as the active route.

If waypoints do not appear when you download them, make sure the drawing you are using is in **Latitude / Longitude** and not some other projection.

Details on GPS receiver interfaces and setup, by long tradition in the GPS hardware industry, are buried in a very obscure portion of the GPS receiver's user manual. It may well be a frustrating exercise to try and find out how to set a route active, how to configure your device to use NMEA 2 and so forth. For example, the manual for a recent Garmin device talks about waypoints and "active" routes but there is no command or documentation
for designating an active route; instead, the user must infer that telling the unit to “navigate” a particular route makes it the active route.

Do an Internet search for pages with advice, tips and tricks on using GPS receivers.

**Track Sequence Timing**

The *Track Sequence* command might not operate continuously if CPU usage is too high. The *Track Sequence* command operates when the system has nothing else to do (to avoid crowding the drawing with too much data) so it may get overridden in extremely heavily loaded systems by higher priority processes. The solution is to avoid running too many demanding programs that place heavy loads on the system processor at the same time while running Manifold with the GPS console and *Track Sequence*.

**Garmin Protocol**

Garmin GPS devices can communicate with using either industry-standard NMEA protocol or using Garmin's own proprietary interface protocol. Manifold can connect to a Garmin GPS device using either NMEA protocol or Garmin protocol.

**Technical Note on NMEA Parsing**

The GPS Console handles NMEA sentences in a generic manner. For example, the handler for the $GPGGA sentence can handle arbitrary $xxGGA sentences. Manifold can handle more than 20 NMEA sentences, including DBT, DPT, FSI, GDA, GDF, GDP, GGA, GLA, GLF, GLL, GLP, GOA, GOF, GOP, GSA, GXF, GXP, HCC, HDG, HSC, MHU, MTA, MTW, MWV, Rnn (where nn is a decimal number), RMA, RMC, RMZ, VDR, VHW, VTG, WPL, ZDA, ZLZ, ZZU. Not all are literally exposed as available fields in the *GPS Columns* dialog, but all will be used as necessary to extract the fields available in the dialog.

Some devices attempt to extend NMEA through the use of proprietary sentences that are unique to that manufacturer. Manifold does not support proprietary NMEA sentences.

**Choosing a GPS Device**

There are hundreds of different brands of GPS receivers that work perfectly well using standard, non-proprietary NMEA format; however, on occasion you may encounter some devices that claim to be "NMEA compatible" that fail to communicate via standard NMEA sentences.

Some such devices simply have bugs in their firmware while others inject proprietary sentences into what is otherwise a standard NMEA data stream. Devices that mix proprietary sentences with standard NMEA sentences can be perversely confusing to new users because they may work for some features, such as reporting latitude and longitude, but not work for other features, such as downloading waypoints. Even well-known brands, such as Magellan, may incorporate such communications incompatibilities into their NMEA interfaces, so users should not take it for granted that an "NMEA compatible" device really is NMEA compatible.

Another source of incompatibility may occur when using devices that connect via USB. This especially may be the case when working with USB devices using vendor-supplied USB drivers, in which case not only might GPS communications standards not be observed but a variety of non-standard approaches to providing Windows drivers might also be a factor.

**Manifold.net** recommends Garmin GPS devices because they are high quality, inexpensive, very reliable and do an excellent job of supporting standard industry protocols. In addition, Garmin has posted for free download all information necessary for software vendors to do a good job of supporting Garmin devices both in NMEA and in proprietary Garmin mode. Garmin also normally provides even many of its least expensive devices with full capability to connect with and interact with PCs. This makes it possible for users to acquire a Garmin device and connect it to their PC at a very low cost. Garmin devices make it easy to download waypoints, routes and tracks and are the only brand of GPS devices currently supported by Manifold for uploading waypoints.

Because of the high quality of Garmin firmware and support for standard protocols, **manifold.net** uses Garmin devices as the "gold standard" for GPS compatibility in NMEA and Garmin interfaces. If a Manifold feature does not work with a Garmin device, it is immediately investigated as a possible bug in Manifold. In contrast, if a Manifold feature works with the Garmin devices in our testing laboratories but is reported not to work with some other GPS manufacturer's device, the debugging process will begin with the assumption that the problem is in that other GPS manufacturer's firmware or communications protocol.
If you have a problem using a GPS device other than a Garmin device, Manifold technical support (at the cost of one or more support incidents) is always willing to investigate the matter for you to help verify that all settings (such as baud rate, etc.) are correct. However, beyond the initial stages of investigation good documentation from the GPS manufacturer may be required for resolution of the problem. Absent such documentation, if tests with a Garmin device do not duplicate the problem the fault will be assumed to be a problem in the GPS device you are using and not in Manifold.

**Support for Proprietary GPS Features**

*manifold.net* is able to provide the best support for those GPS vendors, such as Garmin, who do a good job of providing technical details for their devices for free download on their websites. We are always willing to listen to requests for support of proprietary GPS protocols and features, but only if the GPS manufacturer publishes complete details required for such support for free download and free usage.

When vendors publish on their websites details of formats for communicating with and controlling their devices, for uploading and downloading waypoints, for uploading cartography and so on, it makes it possible for software developers such as *manifold.net* to provide crisp and reliable support for those devices. We believe this minimizes the tech support load on both *manifold.net* and the GPS vendor while it increases customer satisfaction and makes it more likely that the GPS vendor will sell more devices.

There are now hundreds of GPS manufacturers, some of which are not really GPS developers but are more accurately understood to be integrators, in that they take an OEM version of a GPS chipset or module made by some other company and simply package it, relying upon the manufacturer of the module to provide software support. Some such integrators do not provide good support for their products because they do not understand the internal functioning of the modules and software they buy from the original developer.

If your GPS vendor does not provide good documentation online, consider switching to a vendor who does. Given the very low cost of GPS devices and the great competition in this market there is little reason to do business with vendors who do not provide full and precise documentation online.

See the Contacting manifold.net topic if you would like to recommend support for proprietary GPS features.

**GPS Manufacturers**

If you are a bona fide GPS manufacturer, *manifold.net* technical support will provide free Manifold System licenses to you so you can test your GPS devices with Manifold and better support your customers. This offer is open only to manufacturers and not to dealers, distributors, integrators or other non-manufacturing entities.

**Technical Note on Datums**

If your GPS receiver uses some coordinate system and datum other than latitude / longitude and WGS84 and cannot be conveniently reset, it is still possible to use data from that GPS receiver. To do so, first create a drawing in latitude / longitude and WGS84 and acquire the GPS data into that drawing. Next, use the Edit - Assign Projection dialog to specify the coordinate system and datum used by the GPS receiver for that drawing.

See the Technical Note for Experts at the end of the Projections topic for variations in WGS84 and NAD83 datums as used by certain GPS devices.

### Key Windows and Dialogs

This topic summarizes the most frequently used windows, panes and dialogs in Manifold. See the individual topics for each window or dialog for details.

#### Windows

<table>
<thead>
<tr>
<th>Label</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Maps</td>
<td>Map windows are the main user interface in Manifold, because they allow use of many layers.</td>
</tr>
<tr>
<td>Tables</td>
<td>Tables show database table contents and provide a row and column user interface to database information.</td>
</tr>
<tr>
<td>Charts</td>
<td>Charts provide visual summaries of information and a visual framework for data mining through click-back selection.</td>
</tr>
<tr>
<td>Drawings</td>
<td>Drawings are usually opened as layers within a map window. Drawing windows are only used if the native coordinates of the drawing must be re-projected.</td>
</tr>
<tr>
<td>Themes</td>
<td>Themes are formatted drawings. They are a convenient way of showing the same drawing using different formatting choices.</td>
</tr>
<tr>
<td>Images</td>
<td>Images are usually opened as layers within a map window. Image windows are only used if the native coordinates of the image must be re-projected.</td>
</tr>
<tr>
<td>Surfaces and Terrains</td>
<td>Surfaces are 2D presentations of raster data that normally shows terrain elevation data, but which can be any continuously-varying data. Terrains are a 3D view of a surface. If we have Enterprise Edition we also get Profiles and Elevations, which are &quot;cuts&quot; through a surface.</td>
</tr>
<tr>
<td>Forms</td>
<td>Form windows are the visual interface to forms-based programming of scripts as well as to form creation for work with databases.</td>
</tr>
<tr>
<td>Queries</td>
<td>Queries allow creation of SQL queries for selection and manipulation of database information. Results are displayed as tables.</td>
</tr>
</tbody>
</table>

#### Panes

<table>
<thead>
<tr>
<th>Label</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Project</td>
<td>Used to import, insert and organize components.</td>
</tr>
<tr>
<td>Control Points</td>
<td>Control points are used georegister images and drawings. The Control Points pane provides a listing of control points defined in the current image or drawing.</td>
</tr>
<tr>
<td>GPS Console</td>
<td>The GPS Console pane controls acquisition of data from a GPS receiver connected to your computer via a serial port. The GPS Console can automatically move a drawing or map in &quot;moving map&quot; mode as well as fetching data from the GPS on demand or automatically on a regular time interval.</td>
</tr>
<tr>
<td>Info pane</td>
<td>The info pane shows data attributes for objects one record at a time. It is a convenient way of seeing data from drawing tables one record/object at a time, by selecting objects or by stepping data one object at a time.</td>
</tr>
<tr>
<td>Layers</td>
<td>Displays the layer stack in a map. The layers pane is more convenient to use with many layers than the tab controls at the bottom of the map. When used with image windows, the layers pane turns individual R, G, B or alpha channels on and off and also controls whether the image border or background is</td>
</tr>
</tbody>
</table>
displayed.

**Review**

Use with Enterprise Edition and above with concurrent, multi-user editing of linked drawings.

**Selections**

Provides a scratchpad for saving selections that have been made so that they may later be re-used.

The selection pane is very important when working with maps because saved selections are used extensively with the transform toolbar.

**Tool Properties**

Displays settings for the current tool in use, for example, threshold for Select Touch when selecting with images, or the opacity of a paintbrush when editing images.

**ViewBots**

ViewBots are one-line analytic instruments that report a result or otherwise make a calculation using the contents of a window.

**World**

The World pane shows current position and controls Linked Views.

**View Menu**

**View - Properties**

Used to set custom background color, precision factor, zoom ranges and the projection properties of a component. Zoom Ranges control the zoom levels over which a component will be visible in a map, the intrinsic projection properties and the precision parameter.

**View - Properties - Link / Share Status**

Used to see connection parameters and edit modes of linked components and shared components. Essential when managing multi-user editing of linked drawings or using shared components with Enterprise Edition.

**View - Properties - Precision**

The Precision dialog sets a location precision distance that defines the radius of action of many commands and operators, including SQL. For example, some drawing transform toolbar operators like Normalize Topology will snap a line end to a point if the line end is closer to the point than the distance given in the Precision dialog.

This is a critically important parameter that must be understood when using Normalize Topology or other advanced commands.

**File Menu**

**Export - Web Page**

Creates a web page that can be published to the Internet via Internet Information Server. See the Map Server Overview topic.

**Tools Menu**

**Make Image**

Save the open component (map, drawing, surface, etc) as an image. A highly useful way of merging two images into one image. Also used to quickly save a map as an image that can be used in other applications (for example, for use in Microsoft Word or on a Web page). When used to save a print Layout as an image, can save the image to any resolution desired.

**Administrator Console**

Appears only in Database Administrator editions of Manifold. Provides key managerial and user-interface functions which the administrator can use to set up the
database for greater ease of use and capability for all users.

Database Console

Very frequently used to connect to external databases, to browse them and to link tables or other components into Manifold. The number one way of linking components from Oracle or other databases for multi-user editing using Enterprise Edition.

Edit Menu

Edit - Change Projection

Used with components like drawings and images to re-project the component and thus permanently change the data.

Edit - Assign Projection

Used with drawing, image, labels and surface windows to change the interpretation of the data. This is a specialized function that is applied only when manually specifying the projection of a component imported from a format that does not correctly store projection information. To change the native projection of any component other than a map, use the Edit - Change Projection command.

Panes that are regularly left open, like Selections, Layers, Info and ViewBots will automatically switch context as the focus switches from one window to another window.

Panes may be docked into the main Manifold window or left undocked. See the View - Panes topic for more information on panes. Manifold makes heavy use of panes.

The Status Bar

The status bar at the bottom of the screen displays information on command status, location and other useful information. The leftmost region of the status bar is used to display brief descriptive phrases or captions relevant to the current command, somewhat like extended tool tips. Not all commands will show such descriptive phrases.

The rest of the status bar provides readouts that apply to the currently active window. Not all readouts will be active for all types of windows. For example, the Location and Scale readouts will not be active for table windows. The Scale readout will be active only for projected components and maps.

<table>
<thead>

<tbody>
<tr>
<td>Projection</td>
<td>Location</td>
<td>Scale or Size</td>
<td>Selection</td>
<td>Snap</td>
<td>Selection Mode</td>
<td></td>
</tr>
</tbody>
</table>

- **Projection**: The name of the projection in use.
- **Location**: The current location of the mouse cursor, usually in longitude and latitude. Can be in X, Y native coordinates for the projection.
- **Scale or Size**: Show the current scale using either 1:xxx scale notation or by showing the width of the window in miles or kilometers. Enabled only if the component is projected (other than Latitude / Longitude).
- **Selection**: The number of objects selected, if any. Enabled for drawings.
- **Snap**: Shows "Snap" if a snap mode is active.
- **Selection Mode**: Current selection mode: Replace, Add, Subtract, Invert or Intersect.
- **Command**: Name of the current command.
**System Activity**  Changes shape into a 3D "bump" whenever Manifold is busy executing a command.

The location readout may be changed in **Tools - Options** to show the location in different ways. Likewise, a **Tools - Options** setting allows switching between 1:xxx scale mode or xxx mi size mode.

The illustration above shows alternate choices for location and scale readouts. The location shows the longitude and latitude in degrees, minutes and seconds format. The scale readout shows the width of the current view in kilometers.
Security and Access Control

Manifold System is designed to utilize Windows security and access control methods. The correct, most reliable path to security is to learn to use the security features in your operating system. The best way to assure fast, easy and reliable access control is to learn to use the access control features in your version of Windows.

Security and access control when doing GIS in Manifold revolves around sensible structuring of your Windows file system, organization of files and control over various resources such as network access to files, read/write permissions and more. Real security in Windows requires Windows Vista, 2003, XP or 2000 running on an NTFS file system.

For best management of security and access control, manifold.net recommends either Windows Vista, 2003, XP or Windows 2000 within a native Windows domain integrated with Active Directory. A Windows domain with Active Directory can operate with well over a million users. Informed use of Windows and features like Active Directory or Policies will provide enterprise-class security and access control capabilities.

Windows 2000 / XP / 2003 / Vista Resources

- Windows domains integrated with DNS - Domains in a Windows network are large and secure.
- Single or Multiple Domains - Enterprises can organize using a single, large domain or multiple domains with trust relationships between the multiple domains.
- Subdividing Domains into Organizational Units - Individual domains can be easily subdivided into organizational units. Control over those local organizational units can be delegated to local administrators using a simple wizard.
- Active Directory QoS Bandwidth Control - Allocate priority bandwidth to given users based on Quality of Service (QoS) of the network link, who they are, time service required, etc.
- User and Machine Groups - Both users and machines can belong to groups within Windows.
- Groups within Groups - A simple way of organizing access and other permissions is to put groups inside of other groups.
- Organizational Units - OU’s are used to create users with different account policies, to give control of certain user and/or machine accounts to a set of users, and to control user desktops through group policy objects.
- Sites - Windows sites can help an enterprise get organized geographically to improve network performance by compressing replication information that must travel through slower or costly WAN links.
- Distributed File System - A handy replacement for NT’s directory replication service.
- Encrypting File System - Keep files encrypted.
- Sophisticated Security Settings - Windows provides a very wide range of security options that may be applied to fit any organizational or operational need.
- Integrated support for Smart Cards - Smart cards authenticate users by providing a personal security certificate when inserted into the smart card reader. Windows now includes support for numerous smart card readers and media.

For information on configuring these and other security and administration features in Windows please consult any of the many books published on Windows Vista, Windows Server 2003, Windows XP and Windows 2000.
Where to Get Maps

Manifold reads so many different formats it is usually easy to find many sources for maps and their components: drawings, images, surfaces and geocoded tables or other data sets that may be merged into tables. In this topic we refer to data that may be imported as any Manifold component using the generic term "GIS data."

Manifold users working with the United States have a seeming infinity of free data sources to work with. Federal law in the United States places essentially all GIS data sets created by the Federal government into the public domain. Since Federal agencies in the US are the most prolific creators of GIS data in the world, US users are blessed with an abundance of data, usually free of charge. The usual problem in the US is choosing which one of many possible drawings or images is the right one to use.

The situation in the rest of the world is much different and for most users considerably more difficult than in the US. Except for the US, most governments do not place GIS data in the public domain. Most governments charge high prices for any GIS data for use outside of government. Some governments discourage or openly outlaw any competition to state cartographic monopolies. For these reasons, free GIS data for much of the world is difficult to obtain unless you are part of some government entity (military, public health organization, etc.) and can obtain free data.

General Sources for GIS Data

Manifold can read numerous formats for drawings, images, surfaces and tables. Sources for such data include:

The Manifold Site
A "starter" collection of base maps, including Manifold's base World map are available from downloads pages on the manifold.net web site. See the links to various downloads pages given in the Product Downloads page.

Note that some .map files available for download contain numerous drawings. Fetch drawings from these .map files using File - Import - Component to import just the drawing you want into your project.

All .map files on the downloads pages were all saved using the Compress .map files to save space option in Tools - Options to allow faster download. When opened for use the resulting projects may be considerably larger than might be expected from the size of the .map file on disk.

The Internet
The Internet provides more access to GIS data at zero cost than any other method. Become expert at using a good search engine and crawling the web for sources. When downloading from the web, be alert for any accompanying documentation that describes necessary projection information or other metadata. Acquire a fast Internet connection and a large hard disk as well. A revolution in fast and easy access to GIS displays comes from the use of Image Servers within Manifold.

Google KML / KMZ sites
A great way to get point data is to visit sites where Google Earth users exchange data as KML / KMZ files full of placemarks, such as the user forums at http://bbs.keyhole.com/ubb/. Manifold imports KML / KMZ format, so any file like that can be imported into Manifold as a drawing of points. Want a drawing showing all castles in Italy? Locations of famous battles? It's all there.

Government Sites
Agencies like www.usgs.gov, www.nima.mil, and www.census.gov (USGS, NIMA and the Census Bureau) on the federal level and various state and local agencies are placing more and more GIS data on the web for free download. Use government sites to get highly detailed drawings and maps for the area of interest. A very useful collection is at the National Atlas website at http://nationalatlas.gov/atlasftp.html

Non-Profit Organizations
Non-profit organizations such as www.ciesin.org often provide sites with GIS data that originated in government but which have not yet been made available by
Introduction

Universities Numerous universities operate web sites with free GIS data.

GIS Vendor Sites Many GIS vendors operate sites that provide highly detailed GIS data in the format of their GIS systems. ESRI, for example, provides free downloads of highly detailed international data in .shp format from their www.esri.com site. Manifold can read such formats. Read the vendor’s terms and conditions to see if your intended use of the data is permitted. Many vendors allow remarkably free usage of the free data provided on their sites so long as you credit them as the source of your data in publications.

Other Sites “Ezines” focusing on GIS as well as sites run by individual businesses or GIS enthusiasts provide hundreds of gigabytes of GIS data for free. Use a good search engine or ask about in newsgroups to find these.

Peer to Peer Exchange Internet forums like the GeoReference forum at http://forum.manifold.net, are a good place to meet other GIS users for exchange of GIS data. See the Help - Manifold on the Web topic for fast access to the Manifold online community and other resources.

Libraries Don’t overlook public libraries as a source of GIS data. These are usually best for locating paper maps or printed photographs for scanning, a less preferred route to GIS data than direct electronic download via the web. Larger libraries will often have CDs on hand from the Census Bureau or other agencies. Bring a laptop into the library and copy the data onto your hard disk for later use. If it’s public data, it’s your right to copy it.

Government Libraries Many government agencies have libraries that are open to the public. USGS has major libraries in Virginia, Colorado and Northern California that provide access to hundreds of CDs of USGS-published GIS data. Bring your laptop.

Federal Depository Libraries By Federal Law, agencies are required to provide copies of their publications, including electronic publications like GIS data CDs, to Federal Depository Libraries. University libraries will often function as a Federal Depository Library for their particular location. If a library participates in the Federal Depository system, you must be granted free access to that library and allowed to use the Federal materials on file. Again, bring your laptop. Search the web for information on the nearest Federal Depository library to you.

University Libraries University libraries are often open to the public for free or for a nominal fee. Any good university library will have a wealth of GIS data on CD available for use. Most have no problem with use of personal laptops or copying of GIS data that is in the public domain.

Government Sales USGS provides numerous GIS data titles on CD for low costs. The Bureau of Transportation Statistics (BTS) will ship CDs to you for free. Numerous other agencies will sell data. Most government data in the US is sold for reasonable prices, but a few agencies charge illegally high prices. If confronted with a demand to pay $1500 for a couple of CDs, file a Freedom of Information Act request instead. Agencies cannot charge more than the cost of duplicating the data.

GIS Data Vendors For those parts of the world not covered by publicly available NIMA data sets, the only options may be to create your own data or purchase it from a commercial vendor. In the US, the only sources of very timely and high accuracy data are commercial vendors. Vendors like TeleAtlas (www.teleatlas.com) provide good
coverage of Europe. Manifold can read all common commercial formats.

**Satellite Photography Vendors**

Commercial satellite photography vendors such as IKONOS ([www.spaceimaging.com](http://www.spaceimaging.com)) and SPOT ([www.spot.com](http://www.spot.com)) sell satellite images from their huge inventory of existing images. Some companies will even snap a custom picture for you from orbit of the location you desire. Other sources include archives of Landsat and other data.

**Freedom of Information Act**

The United States guarantees access to virtually all unclassified Federal data via the Freedom of Information Act (FOIA). If you see a map created by any Federal agency, you should be able to get the GIS data that was used to create the map with a simple FOIA request. Use a good web search engine to find resources and step-by-step instructions for using FOIA. Before filing a FOIA request, please check carefully to make sure the data you seek has not already been published.

**Key Internet GIS Data Sources**

Internet URLs change frequently. The URLs below were active when this documentation was created. If the URLs are changed, usually drilling down from the main web site for the agency or organization will find the current URL. In addition to USGS Geodata, the National Atlas, the Census Bureau and NIMA, there are many, many other resources on the web. For example, many state governments operate web sites from which GIS data may be downloaded.

**Image Servers**

Probably the greatest change ever in the GIS industry, introducing immediate access to the largest set of worldwide GIS data ever, has been the provision of Image Servers within Manifold. Read the image server topics and the tutorial to learn how to immediately generate map backgrounds and satellite photography for almost anywhere on Earth. The use of Open Street Maps (OSM) image servers in particular provides free, public domain mapping for virtually anywhere on Earth.

**USGS Geodata Downloads**

[www.usgs.gov](http://www.usgs.gov) is one of the best sites in the US for GIS data products. Numerous USGS servers provide many different sites from which data may be downloaded.

[http://edc.usgs.gov/doc/edchome/ndcdb/ndcdb.html](http://edc.usgs.gov/doc/edchome/ndcdb/ndcdb.html) - A Manifold favorite for USGS data. See this site for documentation and detailed information on the various data sets provided. This site provides free downloads for:

- **1:2M DLG** - 1:2,000,000-scale drawings showing boundaries, major roads, hydrography, etc. for the United States. Suitable for background maps and overviews at the state level.

- **1:100K DLG** - 1:100,000-scale drawings showing features in greater detail. Used by many for roads and similar features at the county or city level.

- **1:24K DLG** - Actually published using SDTS format, these are the vector drawing equivalent of USGS paper topological "Quad" maps. Very highly detailed roads, hydrography and much more. Used for local work.

- **1:250K DEM** - 1:250,000-scale Digital Elevation Modules (terrain elevation) suitable for use as surfaces at the county level.

- **1:24K DEM** - 1:24,000-scale Digital Elevation Modules published in SDTS format suitable for use as surfaces at the local level. Equivalent to "Quad" maps. Extraordinarily detailed. Use the SDTS drawing importer to import these (a surface will automatically be created even though a drawing importer was used). Note: USGS is now moving free downloads of SDTS DEMs to third parties.
LULC - In 1:250,000-scale and 1:100,000-scale versions. Land use and land cover data provides information on urban or built up land, agricultural land, rangeland, forest land, water, wetlands, barren land, tundra, and perennial snow or ice. Associated data sets display information in five data categories: (1) political units, (2) hydrologic units, (3) census county subdivisions, (4) Federal land ownership, and (5) State land ownership. The 1:250,000-scale resolution maps yield spectacular maps when thematically formatted in Manifold.

NCLD - A collection of raster data sets, one per state, that provides extensive land use data for the US as rasterized data sets. Derived from the early to mid-1990s Landsat Thematic Mapper satellite data, the National Land Cover Data (NCLD) is a 21-class land cover classification scheme applied consistently over the United States. The spatial resolution of the data is 30 meters and mapped in the Albers Conic Equal Area projection, NAD 83. These are imported into Manifold as surfaces using the Raw Binary Files importer. See the Import a Raw Binary File - NLCD topic for an example.

US Bureau of the Census http://www.census.gov - The Census Bureau has begun placing data on line for download. Drill down to subsequent pages, like http://tiger.census.gov/ to find specific data sets. There are many pages that just serve images: drill deeper to find the actual GIS data sets for free download. A favorite Manifold site is http://www.census.gov/geo/www/cob/ the home page for Cartographic Boundary Files.

TIGER/Line - A highly detailed, complex GIS data set providing streets with address ranges, boundaries and numerous other detailed features for the entire US. The basis for most commercial street maps. See the Census Bureau's Tiger pages.

Boundary Files - States, Counties, Congressional Districts, Metropolitan Areas, Urbanized Areas, Incorporated Places, County Subdivisions, School Districts, Voting Districts, Census Tracts, Census Block Groups and much more. Usually organized by State. Download in .e00 format so that they will import by default into Manifold with the correct NAD83 datum used by most files. Alternately, when importing .shp versions (preferred by many people because the result of importing .shp files are simpler, better organized projects) use Edit - Assign Projection to change the datum to North American 1983 (mean for Conus).

ZCTAs - ZIP Code Tabulation Areas are the Census Bureau's representation of ZIP codes as areas. We predict these will become a standard for demographic work.

Gazetteer - Places, ZIP and other centroids.
find maps and geographic data at the NIMA web site. Use the Freedom of Information Act to pry public data out of NIMA.

VMAP1 - VMAP Level 1 data: the world on 232 CDs at exquisite detail (1:250,000 to 1:100,000-scale). NIMA has released some data, but not all. File a Freedom of Information Act request for what you need if they do not have it available for download.

VMAP0 - VMAP Level 0 data. Updated edition of the famous Digital Chart of the World.

DTED - DTED Level 0, terrain elevation data for the world.

DOI - Georeferenced SPOT satellite imagery for much of the world.

JOGA - Joint Operations Graphic - Air, JOG-A (1:250,000 scale) digital raster graphics images. (scanned paper charts).

ONC - Operational Navigation Chart, ONC (1:1,000,000 scale) digital raster graphics images. (scanned paper charts).

TPC - Tactical Pilotage Chart, TPC (1:500,000 scale) digital raster graphics images. (scanned paper charts).

Bureau of Transportation Statistics

http://www.bts.gov - A "must have" CD for every serious GIS person is the National Transportation Atlas Database (NTAD). In addition to key transportation layers it has many general purpose GIS data sets as well. At the current writing, BTS will ship you an NTAD CD free. It may be "ordered" at zero cost from the BTS web site. Several of the data sets on the Manifold downloads site come from the NTAD. BTS also provides free streets for the entire US in the form of their "DynaMap" street series (vintage 2000).

CIESIN

http://www.ciesin.org - The Center for International Earth Science Information Network at Columbia University: see their Data Resources page for links to the archive of Census related products (detailed demographic data), fundamental GIS layers for China, world population data and more.

International GIS Data Sources

National Imagery and Mapping Agency

http://www.nima.mil - The primary source for public domain international data. See notes in the table above. Just how much data NIMA will continue to provide in a "high security" environment is still open to question.

Bureau of Transportation Statistics

http://www.bts.gov - Provides transportation GIS layers for Canada and Mexico as part of its North American Atlas Database (NORTAD) free CD.

Geobase

http://www.geobase.ca - A new Canadian site providing a wide array of Canadian data, including Administrative Boundaries, Canadian Digital Elevation Data (CDED) Canadian Geodetic Network, Geographical Names of Canada, Landsat-7 images and the Canadian National Road Network (NRN).

Geogratings

http://geogratis.cgdi.gc.ca - Cool Canadian data from Natural Resources Canada for free download, plus links to other free data sites. Includes the National Atlas of Canada.

NASA

NASA is beginning to put large amounts of data online for free download. For example, virtually complete Landsat imagery for the entire Earth in MrSID format (easily
converted into Manifold images) is at:

https://zulu.ssc.nasa.gov/mrsid/

NOAA GLOBE

The Global Land One-km Base Elevation (GLOBE) project provides the latest, most modern, public domain terrain elevation database for the entire world. Currently at http://www.ngdc.noaa.gov/seg/topo/globeget.shtml, the data set may be downloaded in 16 "tiles," most of which are very large files (over 100MB each) when unzipped. Import using the DEM GLOBE Files (*.*) setting in File - Import - Surface.

State Cartographic Bureaucracies

When all else fails and you cannot find your data for free or by trading with colleagues online, the last resort is to purchase it from the local cartographic bureaucracy. For example, the Ordnance Survey (OS) in the UK is the authorized state cartographic monopoly that sells data for the UK. The data is quite good, but because the OS is such an ineptly run bureaucracy it will cost you perhaps 100 times more than an efficiently run organization would charge.

Other resources

If you can find it online in one of the common GIS interchange formats (.shp, .mid/.mif, .e00) it's almost certain you can read it in Manifold. Many vendors provide GIS data for free without restrictions.

Commercial Sources

Although the emphasis on the above is on free data sources, there are many fine companies providing GIS data for a fee. Such companies often begin with government data for a particular region and then enhance it by reorganizing the data into more user-friendly form, correcting mistakes, updating the data and so on.

Creating Your Own Data

Always keep in mind the possibility of creating your own data sets. This may be required for some international users if commercial or government data is not available. There are several methods to create a custom map:

Acquire GPS data points

Manifold includes a connection to GPS devices controlled by the GPS Console. For small regions such as ranches and farms it's remarkably easy to create a map by driving or walking boundaries with a GPS device connected to a laptop running Manifold. GPS data points can be used to mark control points used to georegister aerial photographs.

Scan a paper map

Although almost all modern maps are created digitally, many maps still exist in paper form. This is especially true of historical maps. One can scan a paper map as an image and then georegister it using control points that appear in digital maps that map be obtained. Scanned maps can be used as images (slow and inefficient) or converted into drawings using tracing.

Scan a printed photograph

Printed photographs may be scanned and georegistered like scanned paper maps. Many libraries have archives of aerial photographs that can be scanned. Modern flatbed scanners are very light and are easy to carry into a library together with a notebook computer for scanning.
of materials that are not allowed to circulate outside the library.

**Image Servers**

Overhead satellite photography for much of the world is now available in very high resolution at no charge for many applications using a new generation of image servers like TerraServer, those used by NASA WorldWind, Yahoo!, Google Earth and Virtual Earth. The Manifold image server interface enables fast and easy use of many image server modules within Manifold. Users can easily create their own digital maps of roads and other features by rapidly clicking over an image server background.

**Custom aerial photography**

Custom aerial photography ranges from inexpensive to very expensive custom work. Most GIS purposes can be accomplished with inexpensive, ad hoc aerial photography. Visit a local airport near the area of interest and hire a pilot and a Cessna for an hour. Shoot a roll of film (or use a quality digital camera) from a suitable altitude on a clear day and many images will be very useful once scanned. Georegister them using control points. **Tip:** Crack open the door a bit and shoot down through the crack so no glass is between the camera and the scene. Search the web for other aerial photography tips.

**Custom satellite photography**

Stock satellite photographs with two-meter resolution will frequently sell for under $100. Custom satellite photography from commercial operators is occasionally available for under $500 an image if the satellite viewing swath traverses the target area. Prices will no doubt come down as the amount of stock photography and satellite competition increases.

**Tables as Sources of GIS Data**

Much data is published as tables in various forms that can be used in GIS work even though the tables are not geocoded. A good example is the **Counties** series of data sets published by the Census Bureau on CDs with titles like **Counties 1999** or the **City and County Databook**. Such data sets are collections of tables, often in .dbf dBase II format.

A typical table might consist of records of demographic data for each county where each record has the county **FIPS** (Federal Information Processing Standard) numeric code identifying the county together with other data fields. We can use such tables in Manifold if we first import a drawing that shows counties that also has a **FIPS** code field for each county. We can then form a relation between the drawing’s table and whatever table was imported from the demographic data set. This same technique can be applied to use tabular data in many different types of GIS work.

Tables may also appear in electronic documents using non-database formats. For example, one might encounter a PDF file containing a table, an HTML web site page showing a table or a Microsoft Word .doc file that contains a table. The experienced user will learn Windows techniques for transforming such data into a format that can be read as a table by Manifold.

For example, we might highlight some tabular text in a PDF file, paste it into a Microsoft Word document and the use Word to convert the text into a real table. We could then “clean it up” if need be in Word and save it either as an HTML document containing a single table or write it out as a .csv (“Comma Separated Values”) text file. Sometimes clever use of search and replace to convert tabs to commas or other character manipulations within Word will help us create the table we desire for import into Manifold.

**Notes**

Respect copyright laws: It is important to become familiar with the copyright laws that apply in your jurisdiction. Knowing the law will help you avoid accidentally ripping someone off, and it will also prevent unscrupulous data providers from ripping you off as well.

Web sites change constantly. The URL’s mentioned above or the availability of the data sets described may have changed since the publication of this document.
A Call to Arms

When living in a free society it is easy to become complacent about one's freedoms and rights. If you live in the United States you have a right to get and to use public data, but that right will disappear if you are not vigilant about maintaining it. Even as Internet makes it easier and cheaper than ever for agencies to provide public access to public data, some agencies are using Internet to make it more difficult to get access to public data.

A recent trend, for example, is for many state and federal web sites to present only PDF files or web-served images of data instead of the real data themselves in some publicly accessible GIS format such as .shp. Even in cases where the law requires delivery of public data in an open, non-proprietary format, some agencies will deliver data only in a proprietary format, such as "MrSID".sid format, that cannot be accessed through genuinely public means. This game can be played in a very devious manner.

For example, a common misconception is that .sid format is OK to use for public data because the makers of the format at Lizardtech (an appropriately reptilian name) provide a "free viewer" which can display the data and export it to open formats such as GeoTIFF. However, if you try to acquire and to use that "free viewer" you'll find that it is a licensed, proprietary tool which requires users to agree with Lizardtech's grossly objectionable legal positions as a legal requirement of using the tool. It is a bit like justifying illegal restrictions on your right to vote by saying that they are not a factor if you sign an agreement saying that you can vote, but only on the condition that you agree your voting rights can be taken away at will.

Whenever you run across a web site that provides access to only images of the data or which uses proprietary formats, take a moment to email the people affiliated with that web site to ask them how you can get access to the real data or to data in non-proprietary form. In the case of proprietary formats, explain to them the data is not in non-proprietary form if you must agree to objectionable, proprietary legal requirements to view it or to translate it into open form. If the real data is not available, encourage them to post links that allow download of the actual data. If they refuse, ask them to whom in their agency a Freedom of Information Act (FOIA) request should be addressed to get the data. Most states have a statute equivalent to the FOIA that allows you to get access to public data whether the agency likes it or not.

Some agencies mean well: they know that GIS usually costs many thousands of dollars per license so they put effort into providing images in the belief that the public cannot afford to work with the real data. Bring them up to date: tell them that Manifold makes it possible to work with the most sophisticated data to as great a degree of sophistication as one chooses at prices no higher than ordinary Microsoft Office applications. The more sophisticated the data is, the more important it is that users be able to work with it as real data.

See the Public Access to Public Data essay for a rant in support of public access to government data.
Performance Tips

Manifold includes many capabilities previously found only on software that costs tens of thousands of dollars per license. That the software includes such sophisticated capabilities does not imply that any personal computer, no matter how limited or slow, will be able to adequately support use of such capabilities. In particular, work with large images will require lots of RAM and a fast processor. The thousands of dollars we save by purchasing Manifold can be invested into more RAM and more powerful processors that can serve us in other applications as well.

Most Manifold projects using vector drawings on modern computers will operate so fast that thinking about performance is not necessary. When working with large projects or large images, though, we may want to squeeze every bit of performance out of our systems. The following tips will help you achieve the greatest possible performance on your desktop when working with large maps. Many of these suggestions are generic suggestions that will help you create and operate the fastest Windows system possible.

Important Configuration Notice

Very Important: Before starting Manifold, go to the Windows Control Panel Display dialog Effects tab and make sure that the Show window contents while dragging check box is not checked.

- In Windows XP this option is found in the Control Panel's Appearances and Themes - Display choice under the Appearance tab by pressing the Effects button.
- In Windows XP or Windows 2003, from the Start button open the Control panel and then open the Display dialog. Click on the Appearances tab and then press the Effects button. Uncheck the Show window contents while dragging check box.
- In Windows 2000, Windows ME and Windows 98 open the Control panel and then open the Display dialog. Click on the Effects tab, and uncheck the Show window contents while dragging check box.
- In Windows Vista, open the Control Panel and click Appearance and Personalization. Click Customize colors, then click Open classic appearance properties for more color options and click the Effects button. Uncheck the Show window contents while dragging check box.

Checking this box will greatly slow down the system when displaying complex maps and images because it forces a refresh of the window contents with each minor change in mouse position while dragging the window. Make sure the box is unchecked.

Hardware

- Install lots of RAM memory, enough to maintain your entire project in RAM memory if possible. It does no good to have a fast processor if the fast processor is waiting around for virtual memory to be paged back in from hard disk. Don't forget to include RAM required by Windows and background processes. Memory is very inexpensive, so install as many gigabytes as you can. On newer systems, install as much as you can afford, using four gigabytes if you plan on working with large projects or multiple Manifold instances. RAM has become very inexpensive: a few hundred dollars can buy massive amounts of RAM, multiple gigabytes.
- Since 64-bit Manifold can make use of far larger amounts of RAM than 32-bit Manifold, it makes all the more sense to install lots of RAM (3 GB, 4 GB or more if possible) and / or increase the size of the Windows pagefile.
- Install a fast processor. If your budget allows a choice between substantially more RAM or a slightly faster processor, get more RAM and a slightly slower processor. If you are working with very large images and surfaces that will not fit into RAM, then it is more important to install a significantly faster processor and a really fast disk drive.
- Install a 64-bit Intel or AMD processor, preferably a quad core or dual core processor. Modern multi core processors run very, very fast and will offload some tasks at a price that is barely more than charged for single-core 32 bit processors. They are remarkably inexpensive for the speed and quality they give. Shop around and often you'll find motherboard and very fast multi core, 64-bit processor combos for $300 or less.
- Use multiprocessor machines or multi-core processors. Each new release of Manifold adds more functions that are multi-threaded. For example, Manifold will use more than one thread to render image libraries if more than one processor or processor core is available on the computer system. Therefore, image libraries will render faster on multiprocessor or on multi-core processor systems such as those using a quad-core or dual-core Intel or AMD processor.
- Use a modern motherboard with performance features. For example as of this writing some motherboards support full-bandwidth SLI for multiple graphics cards, RAID SATA and can accept 8 GB of RAM. Nice! Extremists may want to try out the over-clocking features available with modern
motherboards, cool their CPUs with water-cooling and other tricks. See the gaming sites for tips and tricks on maxing out motherboard performance.

- Install an NVIDIA GPU card supported by NVIDIA CUDA. Manifold can use CUDA to dramatically accelerate certain tasks. CUDA-enabled NVIDIA GPUs are so ubiquitous that no matter what your budget you can probably get a CUDA-enabled system for no additional cost. Whatever system you buy will have graphics capability in any event, so you may as well procure NVIDIA-based capability that can also dramatically increase performance through CUDA.

- Install a very large disk drive. Large disk drives are faster than smaller drives, because the average access time given is calculated over a larger capacity. It's better to install a larger, reasonably fast drive than a smaller drive that promises extra-fast transfer. Better still, get enough memory to never have to hit disk. An additional bonus to a large disk is that if you have 300 gigabytes of free space you will not hesitate to save interim versions of a project. Frequently saving projects is cheap insurance against undoable user errors and other time wasters.

- Get a fast hard disk, spinning at 7200 RPM or faster and using ATA100 or more recent interface such as SATA. This is especially important if you will work with large images or drawings, which will involve a lot of disk accesses.

- Install a second or third hard disk, so you can keep your Windows page file on a separate disk volume. If your entire job does not fit into available RAM Windows will have to swap it out to disk. Swapping often occurs at the same time that other disk accesses need to be made. With two disk drives in play Windows can launch the heads on one disk drive for read/write operations for swapping at the same time that the heads on the other drive are moving into position for other read/write operations, thus reducing the average access time. This is less important if you have lots of RAM, but as inexpensive as RAM has become disks can be even cheaper: it can be very inexpensive (under $50) to add a second, small, fast hard disk to host the Windows page file. An ideal situation is to have three disk drives, one for the page file, one for TEMP files and one for ordinary working files.

- Think twice before buying SCSI. It's often faster to use the latest generation SATA drives and to spend the money saved over SCSI on larger drives and more drives (for independent action when using page files and temp files). Keep your system page file, TEMP folder and user profile directories on a drive separate from your working files.

- Consider installing multiple disks in a striped RAID configuration for maximum disk throughput. For very large images and surfaces this might not be such an expensive option as it sounds, since large, fast hard disks can now be had for $100 each or less. Whether or not it is faster to use striped RAID than it is to use multiple hard disks for different Windows folders and page files is often a toss-up. Most technical users at manifold.net use striped RAID arrays when they want maximum speed because that requires less thought.

- For 3D terrain windows get a fast graphics card with OpenGL support in hardware and lots of local graphics memory. These are now very cheap, with supercomputer-class GPUs and 256 MB of RAM being sold in graphics cards for as little as $100. It is critically important to use good drivers. Quite often the fastest drivers for your version of Windows will be supplied by the chip vendor who makes the graphics chip in your graphics card. This can make the difference between smooth “fly through” motion and very jerky, a-few-seconds-per-frame motion in terrain views. Manifold requires a functioning OpenGL subsystem to display terrains. If there are no OpenGL capabilities in the system terrain windows will be blank when opened. See the discussion in the Terrains topic.

- For maximum terrain viewing performance, use SLI-capable nVidia PCI Express graphics cards in an SLI-capable motherboard to team multiple graphics cards for rendering. Prices on graphics cards are dropping rapidly: as of this writing, installing two high-end, SLI-capable nVidia graphics cards with 256 MB of RAM each costs a total of $250, an amazing deal for the resultant throughput. It is often faster to use two cards via SLI than it is to spend disproportionately more money for a single card that uses the very latest, super-hot graphics chip. For example, two SLI cards using slightly downrev, but still awesome chips might be had for $150 each and the combination could end up being as fast as or faster than the latest superchip board at $750 each. Of course, if money is no object, get two of the latest boards!

- Use a large video display with high resolution. Larger, high-resolution displays will allow you to keep more panes, toolbars and windows open at the same time. Work goes faster when all controls are in sight. If you are stuck with a small screen or low resolution, learn to use the ALT-SHIFT keyboard shortcuts to rapidly open and close panes. See the Windows topic for tips on keyboard shortcuts.

- Get a flat panel LCD display that accepts DVI direct digital video input and install a graphics card with DVI output. The direct digital connection will drive the LCD flat panel at superb clarity and crispness to reduce eyestrain and fatigue, allowing you to work longer and more effectively.

- Use a wheel mouse with additional buttons like the Microsoft Intellimouse. The additional controls can be very useful for navigating within windows.

**Operating System and Other Software**

- **Very important:** Go to the Windows Control Panel Display dialog Effects tab and make sure that the **Show window contents while dragging** check box is not checked. Checking this box will greatly slow down the system when displaying complex maps and images.
Use any version of Windows 7, Windows Server 2008, Windows Server 2003 or Windows XP. More recent Windows editions provide much better utilization of large memory than do Windows Me or Windows 98. Vista is great, truly superb, but it is not at the present writing as fast as XP.

Use a 64-bit processor and install an x64 Windows version such as Windows 7 x64, Windows Server 2008 x64, Windows Vista x64, Windows XP x64 or Windows Server 2003 x64. Run 64-bit Manifold x64 editions.

Install the latest updates and service packs for the software you are using. Windows, DBMS vendors and others spend billions of dollars on improving the quality and performance of their software by issuing updates, often free updates. Take advantage of that.

Use NTFS for the file system. Do not use FAT or FAT32 (FAT file systems have serious drawbacks in terms of security, safety and performance).

Avoid creating many partitions. Ideally, set up one partition for the entire drive C:.

Set up a fixed-size Windows page file that is far larger than ever will be necessary, several gigabytes or larger in the case of projects involving very large images. This is faster than a dynamically re-sized page file. In Windows 2000 open System in the Control Panel. In the Advanced tab click Performance Options and under Virtual memory click Change. Set the Initial size the same as the Maximum size. In Windows XP, open System in the Control Panel, then in the Advanced tab’s Performance section click Settings. In the resulting Performance Options dialog’s Advanced tab’s Virtual Memory section click Change and then set the Initial size the same as the Maximum size. In both cases the size should be very large, over 2000 MB if possible.

Allow a large enough page file for multiple instances of Manifold if you will be launching more than one instance of Manifold and copying and pasting between them. More than 2.5 gigabytes per Manifold instance is not necessary.

Install the latest version of Internet Explorer. IE installs fresh versions of Windows system facilities such as VBScript and JScript scripting engines, the XML parser and other facilities that are used by Manifold. As newer versions of IE install faster and better facilities, your Manifold installation will also become faster and better.

Avoid running other applications in background.

Minimize the use of memory-resident services. Keep only absolutely vital services on the traybar. The only program sitting on traybars at manifold.net is a readout for system time. A few systems have a volume control icon and some systems have an icon indicating the status of a local SQL Server or Oracle DBMS server. Compare that to the collection of seven or eight icons often seen in traybars when many intrusive, memory-resident consumer applications have been installed.

**Very important:** Do not operate a virus checker in real-time scanning mode. Instead, schedule a regular weekly or nightly virus check. Real-time virus scanning will have a serious impact on system performance because the virus scanner will analyze all of the many temp files created by Manifold in the normal course of work. This tip is especially important when working with large images or surfaces.

When running WinAmp, Windows Media Player or other audio players at the same time as Manifold, switch off visualization modes to reduce processing overhead. Switch off the equalizer or effects as well if you need every processor cycle. If you do not have enough RAM to avoid frequent paging to disk, run your audio playlist over your local network using a different machine as a disk server to avoid tying up the local disk.

If you have multiple hard disks, keep your TEMP directory and page file on one disk and your applications and .map files on a different disk. When working with very large images and surfaces it helps to keep the TEMP directory and system page file on physically separate hard disks. This allows the disk drive heads to seek independently from each other as various files are used. This is less of a factor if you have so much RAM that disk accesses are minimized, and more of a factor when working with large projects that don’t fit into RAM.

When working with server-based OLE DB providers such as SQL Server or Oracle, users are strongly encouraged to maintain primary keys in all tables linked into the Manifold project. A side effect of how such servers interact through OLE DB is that if the table does not have a primary key, performance will be greatly reduced.

Use ADO .NET to connect to DBMS servers instead of ODBC or OLE DB. Use the native Oracle Call Interface (OCI) when connecting to Oracle.

If you have installed a CUDA-capable NVIDIA graphics engine, make sure you also install the CUDA libraries so that Manifold can take advantage of the graphics engine to accelerate computation. CUDA libraries are a built in part of NVIDIA-supplied GeForce drivers, but might not be a part of default Windows drivers. Install the latest drivers from NVIDIA to be sure.

Learn how to operate and administer Windows proficiently. Use a good Internet search engine (such as google.com) to find web sites that teach how to tune your Windows system for maximum performance. If your Windows system is tuned for faster operation then applications that run within Windows, such as Manifold System, will also be able to run faster. Simple Windows maintenance such as defragmenting hard disk storage can result in noticeable improvement in Windows performance.

**Manifold System**
Run 64-bit x64 editions of Manifold System within 64-bit x64 Windows.

Turn on the **Render data progressively** option in the Tools - Options dialog (on by default). This allows the system to be responsive while large drawings, themes, images and surfaces are rendered in stages. Quite often we are rendering a drawing simply to orient ourselves with the attention of zooming in to some smaller region, so being able to begin the zoom command before the drawing has finished rendering is a big time saver. When a component is small enough to render very quickly, progressive rendering will not be noticed because the component will be rendered in a single pass. **Note:** Lengthy operations such as some transforms automatically suspend progressive rendering and resume it upon completion, so that the system does not lose time rendering what might be obsolete data.

Re-project drawings, images, and surfaces into the same projection specified in maps that use these drawings, images and surfaces. All projection parameters must be the same for this to help and not just the name of the projection in use. This is critically important when working with very large images and surfaces. If this is not done then everything from displaying maps in their own window or displaying a layout that includes the map can end up being very slow.

If a map will consist of a large image (or surface) and several drawings in a different projection, create the map using the image and then add the drawing layers. The map will then use the same projection as the image. Large images and surfaces are much slower to re-project on the fly than are drawings, so it is faster for the map to use the same projection and to re-project the drawings for display than the other way around. When working with large images, it is critically important to use the projection of the image for any maps that contain that image.

Turn off any layers you don't need to see in a map.

Close any unnecessary map, drawing, or image windows. Every window that is open will need to be redisplayed on any changes.

When doing analytic work that does not need much visual interaction, use smaller map windows and zoom far into the map so relatively few objects are on screen. The fewer objects that are visible, the fewer need to be computed for rendering and redrawn.

**Uncheck View - Refresh Auto** so no refreshes occur unless you command them with **Refresh**.

Don't use high-resolution data when you will zoom out to levels where the details blur together. Resample the data with Normalize Topology (for drawings) using a lower Location Precision value to create a lower resolution equivalent that makes sense at the zoom level you need. For example, don't use high-resolution shoreline data if the map will show an entire world at once. The details will not be visible on screen, but Manifold will still need to re-compute the display based on a huge level of detail. Working with lower resolution data will also make many commands, such as Dissolve, operate much faster. Many drawings, such as those destined for thematic presentation, can be made ten times less complex/smaller without any objectionable visual effects.

Don't use raster images when drawings are more accurate, faster, and provide more information content. See the Images can be Inefficient essay.

When working with images stored in "lossy" formats such as .jpeg, resample (resize) the image down to the level of resolution truly kept with the .jpeg compression. Expanding the compressed image to a large size with many pixels in X and Y is a mirage, because the detail for high resolution has already been lost. You may as well enjoy the faster speed obtained by using an image at pixel resolution commensurate with the true image information it actually contains.

If you only need to work with part of a large data set, take a moment to cut that part out as a separate drawing or image or terrain and then work with only the necessary part.

**Uncheck the Preview box in image commands with large images if you don't need to see a preview.**

RGBa images are larger and take more time to display than ordinary RGB images. Don't use RGBa images unless you need to use RGBa pixel transparency, or if ordinary invisible pixels within an RGB image can do the job.

Use Zoom Ranges to present the level of detail required - Suppose we would like to show a national map for user orientation when zoomed out but we would also like to show very detailed shorelines when users zoom in. Create a map using two drawings: a highly detailed drawing plus a second, low resolution drawing created from the first by generalizing with Normalize Topology to a lower Location Precision value. Assign zoom ranges to the drawings so that the low-resolution drawing is the only drawing displayed when zoomed out and the high-resolution drawing is the only drawing displayed when zoomed in. When users browse the map in a zoomed out view the display will be fast because a fewer number of coordinates need be used to display the low-resolution drawing. When users are zoomed in the high-resolution drawing will become visible; however, only a portion of the high-resolution drawing will be seen in a zoomed in view so the display will still be fast.

Store the .map file used on a fast, local hard disk - When Manifold operates it accesses the .map file and any temp files created. If the .map file is located on a slow hard disk or on a different machine that must be accessed via a local area network then performance will not be as fast as if the .map file was immediately available on a local, fast hard disk. If you have a very fast network and fast servers this effect might not be significant.

When importing drawings, don't import data fields that will never be used. Many data fields will slow the system down. If a drawing has been imported with superfluous data fields, edit tables using Design to eliminate the unnecessary fields. When working with commands such as Dissolve, check the Transfer box in image commands with large images if you don't need to see a preview. RGBa images are larger and take more time to display than ordinary RGB images. Don't use RGBa images unless you need to use RGBa pixel transparency, or if ordinary invisible pixels within an RGB image can do the job.
Rules for the tables being used to make sure that no fields are being transferred that are not necessary to transfer.

- Uncheck the **Compress .map files to save space** option in Tools - Options to eliminate .map file compression. This will result in larger .map files on hard disk, but saving .map files and opening .map files usually will be a much faster process. Oddly enough, if a project includes very large images or surfaces and you have a very fast processor, it may be faster to use compression because the time to fetch and decompress a smaller sized file may be shorter than the time required to fetch a larger, uncompressed file.

- Always acquire and install the latest edition of Manifold System or the latest Service Pack. Each new build of Manifold System includes optimizations and other improvements. Some optimizations will result in dramatically faster performance in the functions that have been optimized.

- When working with large images and surfaces, keep the image or surface stored in a Manifold .map file. When a large image or surface is opened for the first time after it is imported Manifold will build a series of intermediate views that are used for faster panning and zooming at less than full resolution. Building these intermediate views takes time, so the first time a large image or surface is displayed the window will open very slowly. After that, viewing will be fast. If the image or surface is stored in a .map file, the intermediate views will be stored in the .map file as well (as a built-in part of the saved image or surface). Opening an image or surface already saved in a .map is therefore fast even the very first time the image or surface is opened.

- When working with large images, if they need only to be viewed in a read-only way, consider storing them as compressed images so they load and display nearly instantly.

- Store large images within a fast DBMS server such as DB2, MySQL, Oracle, PostgreSQL or SQL Server.

- Complex queries take longer to accomplish than simple queries. A SELECT clause with some simple computations in the WHERE clause will scale linearly; that is, handling 100,000 records will take about 10 times longer than handling 10,000 records. A SELECT with a GROUP BY or ORDER BY clause will scale slightly worse, perhaps using n log n scaling where handling 100,000 records may take, for example, 12 times longer than handling 10,000 records. Joined SELECTs with spatial computations may scale even worse.

- When re-projecting using the **Clip coordinates** option, make sure to read and take heed of the notes at the end of the Orthographic topic.

- Use native tables instead of linking tables. Tables within the Manifold project are the fastest, shared tables (with caching turned on) from an Enterprise server will be slightly slower and linked tables from an external DBMS provider are the slowest. Retrieving data from a table linked to a fast external data source will take at least 10 times as long as retrieving the same data from a table inside the Manifold project.

- DBMS software other than SQL Server may not always favor OLE DB over ODBC. Some databases have slow OLE DB drivers and fast ODBC drivers, and other databases (like SQL Server) have fast OLE DB drivers and slow ODBC drivers. The performance of an ADO.NET provider might or might not be better than OLE DB or ODBC drivers, depending on whether the provider is entirely implemented in managed code or not and on a multitude of other factors.

- When using external DBMS tables, use the fastest connection possible, which may vary depending on the DBMS in use. For example, when connecting to Microsoft's SQL Server, ADO.NET is faster than OLE DB and OLE DB is faster than ODBC. ADO.NET is **much** faster than ODBC. Consider that connecting to a remote SQL Server can take much longer than connecting to a local SQL Server. For example, suppose that connecting to a table inside the Manifold project takes 1 unit of time. A very rough guide to equivalent times to access the same table using different connection and DBMS technologies is listed in the accompanying table. Clearly, it is very unwise to connect to remote SQL Server installations using ODBC. **Important**: Tables linked from ADO.NET data sources are always read-only. If read-only access is acceptable, ADO.NET is often the fastest possible connection and should be used in preference to ODBC or OLE DB for that reason.

Introduction

- There is no performance difference between storing geometry in external tables (linked drawings) or internal geometry, once external geometry is refreshed. Refreshing geometry from an external table will likely take as much time as it takes to run a fairly modest SELECT query, with the external data source being the bottleneck.
- When querying external tables, running a Manifold query analyzes the entire table and fetches each record from the server, so it might sometimes be faster to reduce the number of records to be analyzed with a server query. The performance gain will depend on the relative complexity of the server query compared to the Manifold query. The more records that can be trimmed on the server side, the better the performance. Transforming data on the server (as opposed to trimming the number of records) will not gain anything.

The User

- Read the documentation and learn as much as you can so you are always using optimal methods.
- Take a few minutes to think about a task before launching into it. There are often many different paths to the same end within Manifold. A good plan will help you choose the best path and avoid unnecessary work.
- Don't fall into the trap of making projects more complicated than they need to be. Most GIS projects follow the 80 / 20 rule, where 80% of the desired result comes from 20% of the implementation effort. Do that 20% first and then try it out. You might find that you are happy with the result.
- Try to find a pre-existing data set that provides what you need before you invest time into building your own. Some people waste weeks of time digitizing raster scans to get a local map without realizing they could download 1:24,000-scale SDTS maps from USGS that provide the same thing for free.
- Try to find the data you need in modern formats that automatically convey all necessary information in a user-friendly way. Dealing with improperly used antique formats like shapefiles or non-GIS formats like DXF can be a huge waste of time if you can find the same data in a modern format allows instant, automatic usage. See Projections and Legacy Formats for a discussion of hassles that can be avoided.
- Become expert at using image servers to fetch satellite imagery on demand.
- Save your work regularly in separate projects so you never have to waste time redoing an entire project after a system crash or undoable user error at some stage.
- Memorize keyboard shortcuts and use them in combination with mouse moves. For example, experts will keep the left hand on the keyboard for CTRL-C and CTRL-V to Copy and Paste while the right hand moves the mouse to select items and manipulate windows and other mouse-based controls. The ALT-SHIFT keyboard shortcuts used to open and close Manifold panes are especially important if you have a small screen. See the Windows topic for tips on keyboard shortcuts.
- Learn to write scripts. Automating a task so that it takes care of itself while you are at lunch or at home is a wonderful time saver. At times a very simple script can replace a long sequence of commands using pre-built tools. When scripting, write the simplest code that works and use it. Write scripts so their internal functioning is obvious and include plenty of comments to boot. The objective is simplicity and maintainability.
- Sometimes you may be called upon to do a job under time pressure. The more time pressure you feel to complete a project, the more important it is to work systematically, steadily and carefully. Don't panic. Take it step by step in a steady pace. If you are short on time you don't have time for errors. Measure twice, cut once.
- Get plenty of sleep and exercise regularly. Fatigue causes errors and panic. Good health will help you think clearly and execute with authority.

People are sometimes amused that we include the user as part of our performance tips. However, the greatest gains in performance are usually achieved by using a better method or algorithm. More often than not the sole factor in whether a better method is used is the expertise and clarity of mind that can be mustered by the user. A healthy, well-rested, expert user is the best performance accelerator around.

General Education

Manifold works with many standard Microsoft facilities and products as well as with other industry standard products. Here are some examples drawn from many such features:

- Built into Manifold are the standard dialogs we would use to connect to data sources using ADO .NET, OLE DB and other such connection technologies.
- The Manifold Internet Map Server works with standard Microsoft Internet web serving technologies such as Internet Information Server (IIS), ASP and ASP .NET.
- We can write scripts in Manifold using standard Microsoft .NET languages or ActiveX scripting languages.
We can use standard Structured Query Language (SQL) to write queries.

Manifold can work with database products like SQL Server or Oracle.

One of Manifold's great strengths is exactly that Manifold uses a wide variety of industry standard products and technologies. Doing so makes it possible for people to apply in a familiar way within Manifold the expertise they have already acquired through the use of standard Microsoft products, and it also makes it possible for Manifold applications to leverage the power and flexibility of many other products and technologies in an industry-standard way.

However, this documentation does not teach such industry-standard products and technologies: it is assumed that if users want to employ such things they either already know how to use them or they have the ability to take advantage of the vast number of publications, web pages and training products that already exist for such industry standard products and technologies. There is no point in duplicating within this documentation those educational and support resources that already exist to a much greater degree.

Therefore, if we want to use a technology such as ADO .NET or ASP .NET or SQL Server we can certainly do so with Manifold. But if we don't know enough about such technologies to use them we should browse the web or go to our local high tech book store and buy one of the hundreds of books that teach the use of such technologies and then dig in and learn how to do so. Part of the point of using such technologies is exactly that they are already very well documented in a huge selection of publications.

Another benefit to using such standard technologies is that if we are unfamiliar with them and then have to learn about them to use them with Microsoft the education we invest into ourselves is not restricted to just Manifold. Learning about something like SQL Server or Oracle or ADO .NET will be useful knowledge in the many thousands of other applications that use such standard things.

**Systems**

Manifold is developed on Intel and AMD processors with average performance and not on unusually powerful machines. Most development is done using Windows Vista, Windows XP and Windows Server 2003. Faster machines are deliberately avoided to force a conservative perspective into development for core system functions. Given enough RAM for the task, required performance with almost any reasonably contemporary systems will be acceptable and performance on better than average systems will be stellar.

As processor speeds continue to improve performance on state-of-the-art machines will become dazzlingly fast. Machines with 4 to 8 gigabytes of RAM, many hundreds of gigabytes of disk drives, 64-bit quad core processors and CUDA-enabled nVidia graphics engines with over 100 stream processors have become very affordable. RAM, in particular, has become almost dirt cheap so there is no excuse for not equipping one's machine with gigabytes of RAM.

See the essay on Using RAM and other Machine Resources for the Manifold "spin" on this topic.

**Very Large Jobs**

No matter how fast Manifold can operate it will always be possible to ask Manifold to perform a task that will take a very long time to accomplish. Some jobs can seem to take an unreasonably long time if, without realizing it, we have suddenly increased the amount of data involved as compared to previous tasks.

Raster data and images can involve dramatically greater work for what appears to be a small increase in image size because the data in images increases as the square of any increase in height and width of the image. An image that's 40% larger takes 100% more work to manipulate. An image that is twice as big will take four times the work. For raster data such as DEMs it is easy to forget that scaling up from a 100 x 100 image to a 1000 x 1000 image will end up requiring 100 times as much work. What used to take one second can take 100 seconds with the larger image.

Many networking and geometric problems involve geometric growth in computation requirements. What appears to be a small increase in the problem can increase computation time from seconds to days. For example, growing the size of a road network so that it covers an entire state instead of a few counties could lead to a tenfold increase in the height or width of the map. The additional area of the map can easily add 100 times as many road nodes and links and thus lead to a million-fold increase in computation time for certain complex network tasks.

When performing computations that grow geometrically it is important to increase the size of the task in small steps. Begin by verifying your procedure with a very small subset of the data and then increase the size of the
problem in small steps so you can see where asymptotic growth in computation requirements begins. Note also that increasing the size of jobs will likely also place greater demands on system RAM.

As memory requirements increase, at some point a machine will run out of available RAM and begin paging to disk. At that point processing will become profoundly slower. See the Using RAM and other Machine Resources essay for why. To avoid this effect, use a machine that is better scaled to the task at hand or reduce the size of the job to what will fit into the machine being used. It is unrealistic to expect a machine with 128MB of RAM to be able to process large tasks as efficiently as one equipped with 8GB of RAM.

Some specialized tasks with large maps will take days to accomplish. People worldwide launch such jobs every day with Manifold using a spare machine that is left "cooking" for a few days to accomplish a desired task. They're happy because such things used to require weeks with older software or hardware. Run some experiments before launching such large jobs so you know what to expect.

Memory and Large Files

When Manifold opens a very large .map file not all of the contents of the .map are brought into memory at once. Components will be brought into memory as needed from the .map file stored on disk. Once they are in memory accesses will occur faster than in the initial usage since, of course, RAM memory is thousands of times faster than hard disk.

The advantage of having lots of RAM in a computer is that Windows editions such as Windows XP or Windows 2000 will leave items in memory until the memory is needed for something else by Windows. If we have ample RAM, as we work with a project the various components will end up in RAM and will stay there. This effect is especially pronounced with x64 Windows editions, which can actually work with large amounts of RAM effectively.

If you do not have enough RAM to run projects in memory, no matter how fast a processor you have you will have much less performance if the system begins paging to disk. That is why RAM is more important than processor speed until you have enough RAM so you never have to page to disk.

Notes

By mentioning certain brands we don't mean to imply anything negative about other brands. At this writing, the current generation of machines being installed at manifold.net use nVIDIA graphics engines and mostly Intel processors. nVIDIA has done a super job of writing good code for Windows and creating innovations like CUDA, which currently provides the fastest general-purpose processing around.

However, Intel and AMD's ATI divisions continue to be a major power in processors and no doubt will respond to nVIDIA's competitive stimulus with advances of their own. Likewise, we expect that NVIDIA's masterful driver work will inspire other processor vendors to pay better attention to writing effective drivers. Leadership positions in CPUs and graphics engines can change overnight, and often have.

From a software perspective, we love seeing the processor and graphics vendors work harder to offer more performance at lower price!

See Also

See the Memory Requirements topic for RAM and hard disk memory requirements.

See the Limitations topic for general notes on Manifold limitations when operated in various Windows systems.
Memory Requirements

Your computer's memory includes Random Access Memory (RAM) and hard disk memory. Manifold System uses both types of memory together with the Windows operating system and any other applications that may be running at the same time. Regardless of the amount of RAM or free hard disk space available, there are certain fundamental limits that cannot be exceeded:

- No single image or surface can exceed 16 EB (exabytes) in size. Since one exabyte is $2^{64}$ bytes, about a trillion gigabytes, as a practical matter there is no size limit for images and surfaces. One will run out of disk space billions of times sooner than the size limit is approached.
- In 32-bit Manifold editions, for components other than images or surfaces (drawings, scripts, tables, labels, comments), no single component can exceed 4 GB (gigabytes) in size. Projects are not limited in size, but no single component of these types in the project can exceed 4 GB. In 64-bit Manifold editions, no single component can exceed 16 terabytes in size.

The intrinsic limits on images, surfaces and other components are so large that they will likely exceed the processing capacity and disk storage capacity of most machines in common use.

Use x64 Windows and x64 Manifold Editions

This is so important it is worth saying right up front: 32-bit Windows editions are crippled by an inability to use more than a relatively small amount of RAM. RAM has become so inexpensive that there is virtually no excuse not to have several gigabytes, at least 4 GB, of RAM in your computer. However, to use that RAM effectively you must be running x64 Windows and x64 Manifold. x64 Windows is more reliable and runs much faster and enables use of x64 Manifold, which runs much faster than 32-bit editions of Manifold.

Hard Disk Free Space Requirements

There are four demands for hard disk free space made by Manifold:

- **Project files** - There must be enough free space on hard disk for the size of project (either compressed or uncompressed) when it is saved as a `.map` file. Obviously, if we have only 500MB of free space on disk we will not be able to save a `.map` file that is 1 gigabyte in size.

- **TEMP files** - When Manifold opens a `.map` file it creates one or more temporary copies in the Windows TEMP folder to allow abandoning edits (that is, to close a project without saving any changes), to enable operation of Undo and for other purposes. Such temporary files can temporarily require four times the size of the project in uncompressed form. Thus, to work with a 1 gigabyte project in all circumstances we should allow at least four gigabytes of free space on hard disk.

- **System paging file** - Microsoft Windows automatically uses virtual memory by swapping processes out to a hard disk file called the system paging file or pagefile. If we have only 512MB of RAM but want to run applications that require 1.5 gigabytes or RAM, Windows will automatically swap parts of the executing processes back and forth between RAM and the paging file so that at any one instant only 512 MB of RAM is used. There must be enough free space on hard disk for as large a pagefile as is necessary for Manifold and any other applications that are running.

Some users have multiple disk drives or have organized a single disk drive as multiple volumes. Make sure you have enough free space on all disk drive volumes involved if the project files, TEMP files and paging file are on different disk volumes. For example, a user might think there are tens of gigabytes of free space available on an E: disk volume where project files are kept without realizing that there is no free space on the C: disk volume where the Windows TEMP files and paging file might be kept.

- **Cache files** - If you work with linked images from OGC WMS servers or TerraServer, Manifold by default will cache images and parts of images. **Caution:** Cache files persist forever and, in extreme cases, use up your free disk space unless they are manually deleted. See the recommended actions in the Managing Cache Files topic.

RAM and Virtual Memory Requirements

For performance reasons it makes sense to have as much RAM as possible and to use x64 Windows and x64 Manifold so you can take advantage of that RAM. It is a good idea to have somewhat more RAM than the maximum project size to allow RAM for Windows and for other applications that may be running in background.
To work with large projects, one must have a system pagefile that can expand to as large a size as is necessary and the free disk space available to host large pagefiles if need be. In addition, it is critically important to have enough free disk space for all TEMP files that must be created by Manifold.

**Very Important:** When working with large projects make sure to set your Windows use of virtual memory appropriately. Some editions of Windows, such as Windows XP x64, will set a maximum pagefile size that is too small by default. Drill down through the Control Panel - System applet's Advanced settings to change the maximum pagefile size to four or five times the largest project you will need to use. For example, if you will be working with 10 GB projects set the pagefile size to 50 GB.

Geometric computations and many other functions use virtual memory for temporary computational requirements. Such virtual memory will be automatically switched by Windows between RAM and disk but can never exceed 2 GB in 32-bit Windows editions. This requirement for internal computational storage space means that while components and projects can be very large, the temporary storage space limitation of 2 GB may prevent some computational operations from proceeding to completion with very large data sets. For example, when creating buffer zones each buffer zone must be able to fit into Windows virtual memory. Running the Buffers transform operator on a drawing therefore will not work unless the buffers to be created will require substantially less than 2 GB for the buffer zone objects.

Although 2 gigabytes, of course, is enough for an immensely large number of buffer zone objects it may not be enough for, say, creating a buffer zone around every object in a 3 or 4 gigabyte drawing. In such cases, divide up the job into smaller parts and perform each in turn.

Users working with 32-bit Windows should keep in mind that the 2 GB process space will not all be available for a particular task. If you are using a 32-bit edition of Manifold, the Manifold process can only use 2 GB of memory. Some of that memory is spent on system services as well as Manifold services such as the window system. This can leave only about 1 GB of memory for tasks such as Normalize Topology or running the Buffers transform operator.

Memory usage patterns vary greatly between various algorithms used within Manifold, but a lack of memory can be encountered if an algorithm has used up some memory (for example, 500 MB) and wants more (for example, 1000 MB), but the system can not provide it. Thus, a times a lack of memory error can occur even though the amount of memory in actual use is well below the limit.

The way to avoid such difficulties is to utilize 64-bit Windows with x64 Manifold editions and to install plenty of RAM. x64 Manifold editions can use 16 Terabytes of memory, the same as can be addressed in 64-bit Windows.

**Saving and Loading Projects**

Manifold will often encounter peak demands for memory when opening or saving a project because it is at that time when reserve copies of projects are being made or are being utilized to allow abandonment of imports or exports or edits, or to Undo operations. When operating with limited amounts of free disk space it is possible for disk space requirements to exceed the amount of free space that is available on disk.

Free hard disk space available might change between the time a project is saved and when later it is opened. For example, we may have created a very large project and saved it and then later used up free space on our hard disk so that little or no free space is available. In such cases we might not be able to open large projects that were previously saved because we no longer have sufficient free space on disk for the TEMP files that must be created when the project is opened.

**Reducing Memory Usage**

When Manifold performs various operations it may need to use memory (either RAM memory or temporary files on disk) to allow Undo or abandonment of the project when exiting without saving changes. Saving the project will free memory that has been occupied by changes made since the last File - Open or File - New operation. Such savings can be very important when working with large amounts of data.

In addition to the suggestions in the Performance Tips topic, reducing the amount of data in tables can reduce memory requirements. At the very least, make sure to convert fixed-length text columns to variable-length text columns. Another space-saving option would be to store data in a linked table (say, within SQL Server) and to map the columns from the linked table to a drawing's table via relations.

**A Note on .map File Compression**
Saving .map project files in compressed form will save a lot of space on disk for routine storage of .map files. However, it does not save any space in TEMP file usage or other memory requirements because all operational work is done on the uncompressed data. The relatively small size of compressed .map files may catch users unaware as their files expand, possibly by a factor of ten, into operational use.

For example, a compressed .map file may be 200 MB, but it could easily expand by a factor of seven when uncompressed into a 1.4 gigabyte project. A 1.4 gigabyte project could require almost six gigabytes of free space on disk for temp files. If we planned on needing only 800MB of free disk space based on the compressed size of the project, we might think we had plenty of free disk space if we had four gigabytes free space available. However, that would be too little to deal with a project of this size once it is uncompressed and in active use.

**Tech Tip**

If for any reason (such as an electrical power failure) you crash Windows or crash Manifold by attempting to work with very large projects without enough free disk space you could end up with some large files in your Windows TEMP folder. Delete these before continuing work so that you do not waste disk space on unnecessary TEMP files.

**See Also**

See the Performance Tips topic for general advice to squeeze the most performance and capacity from your computer system.

Manifold System is designed to take advantage of modern computer systems, which often feature lots of inexpensive memory. See the Using RAM and other Machine Resources essay for information on the technical tradeoffs between using RAM and other resources.

See the Limitations topic for general notes on Manifold limitations when operated in various Windows systems.
Managing Cache Files

When downloading image information for linked images created from OGC WMS image servers, Manifold Image Servers or from TerraServer servers, Manifold provides a cache data option (on by default) to cache image files that are fetched on local hard disk. To prevent cache files from growing without limit, users must clean out old cache files from time to time.

The Cache data option is important because it keeps a copy of the linked image in local disk cache. If this option is on, the next time we open a project containing a linked image, Manifold will be able to use the copy of the image saved in the local disk cache and will not have to go through the process of downloading the image again. The data cache will persist across sessions and projects so that once a tile is downloaded it will not have to be downloaded again. If we have a large hard disk with many gigabytes of storage available we can cache large numbers of large images.

The location of the cache folder is at whatever location is specified in the Data Cache item in the Tools - Options - File Locations dialog, with WMS cache files being stored in a series of subfolders and TerraServer cache files being stored in a TerraServer subfolder. The default value for the data cache location is %MyDocuments%, so by default each user's files will be stored in the user's own cache folder.

When multiple users are working it might make sense to modify the default Data Cache setting for each user so the cache folder location is the same for all users and is on a shared resource available from all machines on the local network. For example, if there is a machine called Storage on our local network with a Cache folder on its C: drive, we might use a Data Cache setting of \Storage\Cache for all users. In that case, any tile files that are retrieved by one user will be available to all users so that tile files for a given view will never have to be fetched twice over the network. This assumes, of course, that the network is fast enough so that use of cache over the network will not be too slow.

It is also important when working with large linked images that the location specified for the cache is on a disk drive with plenty of free space. Users sometimes will ask for download of very large linked images without thinking about how large the resultant image may be and thus end up inadvertently requesting immensely large data sets.

The data cache folder may be moved to a different location so long as the path specified in the Data Cache option is adjusted to point to the new location.

Cleaning Out Old Cache Files

Cache files persist forever until they are manually deleted. Manifold will not clean out cache files or automatically delete older cache files because cache files may be in use by multiple users if they are in shared storage. To avoid running out of free disk space, users should manually delete unnecessary cache files from time to time.

To delete unnecessary cache files, using Windows Explorer browse over to the location specified in Tools - Options - File Locations for data cache files. Set Windows Explorer so it shows file details, including the date each file was last modified and then right click on the Modified column in Windows Explorer to sort the files by the date of their last modification. Delete those files that haven’t been used for a long time to free up disk space.

Using the Manifold ODBC Driver

Installing Manifold automatically installs the Manifold ODBC driver that allows other applications to access tables and queries in Manifold .map project files. Manifold's ODBC driver includes support for OGC clients. Linked and shared components (components used in Enterprise Edition) are handled transparently. The driver uses the internal Manifold SQL engine and supports intrinsic columns as well as spatial, geocoding and other extensions available within the main system.

The Manifold ODBC driver operates in read-only mode and has been tested to work with various versions of Microsoft Office applications such as Access and Excel, the Microsoft OLE DB Provider for ODBC, a wealth of various development tools and utilities and, of course, Manifold System itself. The Manifold ODBC driver supports optional ODBC functionality required by MFC clients as well as optional ODBC functionality required by the latest editions of Visual Studio.

The Manifold ODBC driver may be used in Microsoft Office data sources. This makes it possible to have a .map file that includes a table linked from another .map file.

Note that because the Manifold ODBC driver is read-only, the integrity checking features of Access aimed at doing consistent updates are not supported when Access connects to a .map file through the Manifold ODBC driver.

Configuring a Data Source

The first time Manifold is launched it will automatically install the Manifold ODBC driver. This will add the driver to the Drivers tab of the Data Sources (ODBC) Control Panel applet (located under Administrative Tools in Windows 2000 and Windows XP).

To add a data source, go to the User DSN page within the Data Sources (ODBC) applet and click Add. Select the Manifold Project Driver and click Finish.

In the Manifold ODBC Driver dialog type the name to use for the data source, for example, “My Manifold Connection” and select the .map file to be used for the database. Choose the options desired:

- **Name**: The name by which we want this connection to be known.
- **Database**: The name of the .map file to be used.
- **ANSI-compatible queries**: Use ANSI syntax for queries executed against this data source.
- **Translate Unicode data to ANSI**: Convert Unicode text to ANSI text on the fly. Checked by default. Required for use with applications that do not support Unicode columns.
- **Expose data for OGC SQL clients**: Expose WFS for SQL used by OGC clients.

Click OK. We can now use the created data source from within other applications. We can also use it within Manifold’s own Data Source dialog. We can also add data sources using the ODBC applet’s System DSN and File DSN pages if desired.

To configure an existing data source, locate it within the Data Sources (ODBC) applet and click Configure. We can then make changes, such as changing the path to the .map file or changing the status of the Translate Unicode data to ANSI option and click OK to accept changes.

To remove an existing data source, locate it within the Data Sources (ODBC) applet and click Remove.
Components linked into an Enterprise Edition project are said to be **shared components**. Shared components may be **cached** or **uncached**, as described in the Cached and Uncached Components topic. When working with the Manifold ODBC driver from another application, keep in mind the following two rules:

- The Manifold ODBC driver works only on machines on which Manifold is installed. For example, if machine A has Manifold installed but machine B does not have Manifold currently installed, then an application running on machine A will be able to work with Manifold .map files on either machine A or machine B using the ODBC driver. However, it will not be possible for an application on machine B to work with .map project files stored on either machine A or machine B.
- The license status of the local Manifold installation specifies the degree to which the ODBC driver can access uncached Enterprise server components. For example, if machine A has Manifold Enterprise Edition installed and machine B has Professional Edition installed then machine B will not be able to access uncached shared components stored in .map files on machine A.

Accessing a .map file containing shared components from the Manifold ODBC driver is analogous to accessing the .map file from a local Manifold System application on this machine. The Manifold ODBC driver works by utilizing the facilities of whatever Manifold System program has been installed on the machine so the ODBC driver has the same capabilities as running Manifold System interactively on that machine.

Shared components that are cached may be accessed like all other components. Shared components that are uncached will be transparently fetched from the Enterprise server or will appear empty depending on whether the machine has an Enterprise Edition license. If the machine has an Enterprise Edition license and the Get latest versions of shared components after opening file option is on for the current user, loading the .map file through the Manifold ODBC driver will also fetch the latest version of shared components that are cached.

**OpenGIS Interaction**

The Manifold ODBC driver includes an **Expose data for OpenGIS clients** option that makes the ODBC driver mimic an OpenGIS data source. When the option is turned on, the ODBC driver creates several virtual tables for each drawing in the MAP file on which it is launched so that OpenGIS-aware clients can link to them. By default, the option is turned off.

This option is especially useful for OpenGIS clients that can consume OpenGIS data via SQL, such as TatukGIS. OpenGIS users may also be interested in reading the **WKB** information in the Geometry in Tables topic.
Command Line Options

Manifold provides several command line options when launching Manifold from a command line:

/activate:serial,key  Activate Manifold System.

/activate:<invalid serial>  Pop open the Activation dialog when an invalid serial number is supplied with the /activate option.
Example:

manifold.exe /activate:dialog

will launch the Activation dialog since "dialog" is not a valid serial number.

/activateExt:serial,key  Activate an extension.

/autoexec:<scriptname> <mapfile>  Run the specified script after opening the MAP file specified.

/cfilter:<path>  Launch Manifold using a command filter.

/clist:<textfile>  Dumps the names of all commands available for user interface scripting using the InvokeCommand method of the UserInterface object into a text file. Example:

manifold.exe /clist:file.txt

/logquerytime  Logs the running time of queries into the History pane.

/logrenderingtime  Logs rendering time for component windows into the History pane.

/logscripttime  Logs execution time of scripts into the History pane.

/logtransformtime  Logs time for drawing, image, surface and table Transform Toolbar operations into the History pane. Also logs execution time for the Surface - Transform dialog, spatial overlays and topology overlays in addition to Transform Toolbar operations.

/slist:<textfile>  Dumps the names of all formatting styles available for areas, labels, lines and points into a text file. Example:

manifold.exe /slist:file.txt

The examples shown above for /clist and /slist options will create the specified file.txt file in the same folder as the manifold.exe file, the installation folder used for Manifold.

Those examples will not work in Windows Vista if Manifold has been installed in the default installation folder within the C:\Program Files hierarchy, because Vista in general does not allow writing to such folders by default by ordinary user logins.

In such cases specify a file location that is known to be writeable by the login in use. For example, if we have a folder called C:\tmp that we know is writeable we could use

manifold.exe /slist:C:\tmp\file.txt

Command Customization

Manifold may be customized to control what commands and menu items are available using command filters.
Launching Manifold with the /cfilter:<path> option starts Manifold using a command filter. For example, entering the following at the Windows command prompt (within the installation folder for Manifold) or within a batch file will launch Manifold using a command filter:

```
manifold.exe /cfilter:\myfiles\customizations\mymanifold.xml
```

The above will use the mymanifold.xml command filter file located in the \myfiles\customizations\ folder. See the Command Filters topic for details.

### Scripting

Manifold provides sophisticated scripting to extend the capabilities of the program.

The /autoexec:<scriptname> <mapfile> command line switch allows running a script after opening the MAP file specified in the same command line. For example, the following command line will open the mymap.map project file and then run the myscript script found in that project file.

```
manifold.exe /autoexec:myscript c:\MyProjects\mymap.map
```

See the Scripts topic for details on scripting. See the User Interface Scripting topic for a quick and easy interactive method of discovering command names usable when scripting the user interface.

### Activation

Manifold includes a security system for license authentication that is described in the Activation Keys and Serial Numbers topic. See that topic for a discussion of command line options for activation.

### Formatting

New releases of Manifold may introduce new formatting styles. The /slist command line option provides a handy way for programmers to get a comprehensive list of all area, label, line and point styles available and their names.

### Technical Note

Strictly speaking, it is possible even in Vista to run commands of the form:

```
manifold.exe /slist:file.txt
```

Launching the command prompt window using the Run As Administrator command will allow writing to C:\Program Files even in Windows Vista. If the path to the Manifold installation folder is cited in the PATH variable, the above command can be executed in the context of any folder. However, this is a Vista nuance not related to Manifold so to avoid problems for users who do not have access to Administrator passwords this topic offers the advice to use folders that are known to be explicitly writeable by using commands of the form:

```
manifold.exe /slist:C:\tmp\file.txt
```

For Experienced GIS Users

This topic introduces Manifold to experienced GIS users. It assumes you have a lot of experience working with previous Manifold, ESRI or MapInfo GIS products.

This topic provides a brief survey of Manifold that may allow GIS experts to more efficiently digest the rest of the documentation. After reading this topic, experts should continue to read other topics, even introductory ones, in the suggested order, beginning with the Introduction.

The minimum amount of reading, even for experts, is to read all of the topics in the Introduction chapter as well as all of the topics in the Examples chapter at the end of the Help file. Manifold does many things different than older GIS packages, so even if you know GIS very well do not skip the introductory reading.

Manifold Editions

There are several versions of Manifold System available for licensing as well as optional extensions. Manifold System versions include:

- **Personal Edition** - Includes almost Manifold System features in this documentation, except the Internet Map Server, Database Administrator Edition features and Enterprise Edition features.
- **Professional Edition** - Adds the Manifold Internet Map Server (IMS).
- **Enterprise Edition** - Adds centralized document-oriented storage of components within Enterprise database servers. Adds direct support for object-level storage in Oracle Spatial databases as well as Oracle GeoRaster support. Enterprise Edition also eliminates the requirement for a Manifold logoype in IMS pages and provides the ability to save to .e00 format. See the discussion in the Data Storage Strategies topic for various server storage options available to Enterprise Edition users.
- **Universal Edition** is a product configuration that contains an Enterprise Edition license plus Business Tools, Geocoding Tools and Surface Tools licenses.
- **Database Administrator Edition** is a version of Enterprise Edition that includes the Administrator Console and the Batch Export tool and is intended for use by DBMS administrators. It is used to configure database systems for use with Manifold System when saving drawings or other data in the DBMS to enable concurrent multi-user editing. Administrator Console enables use of friendly names, formatting and other features that once set up via Administrator Console can be used in ordinary Enterprise Edition licenses. Larger Manifold installations will employ mostly Enterprise Edition or Universal Edition licenses for users and will have a few Database Administrator Edition licenses for use by IT managers and DBMS administrators.
- **Manifold System License Server** gives organizations the ability to maintain an inventory of floating Manifold licenses that may be used by any client computer that can connect to the License Server, all without needing to use serial numbers and Activation keys for individual client licenses. License Server provides the economy of floating licenses as well as greatly reduced administrative overhead for organizations that deploy many hundreds or thousands of Manifold licenses.

The Business Tools package is an optional extension to Manifold System that provides additional commands for working with drawings. The extension adds functionality in several areas:

- **Districts (Advanced)** - Redistricting using a condensed, expert level dialog.
- **Districts (Visual)** - Redistricting via an easy-to-use visual, interactive dialog.
- **Drive-Time Zones** - Computation of drive-time zones via an easy-to-use, interactive dialog.
- **Optimal Route** - Finding an optimal route to designated locations using a condensed, expert level dialog.
- **Optimal Route (Visual)** - Finding an optimal route to designated locations via an easy-to-use, interactive dialog.
- **Send Email** - Automatically send email to map objects. Used to send spatially-targeted email.
- **Topology Factory** - An interactive dialog to view and repair common topological errors in drawings.
- **Expanded programmatic access to routing and other functions.**

If you do not have the optional Business Tools package enabled you will not have the above capabilities enabled within Manifold System.
The Geocoding Tools package is an optional extension to Manifold System that provides street address geocoding capability as well as access to the Manifold Geocoding Database data provided on the Manifold downloads site for both US street address geocoding as well as the easy creation of drawings showing US streets. The extension adds functionality in several areas:

- Street address geocoding within the United States using the Manifold Geocoding Database provided on the Manifold downloads site.
- Street address geocoding within North America or Europe using the appropriate edition of Microsoft's MapPoint product as a data source.
- Street address geocoding anywhere in the world using user-provided geocoding data extensions in either range or points of interest formats.
- Street address geocoding using web-based Manifold geocoding servers to provide geocoding services.
- Easy import of drawings showing US streets from the Manifold Geocoding Database provided on the Manifold downloads site as set forth in the Import Drawing - Geocoding Database topic.
- Geocoding Extensions may be used within SQL to allow use of street address geocoding functions within SQL queries.
- Programming objects such as the Geocoder object may be used from scripts or other programs or from within IMS applications.
- Street addresses and ZIP codes may be used in the Edit - Go To dialog.

If you do not have the optional Geocoding Tools package enabled you will not have the above capabilities enabled within Manifold System.

The Surface Tools package is an optional extension to Manifold System that provides additional commands for working with surfaces. The extension adds functionality in several areas:

- The Surface - Transform command dialog allows arbitrary transformation of surfaces, including computations that involve multiple surfaces such as subtracting one surface from another. A very rich collection of operators allows many different types of tasks to be accomplished.
- The Surface - Watersheds command works with a surface and optionally a drawing to find watersheds in the surface (regions sharing a common drainage) as well as streams in the surface or upstream areas in the surface from points in a specified drawing.
- The Transfer Heights command enables rapid transfer of surface values from surfaces to points.
- The Visible Area command shows areas that are visible from given points. The height of viewing points may be automatically adjusted from a height field.
- New options in surface generation allow creating surfaces from drawings and tables using Gravity interpolation, Median-Polish Kriging and triangulation. See the Project Pane - Paste as Surface topic.
- Expanded model choices for Kriging interpolation include Linear, Power, Rational and automatic model choices.
- New transform toolbar operators for interpolation of missing pixels, Interpolate, Interpolate (Parameter) and Interpolate Row.
- Surface Tools adds the ability to work with new Profiles and Elevations components that show cross-sectional cuts through a given path over a surface.
- Expanded programmatic access to surface operations.

If you do not have the optional Surface Tools package enabled you will not have the above capabilities enabled within Manifold System.

This documentation is written so that it may be used with all editions of Manifold System and with all options. Topics that are unique to a particular edition or option are so marked.

Manifold is Different

Manifold's user interface is significantly different from ESRI or other traditional GIS products. Manifold's user interface is based primarily on Microsoft style as well as user interface standards that are prevalent in professional quality, mass-market applications. Using a more widespread interface style opens GIS to many more people who are already familiar with mainstream applications like Microsoft Office.
Although the user interface is different, experienced GIS people will be able to re-cycle a lot of conceptual ideas. For example, the experienced reader knows what a projection is and that projected coordinates are linear measures, not degrees. Please, however, do not let this general familiarity with the subject matter mislead you into attempting to use the product without reading the documentation.

Even if you consider yourself to be a Windows power user, please read the Windows topic. This describes key Windows and Manifold power moves. It’s wise to learn keyboard shortcuts for opening and closing panes, and to learn how to hot scroll.

Manifold makes heavy use of Copy and Paste As to convert information into different forms. For example, we Copy a geocoded table and then Paste As a drawing to create a drawing from the geocoded table. Labels components are created that show fields by copying a drawing and pasting it as a labels component. Images may be pasted as tables. Please take time to review the Copy and Paste As topic for more on this essential method.

Note: If you’ve Pasted something into a drawing and don’t see it, try Zoom to Fit to make sure it is not outside the window at the current zoom and pan setting.

Terminology

Manifold uses mass-market terminology to refer to points, lines and areas. This is what most of the world’s mathematics and computer community uses. Some traditional GIS packages, such as ESRI’s, use different terms:

<table>
<thead>
<tr>
<th>Manifold</th>
<th>ESRI</th>
</tr>
</thead>
<tbody>
<tr>
<td>Areas</td>
<td>Polygons</td>
</tr>
<tr>
<td>Lines</td>
<td>Arcs</td>
</tr>
<tr>
<td>Points</td>
<td>Points</td>
</tr>
<tr>
<td>Surface</td>
<td>Grid</td>
</tr>
</tbody>
</table>

The above are non-trivial differences in terminology that affect GIS users everywhere due to the prevalence of ESRI terminology and its effect on traditional GIS nomenclature. See the essay titled Terminology in GIS for why Manifold uses the more popular terms. Manifold also replaces some traditional GIS words with words that are more prevalent in computing:

<table>
<thead>
<tr>
<th>Manifold</th>
<th>Traditional</th>
</tr>
</thead>
<tbody>
<tr>
<td>Image</td>
<td>Raster data</td>
</tr>
<tr>
<td>Drawing</td>
<td>Vector data</td>
</tr>
<tr>
<td>Tracing</td>
<td>Vectorization</td>
</tr>
<tr>
<td>Coordinate</td>
<td>Inflection point, or Node</td>
</tr>
<tr>
<td>Network</td>
<td>Graph</td>
</tr>
<tr>
<td>Node</td>
<td>Vertex</td>
</tr>
<tr>
<td>Link</td>
<td>Edge, or Arc</td>
</tr>
</tbody>
</table>

Manifold follows accepted modern network terminology so that the English language versions of Manifold use the word “network” instead of “graph,” “nodes” instead of “vertices” and “links” to mean the connections between nodes in a network.

Although in casual usage most GIS systems refer to the files they produce as “maps”, Manifold uses this word to refer to a specific type of component that contains other components in layers and which may be re-projected on the fly. Manifold uses the word “drawing” to refer to a vector item and “image” to refer to a raster item.
Manifold uses the word theme in a somewhat different way than ESRI. In Manifold, a **theme** is a project component that shows a drawing with the formatting specified by the theme. A drawing can have many different themes, each of which shows the same drawing using different formatting.

**Advice to ArcInfo Users**

Manifold takes a different structural approach than ArcInfo that requires some conceptual adjustment. Unlike older GIS packages, Manifold does not build topological relationships into the data set: rather, topological relationships are computed on the fly as needed. There is no need for users to worry about maintaining topology within drawings and maps in the low-level way that was done earlier. Manifold will do this for you automatically.

Years ago when computers were weak it made good sense to embed topological relationships into the data sets themselves. In modern times it is better to compute topology on the fly. Doing so uses the intelligence of the machine to free the user from having to worry about low-level structural details. It allows us to mix points, lines and areas in the same drawing and to move objects about interactively with great freedom.

We ask ArcInfo users to approach Manifold without worrying about the details of how something is done internally and to just take it on faith that Manifold will compute topological relationships correctly when needed. We suggest a focus on the higher levels of function while learning the system.

For ArcInfo users who would like to experiment with more familiar topology methods within Manifold, the Traditional Topology Tools optional add-in may be downloaded from the [manifold.net web site](http://www.manifold.net). This add-in provides operations using stored topology.

**Accuracy**

Manifold maintains all geographic geometric information using double-precision floating-point numbers. This provides accuracy better than 1/250,000,000 of a meter (literally, less than a two hundred fifty millionth of a meter) at the Equator.

If you do not need very high accuracy, you can increase the speed of many operations by reducing the location precision of a drawing using the View - Properties dialog.

**Files and Project Organization**

Manifold's documents are **projects**, which are saved in a .map file. Projects consist of **components** like drawings (vector data like ESRI shape files), images (raster data, like a GeoTIFF), surfaces (typically, terrain elevation data like a DEM), tables (data attributes for drawings or simply independent database tables) and other items. Create a new project with File - New.

The project is a single Manifold .map file. The project .map file by default contains in one file all of the vector, raster and other data imported into the project. Keeping everything in one file makes it easy to keep track of what's in a project and to share it with other users. Send them the .map file and they have everything.

There are, however, many circumstances when users would like to keep some data outside of a project. We can accomplish that in Manifold by using **linked** or **shared** components. **Linked components** include:

- Linked tables and queries - tables or queries can be either imported into the project or they can be left as external tables or queries that are dynamically linked into the project.
- Linked drawings - drawings can be linked into a project from external data sources, either from geometry columns in tables or queries or from geocoded tables.
- Linked images - images can be linked into a project from compressed image formats, from external databases or from a variety of image servers.

**Shared components** are components saved in a Manifold Enterprise Server and used within an Enterprise Edition project. Enterprise Edition allows saving components within Enterprise servers set up within a database server, which may then be linked into user projects on different machines. Enterprise Edition allows control over whether shared components are cached or not cached. If they are not cached, they will take up no space in the local project but rather will be stored only on the Enterprise server.
See the discussion in the Data Storage Strategies topic for an overview of local, shared or server data storage options available to Manifold users.

In the addition to the above, Manifold supports sophisticated storage of data in enterprise-class databases such as Oracle Spatial. Manifold can use Oracle Spatial, IBM DB2 with Spatial Extender, PostgreSQL / PostGIS or Microsoft's SQL Server 2008 (Katmai) with native spatial DBMS functionality.

In addition, Manifold can confer true spatial DBMS functionality unto almost any DBMS, such as MySQL or regular SQL Server Express. When using generic Manifold spatial DBMS capability, Manifold can store not only drawings but also images and surfaces into the spatial DBMS.

Manifold's extensive abilities to work with external DBMS packages sometimes fools people into thinking that Manifold requires some external DBMS to function. That's not true, as Manifolds' own .map project files provide efficient file-based storage. A Manifold .map project file can store all components of a Manifold project, including images, surfaces, drawings, labels, scripts, comments, queries and other components.

Some people think it is wasteful to import everything into a single file. In an era of nearly free hard disk storage it's no big deal and greatly simplifies exchanging maps: no more scrounging around to see if you remembered all the files you need to make your map. People who disagree are always free to use linked components or Enterprise Edition so that all components can be stored on a centralized Enterprise server.

Except for the case of linked drawings linked from external data sources like Oracle Spatial databases or other geometry types, Manifold does not edit external files "on the fly" in their native formats. For example, we don't open a shapefile in Manifold and then edit it. Instead, we import the shapefile into one or more Manifold drawings, do what we want, and then if we are cursed with having to use shapefiles we can always export the drawing out to shapefile format again.

The reason Manifold does not edit shapefiles or similar formats "in place" is that such formats are too primitive to support the full range of Manifold functions. Editing such files within the limits of what the format can support would require dumbing down Manifold functions or otherwise restricting the Manifold user interface to no more than can be accomplished with such primitive formats. That doesn't make sense: instead, it is better to use the full facilities of Manifold as desired and then, upon export, explicitly do whatever dumbing down is required to fit the target format.

**Note:** The three-letter .map file extension may be used by other applications on your computer. When you install Manifold it will automatically tell Windows to open .map files with Manifold. If you would prefer to retain the assignment of files ending in .map to some other application, in Windows Explorer right click on a .map file and choose Open with and then Choose Program. Choose the program you wish to use to open .map files and check the box Always use this program to open these files and press OK.

**Basic Steps to Running Manifold**

- Launch Manifold and note that the project pane is open (it is by default and can be toggled on/off with SHIFT-ALT-P).
- Import the drawings to be used. ESRI users will import .shp or .e00 files, for example. When importing from .shp you may need to set the datum manually, since shapefiles do not save projection info. See the Import a Shapefile example.
- To show drawings in layers, create a map that contains those drawings as layers.
- To change colors or otherwise format, click on the layer to be formatted and change settings in the format toolbar. If you would like to show a drawing using different formats, use a theme to do so.
- To print something, either use File - Print for casual printing or create a layout for more sophisticated printing and then print the layout.

**Importing Files**

Import vector data into drawings or raster data into images by clicking File - Import. There are importers for every GIS and raster image format in common use as well as lots of uncommon formats. If there is a format you need that is not currently supported send a note to sales@manifold.net so we can consider adding it to the release in a Service Pack.

Whenever a drawing is imported from a GIS format like MapInfo .mid/.mif or ESRI .shp that has both geometric data and data attributes in the format, both a drawing and an associated table will be automatically created.
Please read the specific importer topic for the file format you are importing within the Import and Export section to see how Manifold handles details for your format.

This topic mentions “drawings and images” as a shorthand way of referring to typical components. Other components are surfaces and labels components. However, since “drawings, surfaces, images or labels” is a bit much we shorten the phrase at times.

**Importing Projected Drawings, Surfaces or Images**

Manifold automatically will import projection information from those GIS formats that save it. When importing projected drawings or other components from formats that do not save projection information, we will have to provide the missing information manually.

As an experienced GIS user, you know it is a bad idea to save projected data in legacy formats like AutoCAD .dx or ESRI .shp because such formats as commonly used do not save the projection parameters that are necessary to make sense of the data. If you encounter projected data saved in such formats, keep an eye out for any accompanying documentation that describes the projection parameters used.

To import projected data from a legacy format:

1. Import the drawing, image or surface using File - Import. Use default settings.
2. Open the component thus created.
3. Use the Edit - Assign Projection dialog to specify the projection information that should be used.

The Edit - Assign Projection dialog allows us to manually provide the correct projection information into the coordinates properties. Manifold will then be able to make sense of the data just imported.

Do not confuse the use of a chosen projection view in a map window (via the Edit - Assign Projection dialog) with the use of Edit - Assign Projection in a drawing window to specify projection information missing from legacy formats. If a projected drawing is imported from, say, .shp format and you fail to tell Manifold the correct projection to use, that drawing has not yet been correctly imported. Subsequent use of the drawing in maps may cause bizarre effects or lengthy delays as the system attempts to compute a new projection for the map based on fundamentally inaccurate coordinates.

**Default Use of Orthographic**

Every drawing and image in Manifold exists in some geographic context. This is so even if we intend to use Manifold as a CAD or image editor to work with drawings and images in non-geographic contexts. By default, files such as .dx that are not in latitude / longitude degrees are imported as if each unit was equivalent to one meter. The scale factor can be changed during import or at any time afterwards. The file is imported into Orthographic projection and positioned with its lower left corner at the intersection of the Equator and Prime Meridian (zero longitude and zero latitude).

When importing images from geographically mute formats such as .jpeg or .bmp the image is automatically georeferenced to the (0,0) lat/lon origin using Orthographic projection as well. Manifold is so accurate that each pixel of a 4800 DPI image can have its own distinct lat/lon geographic location. Of course, if an image originates in a geographically aware format such as GeoTIFF it will automatically be georeferenced to the correct location. Images may be georegistered using drawings or other images that are already georegistered.

**Re-Projecting a Component**

We can permanently change the native projection of drawings, images, surfaces, or labels by opening the component and then using the Edit - Change Projection dialog to change the projection. See the Edit - Change Projection topic.

**Very Important:** Be careful not to use the Edit - Assign Projection dialog to attempt to change an existing projection. The Assign Projection dialog is used when importing projected data from legacy formats such as .dx or .shp, to specify the projection that is to be used. To change the projection of a component use the Edit - Change Projection dialog.

**Maps**
A special type of component is a map. A map shows drawings, images, surfaces and labels components in layers. After importing the various drawings and images we need into the project we create a new map by using **File - Create - Map** to add it to the project. The **File - Create - Map** dialog will offer up a list of components we can include in the map.

Double click on a component in the project pane to open it in its own window. When we first open a map we'll see it uses the projection of one of the components used to create it. When a map is first created, it will use the projection of the largest image or surface used to create it. If there are no surfaces or images in the map, the map will be created using one of the projections of the drawings it contains. At any time we can change the projection used by the map, although it makes sense to use the projection of one of the large components in the map to avoid any performance loss resulting from the need to re-project components on the fly.

Use **Edit - Assign Projection** to specify what projection the map should use. Maps can use whatever projection we like even if the drawings and images they contain use different native projections. Changing the projection used by a map does not change any data or the native projection used by any drawings or images the map contains. Projections shown by a map are computed "on the fly" without any change in the original data. We can change them however often we like without any decrease in accuracy.

There are two ways to change the projection used by a map:

- Use the **Edit - Assign Projection** dialog to set any projection
- If we want the map to use the native projection used by one of the components it contains, right click on that component's layer tab and choose **Use Projection** from the context menu that pops up.

Add drawings, images or labels components to a map by dragging and dropping them from the project pane into an open map window.

Control layers in a map by either dragging layer tabs in the map window or by using the **View - Panes - Layers** pane. Right click onto layer tabs for useful context menus. The Layers pane is much more useful than the layer tabs when there are many layers in a map. Each layer is a different drawing or image. Individual layers may be set to a desired layer opacity from the layers pane.

We can open as many windows into a map as we like. Each window is an independent view with its own pan and zoom.

**Creating New, Blank Components**

If at all possible, click open the map in which a new, blank component is to be used before creating that component. That will assure the new component is created using projection parameters that are a good match to the map.

The **File - Create** menu will add a "blank" component to the project. If a drawing, image, labels or map window is open when the **File - Create** menu is used, the projection of the window that is open will be used to create the new component.

The **File - Create** dialog takes the projection parameters for the new component from whatever window is active at the time the new component is created. If the project pane is active, the component will be created using the system default projection of Orthographic centered at the 0,0 world latitude/longitude origin. If a map window or other component window is active when the new component is created, the new component will be created using whatever projection is used by that active window. This context-sensitive setting of default projection parameters makes it much easier to create new components using projection parameters that are hassle-free by default.

When creating new, blank components to use as layers in maps it therefore makes sense to click open the map and to have it the active window when the **File - Create** command is invoked. This will automatically create the new component with projection parameters that match those in use in the map. This is a very important step to assure easy compatibility between the projections of newly created components and the map.

Another way to create blank components is with a right-click on a map's layer tabs and choosing **Add** to create a new component and add it as a layer to the map.

**Projections and Performance**
Maps re-project drawings and images on the fly into whatever projection is desired of the map. That can be a computationally intensive process when maps include many different images and drawings as layers and when the various drawings and images use different native projections. Maps can work much faster if the projection they use is the same as that used by the images and drawings they contain because then there is no need to re-project on the fly.

If we will be using drawings and images within the same map using the same projection it makes sense to re-project the drawings and images into the projection we use in the map. This is especially true if the map contains big images.

**Drawings and Images**

We can open any drawing, surface or image in its own window by double clicking on the component in the project pane. Drawings, surfaces and images opened in their own windows are shown using whatever native projection they use. If we wish to change the native projection used by a component we use the Edit - Change Projection dialog to change it. This is a permanent change in the structure of the data.

If desired we can use Manifold as a pure CAD editor or as a pure image editor (like PhotoShop) without worrying about any geographic contexts. When we import drawings or images from non-geographic formats such as .dxf or .jpeg they automatically are brought into Manifold as Orthographic projections georeferenced to the (0,0) world lat/lon origin.

For CAD work, we can combine CAD drawings with each other in multiple layers in a "map" just like AutoCAD allows use of multiple layers. For general-purpose image editing like Adobe PhotoShop we can combine images in layers in a map as well. If we switch the status bar read out from lat/lon to X.Y coordinate readout the "map" window will look just like any CAD editor's or photo editor's main workspace window. We'd never know that on a theoretical basis these drawings and images exist just off the coast of Africa or that technically they are in a projection. Remember, even at the thousandths of an inch resolution implied by 4800 DPI scanned images there is no difference over a few meters between an Orthographic projection and an unprojected coordinate system.

That every drawing and image are georegistered to some geographic default has no downside even if we never intend to use them in a geographic context. However, when it comes time to georegister an image or a CAD drawing (like a factory plan blueprint) it is very convenient that they are already georegistered to some default projection and location. Georegistering an image, for example, becomes a simple matter of moving it to the right place at the right scale and orientation and, if necessary, warping it using numerical transforms to match it to known-good geographic data.

Images may be grayscale, palette, RGB, RGBA or compressed images and may be freely converted between the various image types using the Image - Convert To command. An image must be an RGBA image to use per-pixel transparency. See the Image Types topic.

Large images intended for background use should always be compressed images for speed. For example, Manifold can open and display an ECW image that is many gigabytes in size virtually instantly.

**Selection**

Manifold has very rich, regularly organized ways of doing selections that are employed throughout the system. These selection methods must be mastered. Please do not attempt work with Manifold without thorough study of the Selection topic.

**Formatting**

Formats in drawings may be manually specified or automatically derived from the contents of data fields using thematic formatting. Use the Format toolbar to manually set formatting. Lines, areas and points in drawings may be formatted using foreground and background color, thickness or size, and style. All objects of a given type (line, area or point) in a drawing will all be formatted the same way. Text labels in labels components will also have the same format used throughout the labels component. To employ different formats for objects in a map, use multiple drawings.

Thematic formats may be set for foreground color or background color for points, lines or areas. To do so, click into the color well and choose Theme. See Thematic Formatting. Thematic formats to automatically color maps so no two adjacent regions share the same color may automatically be set using the Drawing - Color menu command.
The format toolbar is also used to set many of the display characteristics of elements added to print layouts. For example, we choose the font for a text box in a layout by first selecting it for editing (using CTRL-ALT click) and then making our choices in the format toolbar.

**Themes** are project components that store formatting choices for drawings. Opening a theme shows the drawing with the formatting specified by the theme. A drawing can have many themes, each of which may show that drawing through a different set of formatting choices. Adding a new theme to a project requires virtually no storage space.

**Labels**

Text labels are hosted in Labels components. Multiple labels components are stacked in map layers to create the label effects desired. Each labels component is formatted using the same format throughout the entire layer. To create labels that automatically show field information, we **Copy** a drawing and then **Paste As** a labels component to create a labels component that shows labels at the position of every object in the drawing. If we want to create labels for only some of the objects in the drawing, we first open the drawing and select some of the objects and then **Copy** them. The subsequent **Paste As** will paste labels only for the copied objects. See the Labels topic for more information.

**Georegistration**

We georegister images and CAD drawings using the View - Panes - Control Points pane. We can georegister an image to a drawing, a map or to another image. We can georegister drawings to images, drawings or maps. The usual task is to georegister a target image to a reference drawing using features that are visible in both as control points.

We can also georeference an image without needing a pre-existing drawing if we know the latitude / longitude coordinates of at least two features in the image. For example, we may have an image of a scanned paper map where we have used a GPS device to determine the exact coordinates of a few features in the map. We can use these coordinates to georegister the image so that it can be traced into a drawing.

See the Georegistration topic for details.

**Layer Restrictions**

When working with maps, individual layers in maps can be specified as selectable, editable or clickable using layer restrictions. This is an extremely important capability when creating sophisticated web sites where we do not want background layers to respond to clicks for tools such as the **Info** tool, and is very useful for interactive work in Manifold when we do not want to accidentally select or edit items in a background layer. See the Layers and Commands topic for more information.

**Vectorization**

Creating vector drawings from raster images is an interactive process within Manifold. Vectorizing is called **tracing** within Manifold. We use this term because everyone understands the idea of laying a sheet of tracing paper onto a photograph and then drawing lines with a pencil to outline what is seen in the photo. This is a much more accessible word for new users than "vectorization."

When tracing images to create objects in drawings there are several key controls we leave open for use:

- The View - Panes - Tools Properties pane is used to set tool properties such as sensitivity threshold for **Snap** and **Touch Select** and other tools we will use.
- The View - Panes - Layers pane will likely be left open to allow us to move quickly between layers in the map.
- The Tracing toolbar contains tools specific to vectorizing.
- The Tools toolbar contains editing tools for drawings and images. Drawing tools are used to create areas, lines and points. Image tools are used to interactively edit the colors of pixels. When a drawing window or layer in a map is active the drawing tools will automatically be created.
The speed, ease and quality of tracing depend almost entirely on the characteristics of the raster image being traced into a vector drawing. A very, very few raster images may be automatically traced with satisfactory results. Most images have so much pixel junk that fully-automatic tracing creates such unsatisfactory vector objects that it would have been quicker to create objects using heads up digitization than to correct all the errors in the automatic process.

Manifold has numerous tools with sophisticated tool properties that are designed to increase the speed and accuracy of heads-up tracing. All tracing happens within a map that includes at least one raster layer being traced and an active drawing layer in which objects are created. A typical scenario is to use several different drawing layers (say, with a layer for lines and a different area for points) and clicking each when we want the new objects to be created in that layer.

Most tracing is done using free-hand addition of lines and points into a drawing layer while using an image layer as a guide. If desired, automated tools may be used. The main automated tracing tools are:

- **Trace Point** - Point and click and automatically create a point at the center of a pixel cloud.
- **Trace Line** - Point and click to automatically create a line long the center of line-shaped pixel cloud.
- **Insert Point** - Create a point freehand at a given location.
- **Insert Line** - Create a line freehand at a given location.

Manifold includes a **Trace Area** tool to point and click to create an area within pixel regions. Depending on the quality of the raster image it may be faster to simply insert points and lines using the above tools and then create areas using the lines. See the Tracing topic for details.

**Surfaces and Terrains**

**Surfaces** are 2D visualizations of terrain elevation data or other abstract data. Terrain elevation data may be imported into Manifold from a variety of formats. Surfaces are always imported together with an accompanying **Terrain** component, which shows the data in a 3D view. We can create additional terrains for each surface (at no cost in storage) that show the same surface colored using different thematic palettes.

Surfaces may be viewed in shaded relief or otherwise used like 2D images and can be dragged and dropped as layers into maps. They may also be copied and pasted as images. The appearance of the surface is governed by the View - Display Options settings for the surface. Some of these options provide analytics. For example, a surface can be seen using slope or aspect calculations.

Terrains may be seen in 3D by double clicking open the terrain. When seen in 3D, a wide variety of options can be applied to the appearance of the terrain. Options include automatic coloring by value or overlay in high resolution with images or drawings.

See the Surfaces and Terrains topic for details.

**Tables and Database Management**

Manifold has absolutely **immense** database capabilities that dwarf any other general purpose GIS. Database operations begin by importing or creating tables. When importing a drawing one or more tables will automatically be created in association with that drawing.

Manifold can import tables from almost any source. When a table is imported into Manifold both the table and the data it contains are brought into the .map project file and maintained by Manifold. Take time to study the numerous capabilities of Manifold tables. The context menus available when right clicking onto columns, rows, and cells provide a wealth of services, such as more like this searches. Table menus also include important capabilities such as **filters, grouping** and **sorting** which may be multilevel.

Tables may also be linked into a project. Linked tables stay outside the .map file within their original database files or database provider. If the file format or provider is one supporting multi-user accesses, Manifold can open those tables and use them even as other applications may update them.

Manifold has three methods for reaching out to either import or to link to a table. Using **File - Import - Table** may be used to open any of the basic database file formats commonly used within Microsoft Office installations.
For more extended access to database files or providers, using **File - Import - Table** and choose **Data Sources** () in the **Files of Type** box to launch the Data Source dialog. The Data Source dialog allows us use whatever connection type is desired, for example, files of type **OLE DB, ODBC, ADO .NET** or native connection technologies such as **OCI**, the Oracle Call Interface. By default, Manifold installs the standard suite of Microsoft OLE DB providers as well as ADO .NET connections.

Manifold provides two specialized dialogs to manage interactions with external databases. The Database Console is available in all Manifold editions and can be used to connect to databases, to manage them, to execute queries within the DBMS server's own SQL and to rapidly import or link components from the database. The Administrator Console is available in Database Administrator Edition and provides specialized functions of interest to database administrators in settings where many people are using Manifold to connect to spatial DBMS servers.

**Relations**

Any table in a project may be linked to another table via a relation so columns from the one table become visible in the other table. Open a table in table window and then choose **Table - Relations** from the menu. Choose the table that is to be linked and the key fields in each table that will be matched to form the relation. Choose the fields from the linked table that are to be included when the table is displayed.

Relations in Manifold are like forming a relation in classic relational databases except that the relation formed is a "soft link" by default. In a classic relation, deleting a record in one table will also delete it in the table linked by a relation. When tables are linked in Manifold using the **Tables - Relations** dialog deleting a record in one table will not delete the linked records in other tables by default.

When a drawing is imported into or created within a project a table for it is created automatically. The table will contain at least one field, the object **ID** field, that is a key field connecting each object in the drawing to a row in the table. If drawings are imported with additional data fields for each object, those fields will appear in the table as well. Imports from some formats, such as SDTS, may also create additional tables that are joined by relations to the drawing's table.

Objects in drawings may also be connected to records in external tables by using relations. The process is simple. First, import the drawing. This will create both a drawing and the drawing's table. Next, link the external table into the project using **File - Link - Table**. Finally, open the drawing's table and use **Table - Relations** to form a relation between the drawing's table and the external table using some field in each to match up records.

**Transfer Rules**

Many editing / transformation operations in drawings (see Transform Toolbar - Drawings and Drawings - Dissolve, for example) will create new objects from existing objects. When new objects are created from existing ones the system must know how to transfer data attribute fields from the existing objects into the new objects. The Transfer Rules dialog in tables sets forth the rules to be used for each particular column.

**Queries**

Manifold includes full SQL / DDL / DML language capability. Create a query using **File - Create - Query** and then double click on it to open it for editing. Henceforth, when the query is run by right clicking on it and choosing **Run** it will execute the SQL statement and display the results as a table. Action type SQL queries may also be created in this way. Queries may be opened for editing and **Run** at the same time so that the SQL query and the table it produces may be seen at the same time.

Manifold SQL provides numerous extensions. See the Queries topic for more information on queries and the Spatial Extensions and Geocoding Extensions topics for a list of extensions to SQL in Manifold that allow creation of SQL queries that make spatial comparisons or employ the geocoding engine for work with street addresses. The **SQL Reference Guide** chapter in Help provides many detailed topics as well.

**Decision Support System**

The Decision Support System is a means of ranking records in tables by how they score in flexible queries. Flexible queries use flexible profiles as criteria instead of fixed criteria as used in traditional SQL.
Manifold provides two main charting systems:

- **Minicharts** are used with drawings to portray a small chartlet for each object in the drawing. These should be used with restraint to avoid overwhelming the viewer.
- **Charts** are created from tables. They show the contents of tables with multiple series (fields) grouped as desired.

### Analytics

Manifold has many methods of analysis.

- Analyses that create numbers are often done using **ViewBots**, which are one-line analytic instruments that can be set to look at the contents of a drawing or other component. ViewBots are a spectacularly useful part of Manifold.
- Analyses in tables may also be done using **Active Columns**, where the column dynamically reports the result of a formula.
- **SQL** may also be used for analyses, especially when using computational queries or crosstab queries to explore grouping.
- Analysis involving the creation of new objects, such as drawing a Voronoi tiling, will normally be accomplished using Transform toolbar operators. The transform toolbar is also used with tables to perform computations on fields and to manipulate the table.
- Transformation of images may be done with the transform toolbar as well as with **Image** menu tools.
- Some analytic operations are implied: for example creating a slope or aspect map from a surface is a simple matter of changing the display option for the surface to **Slope** or **Aspect**.

### Programming

There are many capabilities within Manifold that may be programmed in an "ad hoc" way. For example, **Active Columns** allow inclusion of an ActiveX program that computes the results seen in a table's column. For programming in the classical sense, Manifold approach to customization and programming takes one of two pathways:

- **Scripting** within Manifold is accomplished using Visual Basic Scripting Edition within Manifold's drag and drop scripting environment to create event-driven, forms-based scripts. Scripting using straight scripting text may be accomplished in any ActiveX scripting language if it is installed on the system. By default, Manifold uses VBScript and Javascript. If their scripting engines are installed on your system, you may also use other scripting languages such as PERL, Python or REXX. Cool!
- Manifold scripting can also be done using any .NET language, such as C#.
- Programming from external programs can use any Microsoft compatible language and development system, most likely Visual Basic .NET or Visual C++. Manifold itself is written entirely in Microsoft Visual C++ within the Visual Studio .NET development environment.

Manifold does not use VBA because we feel it is neither right for beginners nor suitable for experts. VBA is too clumsy for casual usage while being inadequate for professional programming. VBScript is a better choice for beginners and real VB or VB .NET or VC++ the right choice for professionals.

Our feeling is that industry-standard scripting languages have attained far greater support among computing users for casual usage. By using any ActiveX scripting language or .NET language for scripts in Manifold we provide a wide range of exquisite scripting languages to our users, all for free.

For professional program development, we feel that serious programmers already have invested in either VB or VC++ for program development. Using these languages, therefore, represents no additional cost for professional programmers while gaining the power and flexibility of a real compiled language and serious development environment.

Manifold also provides a Debugger similar to those used in professional programming environments for use with ActiveX scripting languages. The Debugger allows stepping through multiple scripts with automatic stops at breakpoints, paused execution and stepping into, over and out of routines. The **Call Stack**, **Variables** and **Watches** panes provide dynamic, editable displays of variables, functions, computed values and contexts.

See the Programming Manifold topic for more information.
Printing

Any component may be printed by opening it in a window and choosing File - Print. For more sophisticated printing composition, a layout component is created and opened and any other components to be printed are dragged and dropped into that layout. See the Printing topic.

Print layouts are highly WYSIWYG (What You See Is What You Get) so there is no need for a print preview.

Internet Map Server

Manifold Professional Edition and high versions include a powerful Internet Map Server (IMS) that can be used to create highly sophisticated map-enabled web sites. Many classes of web sites can be created with no programming required. Manifold IMS works on Microsoft Internet Information Server (IIS) machines.

To create a web site using Manifold IMS, create a Manifold project containing the component (normally a map) that you want to be published. Open the map and choose File - Export - Web Page. Choose the options desired and press OK. Manifold will automatically create the necessary .asp files required for the web site.

Although the GIS part of creating a web site with Manifold IMS is very simple, the Microsoft IIS side of operating web sites must be understood by the webmaster.

Multi-User Editing

Manifold supports full, concurrent multi-user editing of linked drawings with Enterprise Edition being required for full resolution of editing conflicts. See the Multi-User Editing of Linked Drawings topic for details.

Learning Manifold

The best path is to begin at the Read Me First topic and to then go through the Introduction book. Do not skip the Windows topic or other topics in the Introduction.

We suggest working through all of the Examples in sequence. As time permits, read through the topics in the Drawings, Images, Maps, Labels, Tables, Surfaces and Terrains and Queries books. It is OK to skip the detailed reference topics on various transform operators during a first reading.

Performance

Like all large, sophisticated professional tools Manifold provides great power and flexibility to users in how they choose to do GIS. There are often many different ways of accomplishing the same end in Manifold through different means. Users can choose the method that is exactly right for their intended goal and for their preferred means of reaching that goal. Providing such great flexibility and free choice for users also means that users can choose to conduct their GIS affairs in a highly inefficient way. For a guide to best practices for maximum efficiency, see the Performance Tips topic.

Notes

The reasoning behind Manifold’s user interface is explained in the essay titled User Interface Design. Other Essays present a sometimes radical Manifold spin on various topics in GIS that may amuse or irritate the expert reader.
Data Storage Strategies

How we decide to store our data says a lot about how we can use that data. Data in the case of Manifold consists of drawings, images, surfaces, tables and the like. Manifold provides such a rich spectrum of capabilities for storing and working with GIS data that sometimes beginners are confused by the many options possible.

The usual approach in the GIS industry (or, for that matter, in most other software industries) is to have two classes of storage, which may be loosely categorized as:

- **Local, Desktop storage** - Applications store data in individual files, just like Microsoft Word saves documents in .doc files or Excel saves spreadsheets in .xls files. This is simple and easy for individuals but not a good model for enterprises or multiuser applications.

- **Linked, Server storage** - Applications store data in centralized DBMS servers, to which users running client software can connect to link to whatever data they need. Enterprise-class database systems are usually used as the centralized server. This provides administrative centralization and support for multi-user work, but at the cost of added complexity.

Manifold can store data using either of the above models, and in addition introduces a third model, unique to Manifold, that splits the difference between the above two models:

- **Shared, Enterprise Edition** - This is a simplified Enterprise server shared storage model designed for use by small and mid-sized organizations which desire the simplicity of desktop storage while having some of the organizational advantages of server storage. Data is stored as components within the Enterprise server, like documents within a file cabinet, which can then be shared in their entirety into a particular project.

The result is three levels of storage supported by Manifold, which may be freely intermingled with each other. These three levels of storage may be summarized as:

- **Local components stored in .map project files** - This is the classic document-oriented desktop storage model: Users work with individual .map project files that contain the drawings, images, tables and other components they are working with. This is a typical approach for individuals or very small organizations, the classic "one file, one user" approach employed by Microsoft Office applications. Data is stored in the form of .map project files, which are the "documents," and the "file cabinet" used to store those documents is simply the Windows file system, using folders and other Windows facilities to keep things organized. There is no real multi-user activity done with this system. If someone else needs a drawing we've created, we give them a copy of the .map file containing the drawing. We hope that if they make any changes we will be able to reconcile any such changes with whatever other copies of that .map file we have on hand. Any Manifold version can use this storage model.

- **Linked components stored in database servers** - This is the classic, object-oriented server storage model. Drawings, images and tables are stored in a general-purpose way within a database server. Users can link such items into their local projects. This is the general-purpose, "one server, many users" approach used by large enterprises. It is called object oriented because the technology of linking drawings from general purpose geometry storage in database servers allows the entire drawing to be freely edited, down to creating, editing and deleting individual objects, that is, individual points, lines and areas. The "file cabinet" is the database server, and users can link entire components (drawings, images, tables, queries or surfaces) into their projects or, in the case of drawings if certain spatially-enabled DBMS servers are used, only that part of the drawing that is of interest. Concurrent, multi-user editing of drawings is fully supported. Enterprise Edition is required for full capabilities with this model.

- **Shared components stored in Enterprise servers** - This is a uniquely Manifold Enterprise server storage model that combines benefits of desktop and server storage models. Drawings, images, tables and other components are all kept in a centralized Enterprise server, which is simply a database configured in a Manifold-specific way to store all Manifold components. Manifold users running Enterprise Edition can link items from the Enterprise server into their project. This is a simplified "one server, many users" approach that provides component-oriented, server storage for small or mid-sized organizations. Individual users still can keep their projects saved as .map project file "documents," but the content of those documents is now fetched as whole components that are linked in from the Enterprise server "file cabinet." Multi-user editing does not occur simultaneously, but a shared component can be checked out by a user, edited, and then checked back into the server. Any changes made will be automatically propagated into any project that uses that shared component. Enterprise servers require use of Enterprise Edition on client desktops.
The above summary is just one way of looking at the many capabilities that Manifold provides for storing data. It helps explain why it is that Enterprise Edition includes a dedicated system for working with Enterprise servers even as it also includes very general-purpose features for saving linked drawings in DBMS servers using formats like OGC WKB or Oracle spatial SDO_GEOMETRY.

The advantage of Enterprise server storage is that it provides an easy-to-use way of storing any Manifold component, even scripts and comments and layouts, within a centralized server from which the component can be shared by many users within many projects. Enterprise servers provide simplified administration and ease of use for users. The check out / check in editing model provides easy editing by those who have permission to do so while removing the need for training users in the nuances of concurrent multi-user editing. The disadvantage is that Enterprise server storage is specific to Manifold only (although data can always be exported to other interchange formats) and does not allow concurrent multi-user editing.

Although it is more complex than using Enterprise servers, the general-purpose server storage model has a lot of appeal for interoperability with other programs. If a standard format, such as Oracle, is used, then potentially very many different applications can interact with that same geospatial data in a (hopefully) vendor-neutral way. The disadvantage is that only some types of components can be stored in this way and that greater expertise is required to exploit such servers. The availability of concurrent, multi-user editing is both an advantage and a disadvantage. Along with the obvious benefits comes the greater user expertise required to resolve editing conflicts that may arise from simultaneous editing of objects by different users.

One other potential use of server storage is the use of spatially-enabled DBMS servers to store GIS data. Such servers have the ability to perform some spatial operations, such as fetching all objects in a drawing within a particular area of interest, and therefore can be used to increase performance and capacity by offloading some work from the GIS desktop. See the Spatial DBMS topic for more information about spatially-enabled DBMS servers.

Manifold projects can mix and match the storage models above, and the intermingling of different storage models has been encouraged by advances in storage technology coupled with reductions in cost. In earlier days, for example, an individual user simply could not afford access to, say, Oracle spatial servers. In modern times, Oracle Express Edition can be used for free. Manifold also provides generic spatial DBMS capabilities for almost any DBMS, including free servers such as MySQL, which can now not only store drawings but also images and servers with almost unlimited capacity.

Because the cost of enterprise-class DBMS products has come down to zero in some cases, even individual users can employ server storage if that makes sense for them. Likewise, some aspects of server storage have appeared in the form of web servers that play a role (albeit at usually slower performance) once played exclusively by database servers. Users can freely combine storage models to achieve exactly the result desired.

For example, we can have a project that contains purely local components, links in an image from a web-based image server, shared queries or scripts from a shared Enterprise server and drawings linked in from an Oracle Spatial server. The linked image may be used for background only, so it doesn't matter that it cannot be edited, the scripts or queries may be something a more experienced user in our organization has shared to our department's Enterprise server, and the drawing might be an area of interest linked in from some vast, 200 GB "seamless" drawing maintained on our organization's Oracle cluster. Our job might be making edits to the vast Oracle drawing assisted by the scripts and queries provided by our colleague while the background drawing helps us stay oriented.

Advice to Users

The following guidelines reflect how most users tend to choose Manifold System versions and the storage strategy employed. Feel free to modify these guidelines for your own needs, as most users do.

- Individual users with relatively small and mid-sized projects usually keep everything in the same .map file, especially while learning Manifold. The main exception is that large images used for backgrounds should be saved in .ecw form and linked into projects. As users get more sophisticated and find themselves with very large data holdings, they will be careful to keep their Windows systems well organized.

- More advanced users with larger data holdings will often turn to Enterprise Edition to organize their data in Enterprise Servers. That's an especially useful strategy if a particular drawing is used in many projects (that could be stored on various machines in one's office) and the drawing is updated from time to time. It's a lot easier to simply check out the drawing, edit it and check it back into the Enterprise server than it is to track down each project that uses that drawing and then to manually update each project by copying and pasting from a reference project somewhere.
Most organizations with more than one person doing GIS will use Enterprise Edition, initially to store data within Enterprise Servers to help keep things organized. This is a good solution when simultaneous, multi-user editing of drawings is not required.

When simultaneous, multi-user editing of drawings is required, organizations will use Enterprise Edition and will save their drawings in a database such as Oracle, SQL Server, IBM DB2, PostgreSQL, MySQL or some other convenient DBMS.

Very large organizations tend to centralize their operations around storage in databases using either Oracle spatial technology for drawings or WKB geometry storage in SQL Server to allow interoperability with the many applications interacting with GIS data in such organizations.

Organizations working with many users and large images will almost always store the images in a spatial DBMS, either using Manifold's generic spatial DBMS capability with whatever DBMS is in use or choosing a spatial DBMS that includes raster support, such as Oracle Spatial with GeoRaster.

On occasion, individual users with large images or image libraries will also store them in a spatial DBMS, either using Manifold's generic spatial DBMS capabilities or using the free download of Oracle Enterprise Edition to get GeoRaster storage capability if their uses fit within the permitted scope of the free download Oracle license.

At any time, of course, if an application requires that a linked drawing be created from data stored outside the project (be it a personal database of some kind in Access .mdb format or be it a huge corporate database leveraged by a big IMS application), then we will use linked drawings or linked tables as necessary to bring data into our project from other data sources.

Note that at any time we can always convert a linked or shared component into a local component by unlinking it or unsharing it. Doing so makes a snapshot of the data supplied by the data source as of that instant. This is a handy way of capturing entirely within the project's .map file the current content of a project that includes linked components, so that we can send that snapshot to a colleague who might not have the ability to link to the same data sources.
Spatial DBMS

This topic continues the discussion begun in the Data Storage Strategies topic. In this topic we look more closely at storing GIS data, in particular drawings, within database management system (DBMS) packages. This topic provides a general introduction to the Manifold approach to spatial DBMS. See the Spatial DBMS Facilities topic for detailed information on Manifold spatial DBMS capabilities, including information on supported spatial DBMS products.

The use of spatial DBMS technology is a great way to store and work with drawings and images of immense size with high performance. Manifold provides a wide range of capabilities to take advantage of spatial DBMS:

- Manifold can store drawings within major spatial DBMS products (IBM DB2 with IBM Spatial Extender, Microsoft SQL Server 2008 spatial, Oracle and PostgreSQL/PostGIS) using the native spatial DBMS facilities within those products.
- Manifold can store drawings, images and surfaces in almost any DBMS using Manifold-managed spatial DBMS capabilities.
- Manifold can store images and surfaces within Oracle DBMS products supporting Oracle native GeoRaster capability.
- In addition to using Manifold or native spatial DBMS capabilities, Manifold can also connect to ESRI-style SDE geodatabases and Personal geodatabases and import and link (for read/write editing) drawings in SDE or Personal geodatabases.

DBMS products have become so powerful, so inexpensive and so easy to install that more and more GIS applications now take advantage of DBMS. GIS users from individual hobbyists to the largest enterprises can now benefit from spatial DBMS technology through Manifold.

Manifold Enterprise Edition or above is required to connect using native connections to spatial DBMS such as Oracle Spatial, DB2 with IBM Spatial Extender, SQL Server 2008 spatial and PostgreSQL / PostGIS. While Personal and Professional editions can make use of spatial DBMS in some cases once configuration has been done with Enterprise Edition, in general Enterprise Edition or above is required for spatial DBMS work.

Two Types of Data in Drawings

Most GIS packages, Manifold included, use two types of data to make up drawings:

- One type of data is the geometric information that defines objects in the drawing. This type of geometric information is often simply called the geometry of the drawing. It specifies the shape and location of the points, lines and areas of which the drawing consists.
- The second type of information is the data in the optional attributes that may be attached to objects in a drawing. For example, a drawing that consists of points showing the locations of cities might also have attributes that give the name of each city, the population of that city and other information.

GIS packages use geometry to draw the shapes and locations of points, lines and areas in a window. Attribute data is normally shown using a row and column table visual interface like that used in DBMS packages. A drawing may or may not have attributes for the objects it contains, but it always has geometry because without geometry there would be no points, lines or areas in the drawing.

Storing Attribute Data in a DBMS

A GIS package becomes more flexible, useful and powerful if it can work with attribute data that is stored in an external DBMS. That's very useful even if the GIS continues to manage all of the geometry.

Many GIS packages have this capability, although it is usually limited to read-only linkages or available only in a limited number of data access methods, such as ODBC. Manifold allows linking of attribute data from an external DBMS with full read / write / edit capabilities using a very wide range of data access methods. See the Relations topic and the Attaching External Tables to Drawings topic for Manifold techniques for using attribute data from external sources.
Linking attribute data from a DBMS brings a lot of advantages to GIS users. The foremost advantage is that there is much more data maintained in commercial DBMS products than exists in GIS storage, so being able to link data into GIS projects from an external DBMS gives access to a much wider range of data.

The second key advantage is the ability to dynamically update a GIS project using data that is maintained in some external DBMS. Suppose, for example, we want to graphically display the sales of our company in various regions by thematically changing the color of regions in accordance with a sales attribute for each region. If the sales attribute is automatically fetched into the drawing from our corporate DBMS, whenever that corporate DBMS is updated by some other process (such as, perhaps, by our company’s order entry system), our drawing will automatically be updated as well.

A third advantage is that storing attribute data in a DBMS also can take advantage of ubiquitous data interchange between applications that can work with DBMS. If our attribute data is stored in a DBMS there are likely thousands of applications and utilities that can work with it without having to know anything about our GIS package. Applications can connect to the DBMS as they have long known how to do, while the GIS takes data as needed from the DBMS.

**Storing Geometry Data in a DBMS**

There are many benefits to storing attribute data in an external DBMS even though geometry continues to be managed exclusively within the GIS. But so long as the GIS manages geometry users will be subject to whatever limitations that may involve. There are usually several limitations imposed by having geometry managed exclusively by the GIS package.

The first limitation is that GIS packages usually do not have the sheer capacity and cluster scalability of mainstream DBMS packages like Oracle or SQL Server. As a result, the number of objects in a drawing will normally be limited by the performance of the GIS running on a single machine.

A second limitation is often a restriction to single users or single processes working with the geometry data stored by the GIS. Mainstream DBMS packages have evolved to meet intensely multiuser, multi-process needs but most GIS packages (Manifold is an exception) have not been built with the multi-process, transaction-oriented architecture required for intensively multiuser operations on geometry.

A third limitation is limited dynamic interoperability between different GIS packages and other applications. GIS data can be interchanged more or less successfully in a static, limited way using well known formats such as shapefiles, but cannot in general be interchanged dynamically as is taken for granted with DBMS servers.

A GIS that can store geometry in a DBMS can escape the above limitations. Storing geometry in a DBMS can take advantage of the capacity and scalability of the DBMS, resulting in drawings that can be terabytes in size. If a DBMS stores geometry, a GIS can operate as a client to the DBMS server in multi-user settings, taking advantage of the extensive apparatus a modern DBMS will provide to manage the simultaneous use of data by many different users. Storing geometry within the DBMS using data types native to the DBMS allows interchange with any application that understands those data types, which is usually many more applications than can parse the proprietary internal formats used for geometry storage within even very popular GIS products.

Manifold can work with geometry stored in databases using the widest and most flexible range of data access methods of any GIS system. In fact, Manifold can do so simultaneously with many different data sources and access methods, including geometry stored within Manifold itself.

**Native Geometry and Non-Native Geometry Types**

All data stored in a DBMS is ultimately in binary form. When storing geometry within a DBMS the question is what internal format the DBMS should use to order the binary data used to store that geometry. There are two approaches.

One approach is used in DBMS products sold as “spatial” DBMS. A spatial DBMS will have a pre-defined way of organizing binary data to represent geometry, and this pre-defined way of organizing binary data is built into the DBMS in the form of a data type, such as `SDO_GEOMETRY` in Oracle Spatial or `ST_GEOMETRY` in IBM’s DB2 Spatial Extender. Because this data type is built into the DBMS it is called a *native* geometry type. The data is still binary data, of course, but it has been organized in accordance with a formal expected for geometry data by the DBMS. When a DBMS product has its own, native geometry type it also usually supports that data type with additional infrastructure, such as the automatic creation of spatial indices or the provision of DBMS server commands that understand that data type.
The other approach is used with DBMS products that do not specify a pre-defined way of organizing binary data to represent geometry but which allow applications to utilize a generic binary data type. Almost all modern DBMS packages provide a generic binary data type that can be used to store binary data unstructured by the DBMS. Often referred to as a blob, such generic binary storage can be employed by applications as they see fit. When such generic binary storage is used to store geometry in a form not built into the DBMS it is called a non-native geometry type. Although the use of non-native geometry types allows storing geometry within general-purpose DBMS products without requiring a special "spatial" form of a DBMS, it does require a GIS application that supports the geometry formats to be used.

Manifold can use either native or non-native types of storage when available within a DBMS and can even use both types simultaneously. It is important to note that in either case the data is stored in binary form using some organizing format to represent geometry in that binary data. The difference is that in the one case the DBMS has its own special format for organizing that binary data and in the other case it is the GIS interpreting that binary data. Both cases can be equally fast if the non-native type is an efficient geometry format such as Manifold's SDO_GEOMETRY, since in both cases the speed is a function of the DBMS's ability to work with binary data, perhaps as assisted with specialized indices.

The main advantages of using a native geometry type within a spatial DBMS is first, that doing so provides interoperability with any application that uses the native type, and second, using a native type automatically takes advantage of the infrastructure within the spatial DBMS that supports that native data type. The disadvantage is that a native geometry type might not be available within the DBMS package we desire to use, or that it may involve extra cost.

The main advantages of non-native binary storage are first, Manifold makes use of spatial DBMS functionality utilizing non-native types within virtually every DBMS and second, using a choice of non-native geometry types can open the door to greater flexibility than is possible by committing to a single data type within a single DBMS vendor. A possible disadvantage is that choosing from a variety of geometry types can make interoperability with other applications more difficult. However, if a generic geometry type that is well-understood and accepted by many applications, such as WKB, is used, then interoperability might well be preserved.

**Spatial DBMS**

A spatial DBMS can make it especially convenient to leverage the power of the DBMS by using native geometry types within the DBMS and by extending the internal logic of the DBMS to handle spatial operations of interest for GIS applications. When a DBMS offers a native geometry type together with supporting capabilities (such as spatial indices) it is referred to as a spatial DBMS.

GIS has become such big business that major DBMS vendors have extended their DBMS products with native geometry types as well as with supporting capabilities. Locator capability within regular Oracle DBMS editions as well as Oracle's dedicated spatial product, Oracle Spatial, provide Oracle's SDO_GEOMETRY type as well as Oracle GeoRasters and powerful spatial operations. Other DBMS packages such as IBM DB2 have spatial extenders and open source DBMS packages such as PostgreSQL now include "spatial" capabilities as well.

Microsoft SQL Server allows third parties to extend the DBMS product to provide a native geometry type and spatial operators, as several third parties have done. In addition, Microsoft's new SQL Server 2008 includes Microsoft-engineered geometry types, GEOMETRY and GEOGRAPHY, together with supporting spatial capabilities.

The availability of a spatial DBMS with a native geometry type together with built-in spatial operators confers enormous benefits to a GIS package that can integrate well with that spatial DBMS. Capacity and scalability can increase to whatever the DBMS can handle, terabytes in the case of modern DBMS server clusters. Even if a GIS cannot manage terabytes at one time, by using the spatial capabilities of the DBMS to extract data in manageable area of interest (AOI) subsets, a GIS user can work effectively with that part of the data of interest taken from a data set that is much larger than the GIS client alone could handle.

When geometry is stored in a spatial DBMS multiuser and transaction issues need no longer be limited by the GIS but instead can be handled by the formidable apparatus of the DBMS while the data itself can be protected by the transactional integrity of the DBMS. DBMS servers provide transactions, triggers, views and many other capabilities not often found within a GIS.

Because mainstream DBMS packages are used by organizations for many more applications than GIS, storing data within the DBMS package's own native data types tends to assure interoperability with a far greater number of applications than can work with any one GIS vendor's proprietary formats, potentially including a greater number of GIS packages as well. GIS vendors may not be able to agree among themselves to open their formats to each other, but every GIS vendor knows they are not in the game if they do not support Oracle's SDO_GEOMETRY or Microsoft's new GEOMETRY type in SQL Server 2008 spatial.
Spatial Indices

The spatial logic in a spatial DBMS normally consists of enabling infrastructure in the form of spatial indices maintained by the DBMS together with a collection of spatial operators that can be executed server-side by the DBMS server. A spatial index is a specialized form of DBMS index maintained for the geometry type that makes it possible to quickly identify objects based upon spatial characteristics, such as the location and extent of a particular object. Spatial operators are normally functions that ascertain spatial relationships, such as finding all objects that are contained within a given object.

When Manifold adds spatial capability to an ordinary DBMS, spatial indices will be created and used. There are important requirements and limitations to spatial indices in such cases that are covered in the Manifold Spatial DBMS Facilities topic.

Adding Spatial DBMS Capability to "Ordinary" DBMS

Manifold can confer spatial DBMS functionality to almost any DBMS package even if the DBMS does not itself have "spatial" features such as a native geometry type or spatial indices. Manifold does this by providing Manifold-sponsored spatial infrastructure within the DBMS to support usage of non-native geometry as is done with native geometry types within a spatial DBMS. Manifold utilizes geometry types desired by the user and creates spatial indices which the DBMS then operates.

Note that there is nothing about a "spatial" DBMS's native geometry type which makes it any better or worse as a binary format for storing data than, say, Manifold's own GEOMETRY type. Embed within a DBMS a spatial index tailored for GEOMETRY and we have almost all of what people really use within a spatial DBMS. In fact, Manifold GEOMETRY is actually significantly more efficient and powerful than the native geometry types used by either DB2 or PostgreSQL. It is just that those DBMS have some facilities that assume their native geometry type is in a particular format.

When Manifold provides spatial infrastructure, Manifold creates a spatial index in the target DBMS for Manifold geometry data stored in the DBMS. In such cases, Manifold stores geometry data as a binary blob, but it does so in a way the DBMS would do if it had its own geometry type, that is, with a spatial index maintained to allow sophisticated and powerful manipulation of that geometry data. The spatial index established by Manifold is maintained by the DBMS server using the power of the DBMS package and will automatically be updated if a linked drawing is edited. This confers upon ordinary DBMS packages a true "spatial" capability maintained together by the DBMS and by Manifold.

Manifold requires no add-ins to be installed in order to provide the above spatial capabilities to virtually any DBMS. However, because SQL Server 2005 is so popular in the Manifold user community and because SQL Server 2005 allows add-ins to extend functionality within SQL Server 2005, Manifold provides the free Manifold Spatial Extender for SQL Server 2005, an add-in that enables Manifold-managed spatial DBMS capability within SQL Server 2005 to operate with especially high performance.

Some people may say that a DBMS cannot be considered a true "spatial" DBMS unless in addition to having a geometry type plus supporting spatial infrastructure such as spatial indices it also has the ability to do server-side spatial operators, for example, to have operators such as a CONTAINS within the DBMS package's own SQL. Server-side operators are very important when the spatial DBMS is used as the "black box" infrastructure behind some application, such as a web site where data from the database is fetched using SQL queries or other code. However such server-side spatial operators are not usually employed when a rich GIS package is used as a "front end" to the spatial DBMS.

Server-side spatial operators are almost never used in an environment where the interaction with the spatial DBMS occurs through a very rich client like Manifold. The reason is that most people prefer a point-and-click user interface for spatial tasks and find it difficult to work within a black-box, command-line (that is, exclusively SQL) environment as often ends up being the only useful way to work with server-side spatial components. As a practical matter, when a GIS package like Manifold provides the user interface perhaps the only server-side operation executed by most users is an Area of Interest (AOI) specification to grab a manageable subset of some very large drawing. However, AOI does not require server-side spatial operators - it requires only a spatial index as conferred by Manifold.

Therefore, the use of a Manifold-declared spatial index together with straightforward Manifold GEOMETRY storage within an "ordinary" DBMS such as MySQL or Microsoft SQL Server 2005 (as opposed to built-in spatial support in SQL Server 2008) can provide the benefits sought by users through "spatial" DBMS. It is a way for GIS users to get outstanding price/performance by using ordinary DBMS packages, even possibly free packages, as true spatial DBMS servers storing data of effectively limitless capacity, storing drawings, images and surfaces, and to leveraging the power of increasingly multiprocessor systems and increasingly immense RAM.
In fact, by using the spatial DBMS capability conferred by Manifold onto a regular DBMS we can usually gain more "spatial" capabilities than are provided by some spatial DBMS packages. For example, Manifold conferring spatial capability onto an ordinary DBMS allows us to store images and surfaces as well as drawings while most spatial DBMS packages can only store drawings. See the Spatial DBMS Facilities topic for information on storing images and surfaces.

**Notes**

Users sometimes ask why Manifold supports so many different ways of doing spatial DBMS, at times even different ways using the very same DBMS product. The answer is that the Manifold user community includes a very large number of different organizations and individuals who have very diverse interests and the company likes to provide as many options as possible to suit different tastes.

Although it is true that providing "generic" spatial DBMS capabilities which will also work within a native spatial DBMS such as Oracle may seem redundant, the internal architecture of Manifold is so modular that there is not a great engineering cost for making all forms of spatial DBMS storage available regardless of what data store is employed. This provides flexibility and freedom of choice which helps users get the maximum possible value out of their technology investments.

For example, although using native Oracle Spatial capabilities is clearly the first choice for GIS professionals working with Oracle, it could be that to take advantage of some third party utility or application that does not understand native Oracle Spatial but does understand, say, OGC WKB we would like to make some data available in our Oracle data store in OGC WKB form but still have a generic spatial index in play for good performance. Manifold makes that possible and easy.

Although all Manifold editions can work with attribute data and can store geometry using blobs, only Enterprise Edition and above can take advantage of spatial DBMS to store geometry using a spatial DBMS server's native geometry type.

This topic has discussed two forms of data, geometry and attribute data, in connection with drawings. However, there is also a third class of data, raster data for images and surfaces, that is also often stored within a spatial DBMS. All spatial DBMS packages enable storage of geometry for drawings, but not all enable storage of raster data for images and surfaces.

Manifold can work with raster data in some spatial DBMS packages, for example, Oracle Spatial. However, even within a particular DBMS product line raster capability may be an option not found in all versions of that DBMS. For example, the free Oracle Express package has Locator capability in it to allow spatial DBMS work with drawings, but Oracle Express does not include Oracle's GeoRaster type to enable work with images. One must step up to the full Oracle Spatial package to get GeoRaster capability.

When using Manifold's generic spatial DBMS capabilities, nearly any DBMS can be used to store images and surfaces. Excellent!

This topic continues the general introduction to geospatial data storage covered by the Data Storage Strategies and the Spatial DBMS topics. This topic should be read together with those two topics, which introduce terminology and concepts used in this topic as well. This topic breaks out information specific to ESRI use of databases for new types of ESRI geospatial storage for the convenience of ESRI users. The features in this topic require Manifold Enterprise Edition or above.

ESRI, a legacy GIS vendor, has introduced a variety of products that can work with geometry and attribute data stored in DBMS servers. These are not spatial DBMS servers as such are generally understood, but rather are software products and middleware software that manage data stored in real DBMS servers using either blob or geometry types if the DBMS is a spatial DBMS. It is a classic case of a GIS vendor providing their own spatial capabilities for a DBMS by using their own non-native geometry types together with supporting capabilities supplied by the GIS vendor.

Manifold can also work with non-native data stored in databases using ESRI conventions. In such cases Manifold will work with ESRI's geometry types and supporting metadata tables using ESRI conventions for compatibility with ESRI products.

Nomenclature

Many users are baffled by ESRI nomenclature when it comes to parsing the bewildering variety of marketing phrases ESRI has used to describe ESRI "geodatabase" formats. If you feel baffled, you are not alone. In a nutshell, ESRI at one point introduced the idea of storing geometry in DBMS using a format that more or less boiled down to storing shapefiles within blobs. This was done in a complex way using middleware called ArcSDE that worked with serious databases like Oracle, and it was also done in a somewhat simplified way in Personal Geodatabase products that used Access .MDB files and were later apparently updated to work with MSDE (a free version of Microsoft SQL Server) or with SQL Server Express. In recent years, the ArcSDE product name seems to have been dropped by ESRI: more recent versions of this technology have been packaged as part of the ArcGIS product family and have been referred to as geodatabases.

All such storage methods are technically similar and are generally referred to as SDE geodatabase formats or as Personal geodatabase formats when in the somewhat simplified form that uses Access .MDB for file-based storage. Since all such formats are similar or derived from ArcSDE, they are referred to by Manifold documentation as ESRI SDE or as ESRI Geodatabase or as Personal Geodatabase data sources, the various terms being used interchangeably, regardless of which file format or DBMS system is used to store the data.

The terms are used interchangeably because some ESRI users come from a long ArcSDE tradition and don't realize that "geodatabase" is the new term for the same old thing, while some newer ESRI users might not realize that their "geodatabase" is really SDE technology with a new name. Because of the confusion caused by ESRI names for their SDE and their Personal technology being so similar, Manifold documentation will often refer to SDE and Personal geodatabases to underline that a particular capability is available whether one is working with either SDE geodatabases or the somewhat simpler Personal geodatabases.

Manifold can also connect to ESRI SDE and Personal geodatabase data sources for full read / write / edit capability. The only limitation is that unlike all other work with all other spatial DBMS, Manifold will not create new SDE or new Personal geodatabases, nor will Manifold add new drawings to an existing geodatabase. If we already have drawings in an SDE or Personal geodatabase, Manifold will happily import or link to those drawings. We can edit those drawings, adding new objects and deleting or editing old objects and in general perform whatever operation we like. For example, we could link to an existing drawing in a geodatabase and then copy and paste objects from some other drawing into that drawing. However, we cannot create new drawings or new geodatabases.

ESRI ArcSDE / ArcGIS / Personal Geodatabases

ESRI's ArcSDE product stores drawing geometry and other GIS data within ordinary, non-spatial DBMS servers. ESRI products refer to such data as geodatabases or SDE data sources (see notes on nomenclature above).

Technically, one can organize an SDE data source on almost any database. However, since this can not be done in a database-neutral fashion and since setting up an SDE data source involves creating database-specific objects, SDE data sources are only organized on big-name databases explicitly supported by ESRI, such as IBM DB2, IBM Informix, Microsoft SQL Server 2000 or 2005 and Oracle. SDE data sources using Access .mdb appear to have been replaced with SQL Server Express 2005. Personal geodatabases seem to be found almost exclusively within .mdb files.
Manifold knows to look for SDE or Personal geodatabase data if we use Database Console to connect to a database. Manifold usage of SDE or Personal geodatabase data sources uses Database Console as the primary interface and includes:

- Connecting to an SDE data source.
- Listing the drawings in an SDE data source in Database Console.
- Importing drawings.
- Linking drawings in read-write mode.

When importing or linking drawings from SDE or Personal geodatabase data sources Manifold will fetch the coordinate systems (projections) in use from ESRI metadata. Importing or linking a drawing assigns it the coordinate system stored on the data source.

Manifold will convert ESRI style objects within the SDE database into Manifold equivalents. For example, reading data from an SDE geodatabase reads parametric curves, flattening them into lines with straight line segments. As of the current writing Manifold does not accept "multipoint" values, although this capability is expected to be added in future editions.

Although Manifold can connect to an existing SDE database, read (import) drawings, write drawings, link drawings and edit drawings, Manifold will not export new drawings to an SDE database nor will Manifold create a new SDE database.

See the Spatial DBMS topic for more information on the advantages and disadvantages of spatial storage within a DBMS.

Notes

Why doesn't Manifold create new ESRI geodatabases?

There are two reasons for this limitation. The first reason is that it does not make sense to create new SDE databases since these are significantly inferior to using native standards within a true spatial DBMS like Oracle or SQL Server. This should not be an obstacle for ESRI users who are operating legacy SDE databases, since such users normally have ESRI software available should they ever need to create a new SDE database.

The limitation does not affect non-legacy users since new GIS users will never choose SDE over a real spatial DBMS. In modern times it does not make sense to create a new SDE database when true spatial DBMS servers, like Oracle Spatial or SQL Server 2008 spatial, are now available. Using a true spatial DBMS provides far greater reliability, performance, flexibility and interoperability with other applications and usually dramatically lower costs as well. It therefore makes no sense to use SDE if we have a real spatial DBMS available.

The purpose of Manifold's ability to work with SDE is therefore to provide the capability of dynamically working with existing SDE databases in legacy installations so that ESRI users can enjoy the convenience of working with that data and, eventually, rescue it when they transition to modern spatial DBMS.

The second reason is that from a technical perspective both SDE and Personal geodatabases are regarded by Manifold engineering as lacking desired reliability due to the convoluted architecture employed in those ESRI technologies. Simply put, the manifold.net team does not want to be blamed for problems arising from that lack of robustness. If someone wants to create a new drawing in an ESRI geodatabase and they run into problems when using an ESRI tool to create that drawing, then the problem is clearly ESRI's fault. In contrast, if Manifold were used to create that new drawing no matter how well Manifold accomplished the task if problems arose due to the basic architectural unreliability of ESRI geodatabases it would be Manifold that would be blamed. No thanks!

The Data Source Dialog

GIS work often involves reading and writing information stored in database servers or data files. Manifold allows us to work with information in databases in many different ways and allows us to connect to all database and data file technologies in common use in Windows systems.

Examples of connecting to data include:

- Connect to a SQL Server database server within Database Console to examine the contents of that database.
- Upload an image from a Manifold project into an Oracle Spatial DBMS.
- Link a surface into a Manifold project from a MySQL DBMS.
- Link a drawing from a SQL Server database.
- Import a table from an Access .MDB file into a Manifold project.
- Link a table from an Access .MDB file into a Manifold project.
- Import a table from a .CSV text file.

Manifold provides two pathways to connect to data:

- For simple connections to simple data, we can use the File - Export, File - Import and File - Link commands to connect to simple file types such as CSV, DB, DBF, HTML, MDB, WK and XLS directly by choosing the desired file type in the Files of Type box in the dialogs. This is similar to how we would work with such files in typical Windows applications.
- For more complex data sources or more sophisticated uses, when launching the File - Export, File - Import and File - Link commands we would choose Data Sources () in the Files of Type box in the dialogs. This launches a standard Manifold dialog, the Data Source dialog, as a simple user interface for connecting to databases and data files. The Data Source dialog can also connect to simple file types as above and is used to connect to those simple file types for more sophisticated uses, such as linking a drawing from a table stored in a file. The Data Source dialog is always used when linking a drawing or linking a surface.

The Data Source dialog remembers a list of previously-used data sources and allows point and click connection without requiring users to remember what can be complex connection settings or obscure locations on hard disk.

The remembered list of previously-used data sources will be available within the Data Source dialog no matter what part of Manifold needs to connect to a data source. For example, it is frequently the case that if we import data from a database we might also want to export data to that same database. It is therefore very convenient to have that database connection already in the Data Source dialog's list whether we launch commands from the File - Import or the File - Export menus.

The first time we use a data source we will have to add it to the list in the Data Source dialog. Thereafter, the data source will be remembered in the list.

The Data Sources dialog works with all data source connection technologies supported by Manifold. The Data Sources dialog works with the Database Console, the Administrator Console and is also available when importing, linking and exporting components such as drawings, images and surfaces via the File - Export, File - Import, File - Link and similar dialogs. Choosing Data Sources () in the Files of Type box in such dialogs will invoke the Data Sources dialog.

Data Sources

There are generally two types of data sources we use with Manifold:

- **File-based data sources** - These are simply data files, such as .CSV (comma separated values) text files, .XLS (Excel), .DBF (dBase II / FoxBase), .MDB (Access) or other files. Some such data files can be very simple, such as plain, human-readable ASCII text files while other such data files, such as .MDB, can be more complex and require software that understands their internal organization to utilize. What file-based data sources have in common is that they all store data in files within Windows and applications that want to utilize the data in those files will open, read and write those files using some suitable connection methodology. Manifold can connect to all popular data file formats using either a connection technology specific to that data file such as, for example, Microsoft Jet for standard...
Microsoft file types such as Access .MDB or Excel .XLS, or a generic connection technology such as ODBC, OLE DB or ADO .NET.

• **Database servers** - DBMS servers are software products like Oracle, SQL Server, DB2, PostgreSQL, MySQL and similar that provide information through software connections. When we connect to a DBMS server we may not know exactly how the server stores information since we never actually connect to a specific file. Instead, the DBMS server provides whatever information we need. Manifold can connect to all popular DBMS servers using either a connection technology specific to that server such as, for example, OCI (Oracle Call Interface) for Oracle, or a generic connection technology such as ODBC, OLE DB or ADO .NET.

Either of the above types of data source can be added as a data source within the Data Source dialog. In addition, a third way of specifying a data source connection, DSN and UDL files, can also be specified as a data source.

DSN and UDL files do not themselves store data but instead are a way of saving within a file the information required to establish an ODBC or an OLE DB connection with a given data source, which could be file-based storage or a database server. A DSN connection describes a connection using ODBC and a UDL file describes a connection using OLE DB. Opening the DSN or UDL file within Manifold establishes the connection specified by that file.

**Using the Data Sources Dialog**

On first use the Data Sources dialog has no data sources listed. We first add a data source to the list. We can then double-click the data source to connect. The Data Sources dialog will remember data sources for future use, including in future Manifold sessions.

**To Add a Data Source**

1. Choose an operation, such as pressing the ... button in the Database Console, that launches the Data Sources dialog.
2. Click on the Add Data Source button. This launches the Connect To dialog.
3. In the Connect To dialog choose the connection method desired in the Files of type box and proceed through the dialogs for that connection method to add the data source.

**To Connect to a Data Source**

1. Launch the Data Sources dialog.
2. Double-click on a data source, or, click on a data source in the list to highlight it and press OK.

**To Delete a Data Source**

1. Launch the Data Sources dialog.
2. Click on a data source in the list to highlight it.
3. Click on the Delete button.

**Data Sources Dialog Commands**

- Add Data Source - Add a new data source.
- Delete - Delete highlighted data source.

(Contents pane) Displays a list of data sources, showing the name and type of connection for each.

Name Name to use for the highlighted data source.

(Connection string) Connection string to use for the highlighted data source.
Click to edit connection string using the standard dialogs for that connection technology.

Any PASSWORD and PWD parameters used in a connection string will be masked in the connection string to protect security.

Data Source Connections for Spatial DBMS

In addition to the usual roster of ADO .NET, OLE DB, and ODBC connections Manifold Enterprise Edition and higher editions provide specialized native DBMS connection choices that are used when adding a new data source using a spatial DBMS in the Data Source dialog.

DB2 Data Sources
Connect to IBM DB2 equipped with the DB2 Spatial Extender using IBM’s native spatial connection technology.

Oracle Data Sources
Connect to Oracle using OCI, the Oracle Call Interface to utilize Locator or Oracle Spatial facilities.

PostgreSQL Data Sources
Connect to PostgreSQL equipped with the PostGIS spatial extender using native PostgreSQL connection technology. Connections made using this data source will have any password required masked so that later usage will not inadvertently expose the password.

SQL Server Data Sources
Connect to Microsoft SQL Server 2008 spatial DBMS facilities using native SQL Server 2008 spatial connection technology.

Users sometimes ask if there is a special connection when using SQL Server 2005 as a spatial DBMS with the Manifold Spatial Extender for SQL Server installed. There is no need for a special connection because Manifold when connecting to SQL Server using any OLE DB connection will recognize and automatically use spatial indices managed by the spatial extender when the Manifold spatial extender has been installed.

Example: Create a Data Source for SQL Server Express

Let's add a connection to a local SQL Server Express data source to the Data Sources dialog. This is a straightforward connection for using SQL Server 2005 and not a native connection to SQL Server 2008 spatial.
We begin by launching Database Console and then clicking the [ ] button to specify a data source.

Click the **Add Data Source** button in the Data Source dialog.

In the **Connect To** dialog choose **OLE DB Data Sources ()** in the **Files of type** box.
In the Data Link Properties dialog’s Provider tab we choose the SQL Native Client and press Next.

In the Data Link Properties dialog:

1. Enter the data source and/or location of the data:
   - Data Source: \(\text{(local)\:SQLExpress}\)
   - Location:

2. Enter information to log on to the server:
   - Use Windows NT Integrated security
   - Use a specific user name and password:
     - User name:
     - Password:
     - Blank password: [ ]
     - Allow saving password: [ ]

3. Enter the initial catalog to use:

Pressing the Test Connection button is almost always a good idea at this point, to make sure there is nothing grossly wrong (such as a typographical error) in the information provided. When we are happy the connection is live, we press OK.

In the Connection tab we specify the settings used for our local SQL Server Express installation. In the case of this example we use the default data source name of \(\text{(local)\:SQLExpress}\) and Windows NT integrated security, which is the default recommended by Manifold’s SQL Server Express installation instructions.
Back in the Data Sources dialog we see that a new data source has been added using the default name for the connection. It is usually wise to enter some more memorable name that will help us recognize data sources in a more useful manner. This is easy to do.

In the Name box we can enter the friendly name we would like to use to identify this data source. Given the sophistication of data connection technologies available in Windows we might have many different data sources we use. For example, we might have a connection to a DBMS on a different machine that we wish to name County parcel records on main server or some other useful name that will help us immediately recognize that data source.

In this manner we can add more data sources. When done adding data sources, we can highlight the one desired and press OK.
Back in the Database Console we can see we have connected to the local SQL Server Express database. This database has very little data in it, only three drawings. Note that Database Console will display the friendly name we assigned to this data source.

**Example: Create a Data Source for an Access .MDB File**

Let's add a connection to an Access .mdb database file. We'll connect to the sample Northwind Traders file distributed with many editions of Access.

We begin by launching Database Console and then clicking the [...] button to specify a data source.

Click the Add Data Source button in the Data Source dialog.

In the **Connect To** dialog choose **MDB Files** in the **Files of type** box. Navigate to the folder and file desired and double-click on the file, in this case the nwind.mdb file.
This adds another OLE DB data source, since Manifold automatically connects to files such as .mdb using Microsoft's built-in OLE DB provider for such files. To avoid confusion we should change the name of this data source to something more recognizable.

We change the Name to Northwind Traders Sample MDB and press OK.
The result is that Database Console connects to the Northwind Traders database in the nwind.mdb file.

**Example: Create a Data Source for Oracle Express**

Let's add a connection to a local Oracle Express data source to the Data Sources dialog.

- We begin by launching Database Console and then clicking the [...] button to specify a data source.

- Click the **Add Data Source** button in the Data Source dialog.

In the **Connect To** dialog choose **Oracle Data Sources ()** in the **Files of type** box. This will connect using OCI, the **Oracle Call Interface** native to Oracle.
In the Oracle Data Source dialog we provide the Server name, the User Name and the Password. Settings shown are the default settings recommended in Manifold’s installation instructions for Oracle Express. As always, pressing the Test button to make sure we have entered the password and other information correctly is a good idea. When we are happy the connection is live, we press OK.

Back in the Data Sources dialog we see that a new data source has been added using the default name for the connection and showing that it is a native Oracle connection. We will add a friendly name.
In the **Name** box we enter **Local Oracle Express**. This will help us remember that this particular Oracle data source is a connection to the local DBMS, which will be useful if in the future we create connections to Oracle databases on different machines. Press **OK**.

Back in the **Database Console** we can see we have connected to the local Oracle Express database. (We could use some work on the filter settings in Database Console for this particular connection to suppress display of all the various DBMS objects that are not Manifold components.)

**Linking Drawings or Surfaces**

The **Data Source** dialog is *always* used when linking drawings or surfaces. For example, if we would like to link a drawing from an **MDB** file (such as when creating a linked drawing from a geocoded table), we must first add the **MDB** file as a data source in the **Data Source** dialog and then link the drawing from that **Data Source**.
In addition, when linking a drawing or a surface the Data Source dialog will launch with a "built-in" data source of This Project. Choosing that data source will connect to the project and make available components within the project from which the drawing or surface can be linked. The primary usage will be linking a drawing or surface from a table or query within the project.

**Connection Technologies**

There are many different connection technologies in use in the Microsoft world that we can use to connect to data sources.

When connecting to a native spatial DBMS we must always use the native connection technology if one is available. For example, when connecting to Oracle databases we should always use OCI, the Oracle Call Interface.

Use OLE DB to connect to databases when using generic Manifold spatial indices for spatial DBMS work or when connecting to SQL Server 2005 using the Manifold Spatial Extender for SQL Server or when connecting in a general way to databases. The disadvantage of using OLE DB is that the dialogs required to initiate a connection are more complex. Given that the Data Source dialog remembers previous data sources added to the dialog's list, that is not inconvenient because once a connection is set up it can be used with a simple double-click in the Data Sources dialog.

**Connecting via ADO.NET**

Manifold can also import or link data from ADO.NET data sources. Manifold includes a generic importer that is listed as ADO.NET Data Sources() in the Files of Type box when creating a new data source in the Data Source dialog. In addition, Manifold includes four dedicated importers designed for importing or linking data from the standard ADO.NET providers installed by the .NET Framework: ODBC, OLE DB, Oracle and SQL Server.

The generic import prompts for a .NET DLL (in the Assembly box) with an ADO.NET provider, the provider class, and the connection string.

The ADO.NET ODBC importer displays the standard ODBC data source dialog. The ADO.NET OLE DB importer displays the standard OLE DB data source dialog. The ADO.NET Oracle importer prompts for a server name and login credentials (integrated security or a specific login and password). The ADO.NET SQL Server import prompts for a server name, login credentials (integrated security or a specific login and password), and optional database name.
Some UDL (Universal Data Link), DSN, OLE DB and ODBC data sources may be dependent on the presence of third party database systems or ODBC drivers in the Windows system. For example, to connect to Btrieve databases, we will need a Btrieve ODBC driver on our system. To connect to Oracle databases, we will need an Oracle database server to which we can connect. Manifold automatically installs a variety of OLE DB providers that will connect to most popular data sources.

**Important:** Tables linked from ADO.NET data sources are always read-only. If read-only access is acceptable, ADO.NET is often the fastest possible connection and should be used in preference to ODBC or OLE DB for that reason. If read-only access is not acceptable, then OLE DB should be used if possible.

### Oracle Call Interface

When connecting to Oracle data sources Manifold can use the Oracle Call Interface (OCI), the native Oracle interface for exchanging data. Using the native interface provides better performance and allows using features not exposed through generic database interfaces such as ODBC, OLE DB and ADO.NET.

Exchanging data with Oracle data sources via OCI automatically maps Manifold geometry columns into Oracle SDO_GEOMETRY data. SDO_GEOMETRY values representing collections of geometric entities are not supported.

### Data Link Properties Dialog

When configuring a data source, Manifold uses the standard Microsoft OLE DB data source Data Link Properties dialog to allow connection to OLE DB data sources. It's a lot easier to use than it looks.

Choose the OLE DB data link type desired. Note that in Microsoft's world there are often many different ways to access the same type of data. For example, Manifold can open any Access .mdb file directly, or we can open an .mdb file by using the Microsoft Jet 4.0 OLE DB Provider. If we've installed any "Office" software or other database capable software, we will also have an ODBC driver on our system that can open Access .mdb files as well. So, we could use the OLE DB Provider for ODBC Drivers to open an ODBC data source for .mdb files.

After choosing the provider, click the **Next** button to move to the **Connection** tab.
The **Connection** tab will be pre-loaded with the right connection parameter choices for the type of OLE DB provider selected. In the illustration above, we've chosen the provider for ODBC Drivers and so we see the right connection options for connecting via ODBC. The **data source name** list box will be pre-loaded with the ODBC data sources currently configured on our system.

If we had chosen the OLE DB Provider for SQL Server and then pressed **Next**, the **Connection** tab would be loaded with the right choices to connect to a SQL Server database via OLE DB.

Provide the necessary information for the provider chosen and then press **OK**. The **Advanced** tab shows various advanced options for the specified provider, and the **All** tab provides a summary of the data link properties specified.

Sophisticated database systems such as SQL Server or Oracle may be configured in sophisticated ways. The information in the **Connection** tab and, possibly, the **Advanced** tab reflect the sophistication of such systems. If you are unfamiliar with the specific expectations of the SQL Server or Oracle or other provider that you wish to use, you may have to consult with the database administrator in charge of the installation to determine the correct settings to use.

**Connecting Via ODBC**

ODBC as a database connection technology preceded OLE DB, so there are more ODBC drivers for different types of databases than there are OLE DB drivers. Manifold System connects to ODBC data sources through whatever ODBC drivers are installed on the computer.

ODBC is easy to use if we remember that the slightly tedious part is creating a new "source." Some ODBC sources are quite simple and consist of specifying what type of database driver to use (dBase, Access, etc.).
Other ODBC sources, such as connecting to SQL Server via ODBC, are more complex and require what type of driver to use, which database is to be opened and from which machine or server it is fetched. In the case of some systems, such as SQL Server and Oracle, there are both OLE DB and ODBC drivers.

Set up ODBC data sources using the Windows ODBC Data Sources administrator dialog that is called by clicking on the ODBC Data Sources icon in the Windows Control Panel. This icon is located in the Administrative Tools folder in the Control Panel in Windows 2000 and subsequent Windows editions.

Using UDL Files and OLE DB Data Sources

A Microsoft UDL file is simply a pre-packaged shortcut to an OLE DB data source. We create a UDL file as noted below. We can then use OLE DB data link properties dialogs to configure the data link that will be used by the UDL file. Note that when opening an OLE DB data source or creating a UDL file we end up using exactly the same OLE DB dialogs.

Why bother with creating a UDL file if doing so requires us to use the OLE DB dialogs anyway? It's not really necessary with the Data Sources dialog, which can remember an OLE DB connection perfectly well. However, creating a UDL file can serve as a shortcut for other applications to connect to the same data source.

Creating and Using a UDL File

Creating a UDL file is a standard Microsoft procedure that is documented in Windows (search for "UDL" in Windows Help). Suppose we have an Excel spreadsheet that contains a table and we would like to connect to that table using a UDL file. Our spreadsheet is called MySheet.xls. We would proceed as follows:

1. In Windows Explorer, right click and choose New - Text Document. Create a text document called MySheet.udl. Windows will complain about changing the extension from .txt to .udl. That's OK.
2. Double-click on MySheet.udl to open the Data Link Properties dialog.
3. Configure the Data Link Properties dialog as shown in the illustration below. Press OK. The UDL will now contain a data link to the Excel spreadsheet.
4. Launch Manifold and choose File - Import - Table and then open MySheet.udl. Choose the table desired.
UDL files are normally used to automate more complicated connections than shown above. They may be used to provide user credentials such as a user name and password or to use a complex connection string when required. Windows 2000, Server 2003 and XP all include documentation for creating UDL files as part of Windows help. Other versions of Windows may not include this documentation, although the capability is there if you have installed any one of many packages that install the Microsoft data access routines that enable universal data links.

Performance

The internal Manifold database engine used to maintain imported tables is usually substantially faster than external database systems, and is matched or exceeded only by the very fastest enterprise class DBMS products such as Oracle or SQL Server.

Manifold’s facility with Microsoft data types as well as installation remarks for some Windows versions admonishing users to install Jet service packs occasionally leads to the misconception that Manifold internally uses Jet for database management. That is not the case.

Although Manifold includes a copy of Microsoft’s “Jet” database engine (the same used in Access), Jet is not used to maintain tables that are imported into Manifold. Jet is used only as an accessory to handle external files. All imported tables are managed using the internal Manifold database engine and all queries are executed using the Manifold SQL engine, both of which are purpose-built systems engineered for the specific demands of fast geometry/attribute work in GIS.

When linking external tables into Manifold one ends up using whatever database engine or system is associated with those external tables. Performance will therefore almost always decrease when using linked tables from simple, consumer-style data sources (such as Access or Excel tables) as compared to the speed of imported tables.

Linked tables will be as fast as or faster than internal Manifold tables when the external tables are very large and the provider is a sophisticated engine such as SQL Server or Oracle using a fast connection such as ADO.NET (or, in some circumstances, OLE DB) for SQL Server or OCI for Oracle. Even if they are not as fast as Manifold’s
dedicated engine for smaller databases, enterprise database systems such as SQL Server nonetheless are still very fast. Therefore, it is not likely that any performance difference between imported tables or linked tables will be noticed with smaller tables when enterprise class engines such as Oracle or SQL Server are used.

When using external DBMS tables, use the fastest connection possible, which may vary depending on the DBMS in use. For example, when connecting to Microsoft's SQL Server, ADO.NET is faster than OLE DB and OLE DB is faster than ODBC. ADO.NET is much faster than ODBC. However, ADO .NET is generally read-only, which limits the utility of that technology. Consider that connecting to a remote SQL Server can take much longer than connecting to a local SQL Server. For example, suppose that connecting to a table inside the Manifold project takes 1 unit of time. A very rough guide to equivalent times to access the same table using different connection and DBMS technologies is listed in the accompanying table. Clearly, it is very unwise to connect to remote SQL Server installations using ODBC.

<table>
<thead>
<tr>
<th>Time</th>
<th>Source for Table</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Native table (inside the project)</td>
</tr>
<tr>
<td>8</td>
<td>Linked from a local MDB file</td>

<tr>
<td>10</td>
<td>Linked from a local SQL Server via ADO.NET</td>
</tr>
<tr>
<td>40</td>
<td>Linked from a local SQL Server via OLE DB</td>
</tr>
<tr>
<td>10</td>
<td>Linked from a remote SQL Server via ADO.NET</td>
</tr>
<tr>
<td>250</td>
<td>Linked from a remote SQL Server via OLE DB</td>
</tr>
<tr>
<td>6000</td>
<td>Linked from a remote SQL Server via ODBC</td>
</tr>
</tbody>
</table>

The default connection to Oracle servers is always OCI, so Oracle connections always run at the fastest possible connection speed unless we manually force the connection to use an alternative, such as OLE DB or ODBC.

See the Performance Tips topic for specific tips to maximize table and query performance.

**Working with SQL Server and Oracle**

**Very important:** When working with server-based OLE DB providers such as SQL Server and Oracle, users are strongly encouraged to maintain primary keys in all tables linked into the Manifold project. A side effect of how such servers interact through OLE DB is that if the table does not have a primary key, performance will be greatly reduced.

**Linking to Oracle Tables**

The default connection to Oracle tables is OCI, which greatly simplifies life with Oracle. Connect using the Oracle Data Sources type and all will be well.

However, if for some reason we need to connect using OLE DB or ODBC to an Oracle Server, we should make sure to follow these tips:

- Always set the **Allow saving password** option. If this option is not set, the system will connect for the first time but not at all other times. The intricacies of the OLE DB / ODBC interaction that takes place within the Microsoft OLE DB Provider for ODBC Drivers are such that it is almost never possible for the Manifold to jump into the middle of the connection process and prompt the user for a username and password.

- Do not use the native Oracle ODBC driver. Use the Microsoft OLE DB Provider for ODBC and use Microsoft ODBC for Oracle. The native Oracle drivers are limited to forward-only cursors (which is by far the simplest and the lowest performance type of database cursor allowed in ODBC drivers) and thus are unusable in Manifold or many other programs, such as Microsoft Access. Future editions of Manifold will add special routines to allow use of the Oracle driver.

**Working with OLAP**
OLE DB drivers allow connections to many data sources besides simple database tables. For work with OLAP, for example, Microsoft's SQL Server Decision Support Services (the Microsoft OLAP package) has an OLE DB that can be used to import or link a "table" that pulls data from the OLAP cube. The driver supports Microsoft's MDX language that can be used to fetch information from OLAP cubes. The MDX language is very rich and thus allows sophisticated work with OLAP cubes. Needless to say, the driver works fine with Manifold.

When Logins and Passwords are Required

When linking tables via a connection to some database providers such as Oracle or SQL Server the connection may fail without proper user credentials if security settings in the database provider require a username and password. In such cases Manifold will raise a login dialog that allows specification of a user name and password.

The dialog includes a Remember username and password checkbox that is off by default. Check this box to save the provided user name and password with the table within the .map file. This will enable automatic linking using these credentials the next time the .map file is opened. Note: the user name and password will be saved with the table in encrypted form within the .map file. It is strongly recommended that any such .map files containing your user credentials be protected by setting appropriate Windows access privileges on the .map file or the folder that contains it.

Tech Tips

Manifold can use all of the standard Microsoft DBMS connection technologies, such as ADO .NET, to connect to data sources. There are a huge number of possibilities with such connection technologies that are documented by Microsoft and other educational resources for standard Microsoft facilities. As this documentation is aimed at Manifold and is not intended as a general educational resource for standard Microsoft facilities it will not attempt to duplicate the many educational resources already available for those standard Microsoft technologies.

If you would like to utilize databases such as SQL Server or Oracle and you would like to connect to them using technologies such as OLE DB or ADO.NET, there are very many books on those subjects that provide full details, tips and other useful information on using these standard connection technologies.

The data source selection dialog automatically recognizes data sources which do not support storing drawings, images or surfaces. For example, we cannot store images into a .txt file. Attempting to select a data source which does not support storing components of a certain type during the export of a component of that type displays a warning message below the list of data sources and disables the OK button.

Notes

In a perfect world, every OLE DB provider or ODBC driver or external DBMS they serve that is installed on our systems would work without error. Regrettably, in real life the various database drivers and providers installed in our systems will contain bugs. Even in the case of the high quality drivers provided by Microsoft, one only need read the Microsoft Knowledge Base and the release notes for various Microsoft service packs to see that many bugs have been identified in such drivers. Manifold uses Microsoft drivers and OLE DB providers to connect to various types of database tables. If there are errors in the Microsoft drivers, such errors will affect Manifold as they would any other application.

If you suspect a database driver bug, take time to research the issue within the online Microsoft Knowledge Base. A useful experiment might be to import the table instead of linking to it and seeing if the problem persists. If it goes away, that is evidence that the problem lies in the external database system or is a bug in the drivers for that system. To reduce the likelihood of bugs in external software make sure you have applied the latest service pack for the external database system you are using.

When running SQL within Manifold queries, one is using the Manifold SQL engine. When executing SQL within the Database Console one is using whatever SQL is the native SQL of the external database system. One should be aware that SQL implementations in various database systems can contain numerous bugs. For example, even as well crafted an SQL as Jet SQL used within Microsoft's Access products contains numerous bugs. If an SQL bug occurs within the Database Console, the bug should be tracked down with the vendor of the external database system being used.

NVIDIA CUDA

For many operations Manifold will automatically use multiple processors or multiple processor cores if installed in a computer system. In addition to this basic multiprocessing capability Manifold includes the ability to utilize massively parallel multiprocessing in the form of NVIDIA CUDA-enabled products, such as the NVIDIA GPU plug-in card seen below that provides 480 processors and supercomputer performance for under $500.

It is not an exaggeration to say that NVIDIA CUDA technology could well be the most revolutionary thing to happen in computing since the invention of the microprocessor. It's that fast, that inexpensive and has that much potential. NVIDIA CUDA is so important that all Manifold users should insist that computer hardware they procure is CUDA-enabled. In fact, given the ubiquity of NVIDIA products it is quite likely that a recently-procured computer will already include a CUDA-enabled NVIDIA GPU of some sort.

Introduction

NVIDIA is best known for motherboard chip sets as well as for outstanding graphics processors that have become popular as the basis for graphics cards. In the quest for maximum speed, NVIDIA’s GPUs (Graphics Processing Units) have evolved far beyond single processors. Modern NVIDIA GPUs are not single processors but rather are parallel supercomputers on a chip that consist of very many, very fast processors. Contemporary NVIDIA GPUs range from 16 to 480 stream processors per card, delivering incredibly powerful computing bandwidth. The card shown above, for example, provides 480 stream processors.

Although the market impetus behind the creation of such supercomputers on a plug-in board has been the computational demands of the PC gaming market, such "graphics" boards have become so powerful that the scientific computing community has begun using them for general purpose computing. It turns out that many mathematical computations, such as matrix multiplication and transposition, which are required for complex visual and physics simulations in games are also exactly the same computations that must be performed in a wide variety of scientific computing applications, including GIS.

NVIDIA has supported this trend by releasing the CUDA (Compute Unified Device Architecture) interface library to allow applications developers to write code that can be uploaded into an NVIDIA-based card for execution by NVIDIA’s massively parallel GPUs. This allows applications developers to plug in a teraflop-class, 480-processor, NVIDIA-based card and upload applications to run within the NVIDIA GPU at far greater speed than possible on even the fastest general purpose CPU on the motherboard. For a mere few hundred dollars we can use CUDA to achieve true, supercomputer performance on the desktop.

CUDA offers such tremendous performance gains that many functions within Manifold have been re-engineered to execute as parallel processes within CUDA if such a card is available. If we have a CUDA-capable NVIDIA graphics card installed in our system, Manifold can take advantage of the phenomenal power of massively parallel NVIDIA stream processors to execute many tasks at much greater speed.

Because NVIDIA technology benefits from enormous economies of scale in the gaming market, CUDA-enabled cards have become very inexpensive for the performance they provide. At the present writing CUDA-enabled cards can be purchased for less than $100 for an entry-level CUDA-capable card and easily under $350 for a high performance CUDA-capable card. It is easy and inexpensive to choose a card with the balance between performance and cost desired (more stream processors running at faster clock rate with more memory gives better performance).
CUDA-Enabled GPUs

Dozens of vendors provide graphics cards based upon CUDA-capable NVIDIA GPUs and it is almost not possible for a high-performance PC or motherboard vendor to introduce a product that does not do a good job of hosting such GPU cards. The insatiable demand of gamers for more performance has also spawned an industry of vendors offering ever-faster memory, more powerful power supplies and other systems components that are perfect for creating outstanding GIS desktop and server machines.

The easiest way to see if a particular graphics card is CUDA-enabled is to first check which NVIDIA GPU it utilizes. Next, visit the NVIDIA web site at http://www.nvidia.com and in the web site's search box enter "CUDA-Enabled GPU" to find pages that list NVIDIA GPU products which can be utilized for CUDA-enabled parallel processing. Almost all contemporary NVIDIA GPUs are CUDA-enabled.

If anything, the surprise is discovering that quite a few NVIDIA GPUs aimed at motherboard chipsets or mobile applications like portable computers are also CUDA-enabled, albeit with a smaller number of processors per GPU.

NVIDIA at the present writing provides three families of CUDA-enabled GPU products. All three families may be used with Manifold and CUDA:

- **GeForce** - The GeForce line of NVIDIA GPUs are sold primarily through a wide variety of graphics card and motherboard manufacturers which incorporate the NVIDIA chips into their own graphics cards. Performance tends to be high and prices kept low by fierce competition in gaming markets.

- **Quadro** - The Quadro line of NVIDIA GPUs is manufactured and sold directly by NVIDIA into very high end professional workstation graphics markets. Quadro cards provide extraordinarily high resolutions and massive graphics memory for the most demanding workstation applications. Some Quadro products also appear in high end portable computers, and some Quadro products are also provided in external cabinets similar to Tesla packaging.

- **Tesla** - The Tesla line of NVIDIA GPUs is also manufactured and sold directly by NVIDIA to support high performance computing where supercomputer performance through parallel processing is required. Although they are also available as plug-in cards, Tesla GPUs are best known for being packaged into external cabinets (either desktop or rack mount) that provide two or four GPUs per cabinet.

The external cabinets used for Tesla and some Quadro products attach to desktop computers using a special cable that plugs into an interface card plugged into a standard PCI-E slot. This allows the external Tesla or Quadro configuration to appear to software as if it were a plugged-in PCI-E card just like typical GeForce cards. However, because the actual GPUs are hosted in an external cabinet that provides power and cooling, the host computer does not need to be retrofitted with additional power and cooling.

CUDA Limitations and Requirements

There are several important constraints on CUDA use within Manifold:

- We must have a CUDA-enabled NVIDIA card installed in our system. 200 and 400 series NVIDIA cards at the present writing are the best-known CUDA-enabled cards, but other NVIDIA GPUs are also CUDA-capable (check with the NVIDIA web site and with your graphics card vendor's web site to see if a particular card is CUDA-capable). Hardware evolves so rapidly under the pressure of gaming industry economy-of-scale that almost before this documentation can be published there will be even faster CUDA-capable cards. manifold.net recommends getting Fermi-class (400 series) GPUs. May as well get the best!

- The rest of our PC system must have sufficient speed and power to support the NVIDIA card. For example, memory must be fast enough to handle CUDA bandwidth and power supplies must provide enough power to run the NVIDIA card (or cards) with extra PCI-E power cables. Consult any technology-obsessed, 14 year old gamer for advice on configuring a suitably "hot" system.

- We must have installed NVIDIA's most recent set of drivers for Windows, which may be downloaded from the nvidia.com web site. NVIDIA's latest drivers automatically install software required for CUDA use by CUDA-capable NVIDIA-based cards.

- If we are running a 64-bit Windows system we must have installed NVIDIA's 64-bit, CUDA-enabled drivers for our 64-bit Windows system.

- Writing massively parallel algorithms to implement spatial functions is extremely difficult, even for manifold.net. Therefore, at the present time only a few dozen functions have been implemented within Manifold that can leverage CUDA. Many more are on the way.
Introduction

- Existing CUDA-enabled functions within Manifold are Surface - Transform dialog operators for surfaces. The Surface - Transform dialog is part of the optional Surface Tools extension for Manifold (and also a built-in part of some Manifold System editions such as Universal Edition and Ultimate Edition). If we do not have the Surface Tools extension we will not have the ability to use this dialog and hence no ability to leverage CUDA. New updates and future Manifold releases will likely add many more usages of CUDA in addition to the Surface - Transform dialog operators.

- Functions executed within CUDA cards are virtually instantaneous compared to speed of execution within the main processor. However, the NVIDIA stream processors execute tasks so rapidly that it is difficult to provide data fast enough from disk and memory to keep the processors occupied. The resulting performance in most “real life” applications therefore tends to be limited not by processor speed but rather by the speed with which data can be fetched from hard disk or other memory. In addition, a good portion of various tasks are not bound by computation but instead involve overhead tasks such as writing out results to disk, re-computing levels and other necessary but mundane tasks that are not accelerated by CUDA processors. The net result is that as a practical matter for many tasks CUDA-enabled processors will visibly increase speeds, almost always by a factor of two to ten and at times by a factor of ten to fifty, but not usually by factors of hundreds for the overall task even if the actual computation of parts of the task goes hundreds of times faster.

- We can get the most out of CUDA if the rest of our machine does not slow down the ability to feed the insatiable power of NVIDIA stream processors. For maximum speed we should use 64-bit Windows on at least a quad core machine with lots of RAM and large, fast disk drives. Before configuring a new 64-bit system, check the NVIDIA web site to make sure that 64-bit drivers are available for the Windows operating system you plan to install. At the present writing, Windows XP x64 has been used as a baseline common denominator for development of x64 support by manifold.net with all development in Vista and Windows 7 as well.

Despite the above limitations it is clear that CUDA is a revolutionary technology. NVIDIA GPUs are so fast that a routine comment from developers is that NVIDIA renders the main processor almost superfluous, as if even the fastest multi-core Intel chip is relegated to being nothing but an accessory processor to handle the keyboard and mouse. That is not hyperbole given that NVIDIA GPUs can run jobs 200 or even 300 times faster than even the fastest Intel CPUs. See the demo below for an example.

Such speed advantages are not a competitive challenge that traditional processor vendors can afford to ignore. CUDA is the first of what is likely to be a new wave of massively parallel architectures from competitors such as Intel and AMD. Manifold's parallel code has been expressly written to allow easy implementation on future “many-core” processor solutions from Intel and AMD that will compete with NVIDIA CUDA.

Installation and Configuration

Once we have installed CUDA-capable NVIDIA hardware and NVIDIA drivers there is no need for any other configuration. Note that you must install 64-bit NVIDIA drivers when operating 64-bit Windows.

Make sure to download and install the latest NVIDIA drivers. Current generation NVIDIA software installs CUDA capability as part of the main NVIDIA driver installation. Manifold looks for current NVIDIA software. Because driver installation discs provided within graphics board packages might have been mastered many months ago, it is important to download and install the latest drivers from NVIDIA's web site.

Make sure to download and install the latest Manifold update. Although the nature of CUDA means that few changes need be made to support new NVIDIA GPUs, some changes are required to keep up with rapid evolution. Recent updates have added support for Fermi-series NVIDIA cards, for example. If you don't install the latest Manifold update you won't be able to use Fermi-series cards.

When launched, Manifold will automatically detect and utilize CUDA-enabled hardware. The Use GPGPU technologies (NVIDIA CUDA) option in the Tools - Options - Miscellaneous dialog is turned on by default.

When a CUDA-enabled card is present Manifold will report finding the card in the Help - About dialog in the GPU value. Manifold System Release 8.00 reports CUDA-enabled GPUs either as the more recent Fermi series GPUs or all earlier CUDA-enabled GPUs as pre-Fermi.
The above illustration shows a Manifold Help - About report in a 64-bit Windows system in which two CUDA-enabled cards have been installed, both of which use NVIDIA GPU devices prior to the Fermi series.

If a CUDA-enabled card has not been installed or if current NVIDIA drivers have not been installed or if the Use GPGPU technologies (NVIDIA CUDA) option in the Tools - Options - Miscellaneous dialog has been turned off, the Help - About dialog will report Graphics only for the GPU, as seen above.

If a Fermi series card is present, it will be reported as seen above. All Fermi series cards (for example, GTX 480 or GTX 470 GeForce cards or Tesla C2050 or C2070 cards) will be reported as a Fermi device. The above shows a Help - About display for a 64-bit Windows system that has one Fermi card, a GTX 480, in it.

Functions Utilizing CUDA

At the present writing the following Manifold Surface - Transform dialog functions utilize CUDA if available: Aspect, AvgValue, Blur, CurvGauss, CurvMean, CurvPlan, CurvProfile, DifferenceE, DifferenceN, DifferenceNE, DifferenceNW, DifferenceS, DifferenceSE, DifferenceSW, DifferenceW, Diversity, DiversityIndex, HighPass1, HighPass2, HighPass3, Laplace1, Laplace2, LowPass1, LowPass2, LowPass3, MajValue, MaxValue, MedianCross,MedianSquare, MedianSquare5, MedValue, MinValue, Sharpen, SharpenMore, Slope, SumValue, Tile and TileMedian functions.

Additional functions and use of CUDA are expected to be added with each new Manifold release. New products such as the successor to Release 8 expected in 2010 will include new internal architectures to support CUDA even more effectively.

Demos

We often will be asked to demonstrate the speed of CUDA for colleagues, so it is handy to have a familiar example available that can be quickly run to demonstrate the power of GPU computing. This demo uses the example Montara Mountain surface within an easily-remembered demonstration that shows the power of CUDA.

This example assumes we are running 64-bit Windows XP on a machine with at least one CUDA-capable NVIDIA graphics cards installed. It will work fine on 32-bit Windows as well, but why use old-fashioned Windows when 64-bit Windows has been happening for over seven years? It also will work fine on Windows 7 or Vista or other Windows versions. In this particular example we've installed one GTX 480 card, which uses a Fermi series GPU that provides over 480 processing cores.

The demo also requires a Manifold installation that includes the Surface Tools extension (automatically enabled when Universal Edition or Ultimate Edition are installed) so that the Surface - Transform dialog is available.

The greatest performance difference visible with CUDA appears when the Surface - Transform dialog is used for a complex calculation on a surface that is not too large. This shows off the intense computational performance delivered by CUDA without requiring many disk accesses (which take a proportionately larger amount of time for large files) slowing down the works.

For an example of a complex calculation, suppose we have a surface called MySurface. Launch the Surface - Transform dialog and execute a formula such as:

\[ \text{Slope([MySurface]) + Slope([MySurface] * 2) / 2} \]
Slope([MySurface] * 3)/3 + Slope([MySurface] * 4)/4

This is a nonsensical but complex formula that will execute much faster using CUDA than without CUDA. Although this and the other formulas shown in this example are artificial examples, they share many of the mathematical characteristics of sophisticated "real life" operations on surfaces so they are genuinely representative of real performance gains available through CUDA.

The more complex the formula the greater the advantage from using CUDA. For example, we can compute aspect as well as slope and also use an optional window size parameter for both functions in a formula (using a window size of 5) such as:

\[
\]

Let’s apply the above to a specific example.

We will use the Montara Mountain sample surface to measure computing speed with and without CUDA. We begin by importing the Montara Mountain surface, as is illustrated in examples such as the Combine a Surface and a Drawing in a Map topic.

We rename the surface to a very short, one letter name, s, to facilitate quick keyboarding.
In the Tools - Options dialog's Miscellaneous page we verify the Use GPGPU technologies (NVIDIA CUDA) option has been turned on.

Manifold can log reports to the history pane such as the time required to execute functions. We will also turn on the Log transform time option in the Logging page in the Tools - Options dialog.

Launching the Help - About dialog we can see that Manifold has detected a Fermi series CUDA-capable device installed in the system.

CPU: Intel(R) Core(TM)2 Quad CPU @ 2.40GHz
GPU: CUDA (1 device, Fermi)
RAM: 6190 MBytes
OS: Windows XP (b3790) Service Pack 2
Running in 64-bit mode.

No doubt even a fire-breathing GTX 480 as used in this example with 480 processors per device will soon seem slow given how fast NVIDIA is introducing newer and more powerful devices, but this example using a GTX 480 is still highly instructive for the tremendous gains achievable through GPU computing at very low cost.
With the surface open in a window we launch the Surface - Transform dialog entering the following formula (which may be copied from this Help window and pasted into the dialog):

\[
slope(s,5) + aspect(s,5) + \nonumber \\
slope(s*2,5) + aspect(s*2,5) + \nonumber \\
slope(s*3,5) + aspect(s*3,5)\nonumber
\]

We check the Save result as new component box for two reasons: first, because that uses slightly less overhead than applying the results to the subject surface and, second, because not altering the subject surface preserves it unmodified for the next trial.

Press OK and Manifold launches into action using CUDA to compute the formula, reporting the time required in the History pane:

Surface Transform: 1.494 sec

The History pane reports how long the computation takes, in this case approximately 1.5 seconds. Times may vary slightly depending on precise system configuration: a Fermi series GPU providing 480 stream processors is so incredibly fast that it computes the task almost instantaneously. The time required overall is mostly overhead such as fetching data from disk and getting it through the CPU to the GPU and not actual calculations; therefore, running the same task again will cut the time slightly by about a tenth or a few hundredths of a second as Windows caches the data used for more efficient provision to the GPU.

The result of the Surface - Transform formula computation is a new surface, automatically named \( S_2 \).

Let's now see how long the computation takes without using CUDA. We can measure this in identically the same system for an “apples to apples” comparison by simply switching off the Use GPGPU technologies (NVIDIA CUDA) option in the Tools - Options dialog.

In the Tools - Options dialog's Miscellaneous page we uncheck the Use GPGPU technologies (NVIDIA CUDA) option to instruct Manifold not to use CUDA.
Launching the Help - About dialog again we can now see that Manifold no longer uses CUDA and reports
Graphics only for the installed GPU.

Once more we run the same formula in the Surface - Transform dialog. As before, the time required for the
computation is reported in the History pane, appearing below the last time logged:

Without CUDA the computation takes dramatically longer, over 424 seconds. Wow! Using the CPU instead of the
NVIDIA Fermi GPU took about 284 times longer. It takes so much longer because the computation must happen
on the Intel main CPU, which even when run as a true 64-bit device by 64-bit applications code in 64-bit Windows
is far, far slower than the phenomenal supercomputer speed of the NVIDIA Fermi device. In this case, the main
CPU really is insignificant compared to the speed of the GPU.

It's true the machine used in this example is not the latest, greatest machine: it has an Intel Core 2 Quad CPU
and not the latest Core i7 quad. An Intel Core i7 is indeed a faster CPU than the prior generation Intel Core 2
Quad used in this example. However, most users do not yet have a Core i7, and even if they did the Core i7 is
not remotely as fast as the NVIDIA GPU. If we spend a lot more money to buy a really fast Core i7 we can drop
the time required from about 424 seconds to about 261 seconds, that is, only about 1.6 times faster than the Core
2 Quad instead of being 284 times faster with the NVIDIA GPU. That's no comparison, especially when faster
Core i7 processors cost more than the $300 to $500 cost of a Fermi card. Even a less expensive Fermi card like
a GTX 470, selling for under $350 as of this writing, will execute the job in only 1.7 seconds, about 250 times
faster than the CPU alone.

More complex formulas will require yet longer times. For example, in the same system used above, computing
the formula...

\[
\text{slope}(s, 5) + \text{aspect}(s, 5) + \\
\text{slope}(s^2, 5) + \text{aspect}(s^2, 5) + \\
\text{slope}(s^3, 5) + \text{aspect}(s^3, 5) + \\
\text{slope}(s^4, 5) + \text{aspect}(s^4, 5)
\]
...requires \(2.389\) seconds with CUDA and \(740.955\) seconds without CUDA, about \(310\) times faster with CUDA.

The comparison is especially dramatic when considering that the hardware used for the above example is a typical, highly capable base system with a 64-bit, quad core processor and 8 GB of RAM. It's faster than the dual core CPUs used by most people. A fast system makes for a good demo, because it minimizes the time required for overhead chores accomplished by Manifold as part of the demo. The actual computation of surface values using CUDA is very fast with most of the time required for the CUDA-enabled timings going to overhead such as setting up the job and writing out the resulting surface.

**Very Important:** After doing this demo, don't forget to turn on the Use GPGPU technologies (NVIDIA CUDA) option in the Tools - Options dialog so that future work can take advantage of CUDA!

**Demo Notes**

Experienced demonstrators will usually create the above demo in advance as a Manifold .map project file that has the surface already imported and example computations for the Surface - Transform dialog saved in Comments components as text (a .map file with all that done may be downloaded from the manifold.net web site).

To do the demo, the Comments component can be quickly opened and the desired text copied and then pasted into the Surface - Transform dialog. Showmanship is an important part of good demos so it is important not to allow the audience to get bored while we keyboard a formula into a dialog. Using copy and paste also eliminates the need to remember the exact syntax of slope or aspect functions. The Surface - Transform dialog will "remember" the last formula used in a .map project, but just in case someone changes the formula it is a good idea for demos to have a spare copy of the formula in a Comments component.

Part of showmanship is launching the Help - About dialog after changing the option to use or not use CUDA so that the audience can see for themselves that Manifold is or is not using CUDA. This is the computer demo equivalent of a magician showing the audience "there is nothing up my sleeve."

It is also important to remember to turn on the Log transform time option in the Logging page in the Tools - Options dialog and to have the History pane open, so that the audience can see for themselves the exact timing of each trial.

Although longer demos can show the very much longer periods of time required for non-CUDA performance, it is important not to bore the audience. A comparison of \(1.5\) seconds to seven minutes usually conveys the intended message. \(1.5\) seconds goes by instantly, especially if the demonstrator says a few words about what is going on after pressing the OK button, while seven minutes seems endless and unendurable in comparison.

[The unendurable seven minutes make for an especially memorable demo for those who want to contrast Manifold's CUDA-enabled supercomputer speed with legacy GIS software products that do not have CUDA-enabled supercomputer speed but which do cost several thousand dollars per license to run hundreds of times slower.]

The easiest approach is to do the CUDA-enabled trial first, so the audience sees it goes rapidly, and then launching the interminably long process without CUDA on the second trial as the demonstrator discusses CUDA architecture, the wide availability of NVIDIA-based hardware, the breadth and depth of CUDA-capable devices and the extraordinary economics of scale attained by leveraging mass market interest in massively parallel GPUs for gaming. While all this talk is going on the audience will see with their own eyes that in the background the non-CUDA computation is still painfully crawling along for many minutes to do what the CUDA computation accomplished in a second or two.

More experienced demonstrators will often choose to perform the non-CUDA trial first. This requires greater skill with timing of presentations so that the speaker's commentary coincides more or less with the end of the computation. In this case the demonstrator will launch the transform operation and then spend the next six minutes or so talking about CUDA, describing what the Surface - Transform dialog is about, talking about the Montara surface, describing how even with a quad core main processor this is a long and complex calculation and
every now and then directing the audience's attention to the lengthy computation with a comment such as, "Nope, not done yet...". After such a set-up audiences are inevitably dazzled by the amazing speed of CUDA.

This particular demo uses a completely artificial formula that serves no practical purpose except to illustrate speed of computation. But the formula is very representative in that it provides an easily-understood example of a legitimately complex calculation that has about the same demands on computation of sophisticated mathematics typical of significant computations on surfaces.

"Real life" computations on surfaces tend to use very complex formulas that are difficult to explain to an audience that does not consist of remote sensing or GIS experts. However, just about everyone can understand what slope and aspect are.

**Slope** gives the degree of inclination of a surface. It is a way of finding which parts of a surface are relatively flat and which are steep. **Aspect** gives the directional orientation of a surface, to find which parts of a surface, for example, are facing South. Computing either slope or aspect involves a large number of local calculations over the entire extent of a surface to find the slope or aspect for each individual pixel of the surface. The use of a five pixel window simply controls how many neighboring pixels are considered when computing slope or aspect. The use of a window is a way to demonstrate additional computational complexity by forcing an interpolation of sorts within each local computation of either slope or aspect.

**Other Notes**

The **Help - About** dialog seen in this example shows that this particular system has one CUDA-capable device of **Fermi** class installed. The demo was run using an EVGA GTX 480 card providing a total of 480 stream processors. An outstanding benefit of NVIDIA technology is that speeds are doubling almost every year while costs are remaining constant or are going down.

The **Help - About** dialog reports the number of CUDA-enabled GPUs found. Some cards have more than one GPU in the "card." For example, some double-wide cards (such as the original GTX 295 reference design) are really two circuit cards packaged within the same double-wide fan housing, with a GPU on each card for a total of two GPUs. Such cards will be reported as two GPU devices. Plug in two such cards and Manifold will report four GPU devices. Some cards (such as the GTX 295 "Co-op" series) have a single circuit card with two GPU devices mounted on the card. Installing one such card will likewise be reported as two GPU devices.

Experienced Manifold users will see from the screen shot of the Montara Mountain surface that it has been projected and that a palette coloring the surface by height has been applied using the surface display options dialog. Projections and surface display options have no effect on performance of **Surface - Transform** computations with or without CUDA.

CUDA capability is enabled by default. To turn it off, turn off the Use GPGPU technologies (NVIDIA CUDA) option in the Tools - Options - Miscellaneous dialog. Remember to turn the option back on after doing a demo!

**Troubleshooting**

**No CUDA card reported in Help - About dialog**

- Has a CUDA-capable NVIDIA card been installed in the computer? Note that not all NVIDIA-based graphics cards have CUDA capability. You must have an NVIDIA-based card that supports CUDA. Almost all reasonably contemporary NVIDIA GPUs now support CUDA.
- Have you installed the most recent NVIDIA drivers downloaded directly from NVIDIA's web site? Older drivers, such as those often found on installation DVDs packaged with graphics cards, may not work even if they appear to install some sort of CUDA software.
- Have you changed a graphics card recently? Swapping cards, even within the same series (like switching from a GTX 470 to a GTX 480) may require re-installation of NVIDIA display drivers and restarting the system.
- If you are working with 64-bit Windows have you installed a 64-bit Manifold license? Have you launched the 64-bit Manifold installation? Recall that 64-bit Manifold installations will install both a 64-bit and a 32-bit Manifold executable so that a 32-bit Manifold version can be launched for compatibility with older, 32-bit software (such as Access); however, if you want to work with 64-bit CUDA in 64-bit Windows you should launch the 64-bit Manifold version. See the 32-bit and 64-bit Manifold Editions topic.
- If you are working with 64-bit Windows have you installed 64-bit NVIDIA CUDA drivers? Did you install the right NVIDIA drivers for your Windows system? For example, if you are running Vista x64 you should probably not expect that a driver package provided specifically for Windows XP x64 will work.
Note that as of this writing not all NVIDIA driver packages for all possible Windows versions include CUDA support. Drill down into the nvidia.com web site using search terms such as "CUDA downloads" to see if your Windows version is supported.

- Check to make sure that the Use GPGPU technologies (NVIDIA CUDA) option has been enabled in the Tools - Options - Miscellaneous dialog.

No Surface - Transform dialog

- Have you licensed the optional Surface Tools extension for Manifold and activated it? Launch the Help - About dialog to see if the extension is reported as an installed extension. The Surface Tools extension is a built-in part of Universal Edition and Ultimate Edition and does not require activation if you are using either of those two editions. If you are using some other edition and have licensed Surface Tools, you must activate it by following the instructions in the Installing and Activating a Manifold Extension topic.

- Do you currently have a surface open as the active window or as the active layer in a map? The Surface - Transform dialog is not available if the focus is not on a surface window or a surface layer in a map.

Performance gain not observed

- Launch the Help - About dialog: does Manifold report any CUDA-capable devices installed in the system? If not, see the troubleshooting section above.

- Are you executing functions within the Surface - Transform dialog? CUDA at the present writing works only with functions within that dialog. It makes no difference in other functions or other parts of the system, except of course that since CUDA cards are also very fast graphics cards the performance of 3D terrain rendering will be very good.

- Are you executing functions that are listed as supporting CUDA? Writing formulas in the Surface - Transform dialog that utilize functions not listed as supporting CUDA will not benefit from CUDA.

- Is the data set very small? Some cases of small data compute so rapidly that there is little to gain by using CUDA since even a base system without CUDA will execute the task very rapidly.

- Is the formula very simple? CUDA speeds up computation but not overhead like fetching data from disk. If a computation involves a simple formula there is not much to speed up because the computation will get done very rapidly in any event so the time for the job is mostly overhead.

- Is the data set very large? As with the case of simple formulas, if data sets are very large then overhead tasks like fetching data from disk become proportionately larger compared to the time spent on computation. Since CUDA increases the speed of computation, if computation is a proportionately smaller part of the task compared to overhead there will be less visible effect from CUDA.

- Does your project involve slow system resources? Read the Performance Tips topic carefully to make sure your project and your system are structured for maximum performance. If a project does something that cripples performance, such as using a linked component that must come into the project from a very slow network link, then overhead delays will be very great with or without CUDA.

- Are you sure CUDA has not improved performance? Try timing the task with CUDA on and with CUDA off by turning on and off the option to use CUDA in the Tools - Options - Miscellaneous dialog, as illustrated in the demo above. You may be surprised to find that something which seems to take forever, ten minutes or so, with CUDA indeed takes far longer, like hours or days, without CUDA.

Database Installations

Database Installations

Manifold System is often used with database management systems. In particular, Enterprise Edition is often used with DBMS packages to create Enterprise servers, or to store drawings in databases to allow concurrent, multi-user editing. Manifold traditionally has supported the three top commercial enterprise class DBMS packages, IBM DB2, Microsoft SQL Server and Oracle.
All three of these DBMS packages may be used as a spatial DBMS either using built in facilities (Oracle) or using optional, free spatial extenders (IBM and SQL Server). In addition, all three packages at the present writing are available in free "Express" editions that as of the time of this writing anyone may download from the vendor's website and use at no charge. See the vendor's web page for current availability and for details on the terms and conditions of use.

Because of free availability and superb functionality, these three packages (as well as open source alternatives such as PostgreSQL / PostGIS) are great choices for use with Manifold. The Express versions are for the most part equivalent to the flagship enterprise versions of each DBMS, with some reasonable limitations as follows:

**IBM DB2 Express-C Edition**
- Runs on up to two processors multithreaded using up to 4 GB of RAM. No limit on database size or on the number of users. Can be enabled as a spatial DBMS by downloading the free IBM Spatial Extender for DB2 from IBM's web site.

**Oracle Express Edition**
- Runs on one processor using up to 1 GB of RAM. 4 GB limit on database size. No limit on the number of users. Supports full Oracle spatial SDO_GEOMETRY technology. Does not support Oracle Spatial GeoRaster technology.

**SQL Server Express Edition**
- Runs on one processor using up to 1 GB of RAM. 4 GB limit on database size. No limit on the number of users. Impressive integration with .NET and Visual Studio. Can be enabled as a spatial DBMS by downloading the free Manifold Spatial Extender for SQL Server from the Updates page on the manifold.net web site.

New users skimming this documentation for the first time might mistakenly think that to function correctly Manifold requires installation of a DBMS package. That is not the case. All editions of Manifold include within Manifold itself very sophisticated and powerful DBMS capabilities so that Manifold may be used without any need to install additional DBMS software.

However, in addition to Manifold's internal DBMS capabilities, Manifold can also utilize external DBMS packages like the three mentioned in this topic to provide additional benefits to users. Especially in an enterprise setting, the use of a standard DBMS can provide additional power and capacity, enhanced collaboration with many simultaneous users and greater interoperability with applications already working with that DBMS.

Although the use of a major DBMS package has traditionally been thought of as something of interest only to enterprise users, because the Express versions of the major DBMS packages are so easy to install and because the Manifold interfaces for working with such DBMS packages are so much simpler than was previously the case with older software, many individual users or small groups have found that using a DBMS as a centralized geospatial data warehouse makes sense for them even though only one person is doing GIS.

### Three World-Class Choices

Recent years have seen the emergence of freely distributed "Express" editions introduced by the "Big 3" database vendors: IBM, Microsoft and Oracle.

These editions typically include the main features of the vendor's big-time "enterprise" database product but have been limited in some way. The idea is to make it possible for independent software vendors (ISVs) like Manifold to incorporate usage of such database products so that customers can get involved with the database product, fall in love and then ultimately buy the full-fledged, enterprise version of the database product as their needs grow.

It’s a highly effective strategy, as Microsoft proved by giving away free versions of the "Jet" database engine used in Access for use by ISVs. The result was tens of thousands of software applications that all standardized on the database engine used by Access. Unsurprisingly, when it came time for users of such applications to buy a DBMS package, they mostly bought Access and competitors were extinguished.

When Microsoft entered enterprise DBMS markets with SQL Server, they tried to repeat that strategy by offering the SQL Server database engine in a free, limited edition of SQL Server. Both Oracle and IBM countered that strategy by introducing free Express editions of their own products that raised the stakes on the original SQL Server Desktop Edition.
In a gutsy move, Oracle incorporated a significant amount of its elite spatial technology within Oracle Express. IBM entered the fray by introducing an Express edition of DB2 that has no limits on the number of users that may use the product or on the size of databases. Microsoft pushed forward with an enhanced free edition called SQL Server Express Edition that features especially tight integration with .NET and Visual Studio. The result is that all three Express editions deliver products of astonishing range, power and quality at no additional charge.

In the summer of 2007 IBM made available at no charge the IBM Spatial Extender for DB2 for use with DB2 Express-C, and the Manifold Spatial Extender for SQL Server became available at no charge for Manifold licensees. These developments migrated all three Express editions into competition as spatial DBMS packages as well.

The traditional way to limit a free DBMS version is to limit the number of processors it can use, the size of the database it can host and the amount of RAM it can use. This allows free, extensive use of the package in smaller applications while reserving the profitable, higher end applications for the paid version that has no such limits. Oracle and SQL Server both limit their Express editions to only one processor, one gigabyte of RAM and databases no larger than four gigabytes. IBM limits DB2 Express-C to two processors, four gigabytes of RAM and no limits on the size of the database.

Whichever DBMS Manifold users choose, the availability of three of the best enterprise-class DBMS packages ever created for free download is a testament to the extraordinary competitiveness, technical skill and confidence of these three DBMS vendors. Manifold users can install these database servers to create Enterprise servers for use with Enterprise Edition or as centralized data sources to save drawings that will be accessed by other users.

**No Technical Support**

Important: Manifold.net does not provide any support whatsoever for installation, administration, management, configuration or use of the DBMS products provided by IBM, Microsoft or Oracle.

If you download one of the database packages mentioned above, please keep in mind they are not supported by manifold.net and usually they are not supported by the DBMS vendors, either. If you want a supported DBMS installation, you must purchase a supported DBMS product from one of the DBMS vendors or you must purchase support products, if such are available, for the free DBMS product you are using from the vendor of that DBMS product. Manifold.net does not sell support products for the free DBMS products cited in this documentation.

Please do not waste technical support tokens by sending in tokens for questions about the free DBMS products. Doing so will simply waste a token to no good purpose. See the Technical Support topic for general information on tech support and using tech support tokens.

Developer level support incidents may be used for questions about Enterprise Edition features used with these three database products, but only for the actual Enterprise dialog. For example a question about connecting with Enterprise Edition via Database Console to an Oracle data source will result in an answer limited to the use of the Manifold dialog, such as explaining the purpose of the Server, User Name and Password boxes. Support does not extend to explaining how you can configure users in the DBMS, how to determine what server name is being used or should be used or how to determine whether a given user has connectivity to a given data source.

The DBMS products provided for free by major vendors are each supported by a vast industry of training products. Hundreds of books, for example, have been written on SQL Server alone, ranging from texts aimed at "dummies" to those covering the most sophisticated uses imaginable. Users intending to take advantage of these DBMS products should acquire and utilize the appropriate educational materials. It's not that difficult and many resources are standing by to help people learn and use these wonderful products.

IBM, Microsoft and Oracle are each doing a really extraordinary thing by providing free access to their incredibly elegant and powerful DBMS packages. Each vendor obviously has good business reasons for doing so, in the hope that later sales of full versions will justify the expenses of offering Express editions at no charge, but that only works if the DBMS vendors are not overwhelmed by uncooperative folks seeking free support for the free Express editions. Let's all work together not to ruin a good thing.

IBM DB2 Express-C Edition
Oracle Express Edition
SQL Server Express Edition
IBM DB2 Express-C Edition
At the present writing, IBM provides for free a complete, downloadable distribution of IBM® DB2® Express-C Edition. IBM DB2 Express-C provides the power of IBM DB2 to Manifold System users at no additional charge.

IBM DB2-Express C may be used by Manifold Enterprise Edition users to configure Enterprise Servers for use with Enterprise Edition or to store drawings using geometry data types as well as tables. See the Geometry in Tables topic.

Introduction
IBM DB2 Express-C Edition is derived from the same engine upon which IBM DB2 is built, so it shares the very high performance of IBM's flagship DBMS products. When delivered in IBM DB2 Express-C form, IBM has limited the database engine in two key ways:

- IBM DB2 Express-C may be installed on a multiple CPU machine, but it will execute (run) only on up to two processors or up to two processor cores if multi-core processors are used.
- IBM DB2 Express-C may be installed on a server with any amount of memory, but will use only up to 4 GB of available RAM memory.

Other than these limitations IBM DB2 Express-C provides essentially the full power and breadth of IBM DB2 capabilities. In particular, there is no limit on the size of databases and no limit on the number of simultaneous users.

Manifold System documents use of IBM DB2 Express-C within Manifold applications for several purposes:

- All Manifold System users can use DB2 Express-C to create high performance databases in which tables, drawings, images and surfaces may be stored. Those tables, drawings, images and surfaces can then be imported or linked into Manifold projects. Users may also write scripts that exploit the power of DB2 for the creation of databases and tables that may be used by their projects.
- All Manifold System users can store drawings within DB2 databases for concurrent, multi-user editing of drawings. If we have Manifold Database Administrator Edition we can configure DB2 storage using the Administrator Console to enable user-friendly features such as friendly names, formatting storage for drawings and pre-set import and link options.
- Manifold Enterprise Edition users can create Enterprise servers within DB2 databases hosted by a DB2 Express-C server. Because there is no limit to the size of databases or the number of users permitted to a DB2 Express-C installation, it is a good choice for Enterprise Server applications.
- Manifold Enterprise Edition users can create a spatial index for drawings within DB2 Express-C databases to confer true spatial DBMS capability unto DB2 Express-C. Once Enterprise Edition has been used to create a spatial index within a given DB2 Express-C database, users of any Manifold System edition can take advantage of that spatial index, for example, to link objects from drawings within a given area of interest.
- IBM offers a Spatial Extender for DB2 that provides IBM's own spatial DBMS capability for DB2. As of the summer of 2007, the Spatial Extender became available as a free download for DB2 Express-C. Manifold supports native DB2 / Spatial Extender functionality for those users who are working with Spatial Extender. Although Manifold allows using geometry types from other vendors (including Manifold's own geometry type) together with generic spatial indices established by Manifold, if the DBMS vendor has their own spatial types it makes sense to use them. Therefore, if you are working with DB2 / Spatial Extender manifold.net strongly recommends using native DB2 geometry types and not generic spatial indices or some other geometry type for drawings.

Because IBM DB2 Express-C is the same as IBM DB2 except for the processor / RAM limitations, if a Manifold application outgrows these limits it is very easy to scale upward by installing a full IBM DB2 license. Usually when an application grows so large that it outgrows IBM DB2 Express-C limits it is sufficiently important to merit the additional expense of procuring a full IBM DB2 license.

Installation and Configuration
The installation package currently downloadable from IBM installs IBM DB2 Express-C and configures it to start automatically on system startup.

IBM has distributed several versions of IBM DB2 Express-C. IBM DB2 Express-C Edition is used in this documentation since it is widely used. Consult the applicable IBM website for information on newer versions that may be available.
**Limitations**

IBM DB2 Express-C Edition may be used for Enterprise Edition Enterprise Servers without any technical limitations. However, two small usage limitations apply when DB2 Express-C is used for storing geometry in tables in the database to support subsequent concurrent, multiuser editing. When a drawing is linked from a DB2 Express-C data source the following limitations apply:

- Adding a new object and immediately editing it without refreshing the drawing creates an editing conflict.
- Adding a new object and immediately deleting it without refreshing the drawing will fail.

Therefore, when ever editing drawings linked from a DB2 Express-C data source make sure to refresh the drawing after adding a new object before attempting to edit that object or to delete that object.

**No Technical Support**

*Important:* Manifold.net does not provide any support whatsoever for installation, administration, management, configuration or use of the DBMS products provided by IBM. See the Database Installations topic for details.

Prefer to get your product code and content on media? DB2 Express-C code images and related resources are available on DVD for Windows and Linux platforms. Request a no-charge copy for yourself.

DB2 Redbook Library:

http://www.ibm.com/cgi-bin/software/track0.cgi?i=47501&c=74648&o=1&ef=T&cn=7600833

IBM Redbooks are written by leading IBM technical experts. Small teams write the Redbooks during four- to six-week residencies. Sample these professional-grade publications online at no charge.

Porting to DB2 Universal Database:

http://www.ibm.com/cgi-bin/software/track0.cgi?i=53017&c=74648&o=2&ef=T&cn=7600833

The developerWorks DB2 Universal Database porting site gives you the information you need to port an application and its data from other database management systems to DB2 UDB.

How to buy IBM software products:

http://www.ibm.com/cgi-in/software/track0.cgi?i=51964&c=74646&o=5&ef=T&cn=7600831

IBM DB2 Universal Database Express-C is a no-charge product which is released without formal IBM support. If you decide you need 24/7 support from IBM, you must upgrade to the full version of DB2 Express, or other qualified DB2 products. There are a number of ways to buy IBM software. Please choose the method that best fits your needs.
Oracle Express Edition

At the time of writing, Oracle provides at no charge a downloaded distribution of Express versions of Oracle. Because many people have downloaded it in the past and now use it, this topic uses Oracle® 10g Express Edition. More recent Express editions of Oracle software will probably follow similar procedures. Oracle Express provides the power of Oracle to Manifold System users at no additional charge. Oracle Express Edition is often referred to as Oracle XE for short.

Oracle XE may be used by Manifold Enterprise Edition users to store Manifold components. It may also be used to store drawings using geometry data types as well as tables. Oracle XE includes Oracle's SDO_GEOMETRY technology from Oracle Spatial, which provides superior performance and a range of extra features such as the ability to link only part of a drawing in the desired area of interest in Manifold Enterprise Edition. Oracle XE does not include support for GeoRaster technology, so it can not be used to store images or surfaces in GeoRaster form. See the Oracle Spatial Facilities topic for additional information.

Introduction

Oracle Express Edition is derived from the same engine upon which Oracle Enterprise Edition is built, so it shares the very high performance of Oracle's flagship DBMS products. When delivered in Oracle Express form, Oracle has limited the database engine in several ways:

- User data cannot exceed 4 gigabytes in size (in addition to Oracle system data).
- Each computer can host only one instance of Oracle Express.
- Oracle Express may be installed on a multiple CPU machine, but it will execute (run) only on a single processor or a single processor core if multi-core processors are used.
- Oracle Express may be installed on a server with any amount of memory, but will use only up to 1 GB of available RAM memory.

Other than these limitations Oracle Express provides essentially the full power and breadth of Oracle capabilities.

Manifold documents use of Oracle Express within Manifold applications for several purposes:

- All Manifold System users can use Oracle Express to create high performance databases in which tables, drawings, images and surfaces may be stored. Those tables, drawings, images and surfaces can then be imported or linked into Manifold projects. Users may also write scripts that exploit the power of Oracle for the creation of databases and tables that may be used by their projects.
- All Manifold System users can store drawings within Oracle databases for concurrent, multi-user editing of drawings. Users of Manifold Enterprise Edition can use native Oracle connections for increased performance, use native Oracle data types such as SDO_GEOMETRY, restrict objects in a linked drawing to a desired area of interest, automatically create spatial indices and triggers for increased performance and employ automatic handling of routine database administration tasks when exporting drawings as well as other benefits. If we have Manifold Database Administrator Edition we can configure Oracle storage using the Administrator Console to enable user-friendly features such as friendly names, formatting storage for drawings and pre-set import and link options.
- Manifold Enterprise Edition users can create Enterprise servers within Oracle databases hosted by a Oracle Express server.
- Manifold provides a set of generic spatial DBMS facilities that are normally used to confer spatial DBMS capability to DBMS products that do not have their own spatial capabilities. Because Oracle is a very capable DBMS in addition to providing Oracle's own spatial technology, these generic facilities work with Oracle as well. However, it does not always make sense to use them. For example, in addition to the use of Oracle's native spatial DBMS capabilities, Manifold Enterprise Edition users can create a generic spatial index for drawings within Oracle Express databases. Given the universal presence of Oracle's own spatial technology within Oracle Express this does not make sense and is not recommended.
- A full license for Oracle Spatial (not just Oracle Express) will include Oracle's GeoRaster technology for storing images. If you are using a GeoRaster capable Oracle product it makes sense to use Oracle's own storage technology and not Manifold's generic spatial DBMS storage technology for images and surfaces. However, those users who do not have access to Oracle GeoRaster may want to use Manifold's generic facilities to store images and surfaces within Oracle Express.

Because Oracle Express is the same as Oracle except for the user data size limitation and processor / RAM limitations, if a Manifold application outgrows these limits it is very easy to scale upward by installing Oracle Enterprise Edition or other Oracle product. Usually when an application grows so large that it outgrows Oracle Express limits it is sufficiently important to merit the additional expense of procuring Oracle Enterprise Edition.
**Installation and Configuration**

The installation package currently downloadable from Oracle installs Oracle Express and configures it to start automatically on system startup. See the Installing Oracle topic for details.

**Further Reading**

Because Oracle Express is, in fact, Oracle there is a massive amount of reading material available to users who wish to learn more. In general, any documentation for Oracle will apply to Oracle Express so long as one keeps in mind the above differences between Oracle and Oracle Express.

When searching the Oracle.com site for additional information, search for Oracle Express Edition. Useful links that were current at the time this documentation was written include the following links.

**A Security Note**

When Oracle Express is installed it uses Windows authentication by default. It is strongly recommended that the user work with Oracle Express using Windows authentication.

**No Technical Support**

**Important:** Manifold.net does not provide any support whatsoever for installation, administration, management, configuration or use of the DBMS products provided by Oracle. See the Database Installations topic for details.

SQL Server Express Edition

At the time of writing, Microsoft provides at no charge a downloaded distribution of Express versions of SQL Server. Because it has been widely used in the past, this documentation uses Microsoft® SQL Server™ 2005 Express Edition as an example. Procedures for more recent versions of SQL Server Express are similar.

Microsoft also available by download the newest editions of SQL Server, such as Microsoft® SQL Server™ 2008 Express Edition. SQL Server 2008 has built-in spatial capabilities. SQL Server 2005 does not, but can be used as a spatial DBMS using the free Manifold Spatial Extender for SQL Server.

Introduction

SQL Server 2005 Express Edition is derived from the same engine upon which Microsoft SQL Server 2005 is built. It is a newer and, in many key ways, better alternative to the SQL Server 2000 Desktop Engine (known as MSDE) distributed in earlier Manifold releases.

When delivered in SQL Server Express form, Microsoft has limited SQL Server in several ways:

- A database cannot exceed 4 gigabytes in size.
- SQL Server Express may be installed on a multiple CPU machine, but it will execute (run) only on a single processor or a single processor core if multi-core processors are used.
- SQL Server Express may be installed on a server with any amount of memory, but will use only up to 1 GB of available RAM memory.

Other than these limitations SQL Server Express provides virtually the full power and breadth of SQL Server capabilities. Although MSDE was limited to no more than five users, SQL Server Express no longer has such an artificial throttle on performance. Within the limits of processor, RAM and maximum database size, SQL Server Express always runs at full speed.

Manifold documents use of SQL Server Express within Manifold applications for several purposes:

- All Manifold System users can use SQL Server Express to create high performance databases in which tables, drawings, images and surfaces may be stored. Those tables, drawings, images and surfaces can then be imported or linked into Manifold projects. Users may also write scripts that exploit the power of SQL Server for the creation of databases and tables that may be used by their projects.
- All Manifold System users can store drawings within SQL Server databases for concurrent, multi-user editing of drawings. If we have Manifold Database Administrator Edition we can configure SQL Server storage using the Administrator Console to enable user-friendly features such as friendly names, formatting storage for drawings and pre-set import and link options.
- Manifold Enterprise Edition users can create Enterprise servers within SQL Server databases hosted by a SQL Server Express server.
- Manifold Enterprise Edition users can create a spatial index for drawings within SQL Server Express databases to confer true spatial DBMS capability unto SQL Server Express. Once Enterprise Edition has been used to create a spatial index within a given SQL Server Express database, users of any Manifold System edition can take advantage of that spatial index, for example, to link objects from drawings within a given area of interest.
- Manifold users may download at no charge the Manifold Spatial Extender for SQL Server that provides high performance spatial indices for SQL Server. Users working with SQL Server 2005 Express should always download and install the Manifold spatial extender.
- Microsoft provides native spatial DBMS capability in SQL Server 2008. Manifold supports native SQL Server 2008 spatial functionality. Although Manifold generic spatial indices and the Manifold Spatial Extender for SQL Server will work with SQL Server 2008 spatial, if you have access to SQL Server 2008 spatial you should use that in preference to either generic spatial indices or the Manifold spatial extender.

Because SQL Server Express is the same as SQL Server except for the processor and RAM limitations and four-gigabyte database limit, if a Manifold application outgrows these limits it is very easy to scale upward by installing SQL Server. Usually when an application grows so large that it outgrows SQL Server Express limits the application is sufficiently important to merit the additional expense of procuring SQL Server.

This topic introduces SQL Server Express in the context of simple, default use with Enterprise Edition. If you do not have Enterprise Edition you will not have Enterprise features such as the Server Console. For more sophisticated configuration and usage of SQL Server Express, see the Microsoft documentation for SQL Server and SQL Server Express.
Installation and Configuration

The installation package currently downloadable from Microsoft installs SQL Server Express and configures it to start automatically on system startup. Install SQL Server Express and restart the system. SQL Server Express will appear as a SQL Server installation on the system.

Installing SQL Server Express Edition requires that we first install .NET Framework 2.0. The latest version of .NET Framework 2.0 available at the time of publication may be downloaded from Microsoft.

Installing SQL Server Express Edition:

1. In Windows Explorer, navigate into the folder into which you downloaded the installation files for SQL Server Express Edition and double-click the .EXE file.
2. In the End User License Agreement step of the installation, check "I accept the licensing terms and conditions" and click Next.
3. In the Installing Prerequisites step, click Install, wait until all prerequisite components are installed, and then click Next.
4. In the Welcome to the Microsoft SQL Server Installation Wizard step, click Next.
5. In the System Configuration Check step, inspect all generated warnings and click Next.
6. In the Registration Information step, click Next.
7. In the Feature Selection step, select the desired features and click Next. Default settings work OK.
8. In the Authentication Mode step, select Windows Authentication Mode and click Next. It is recommended to always use Windows Authentication Mode, unless there is a well-understood, significant reason not to.
9. In the Error and Usage Report Settings step, choose to automatically send error reports or feature use data to Microsoft, if you so desire, and click Next.
10. In the Ready to Install step, click Install.
11. In the Setup Progress step, wait until the installation completes, then click Next.

After the installation completes, you will be able to connect to the newly created instance of SQL Server using an administrative login from the machine on which SQL Server has been installed. You may want to configure the instance so it can be accessed by users who do not have administrative rights and/or users working on different machines.

Users planning on using SQL Server 2005 Express as a spatial DBMS should download and install the Manifold Spatial Extender for SQL Server onto the SQL Server machine.

While SQL Server configuration questions are outside of the scope of this Help topic, the following section provides an example of configuring an instance of SQL Server Express for use by ordinary users of a particular domain over a network. The following assumes execution right after completing the installation as shown above, using the same account which has administrative rights:

Allowing other machines to see an instance of SQL Server

1. Press the Start menu button and launch Microsoft SQL Server 2005 - Configuration Tools - SQL Server Configuration Manager.
2. In the tree on the left, select SQL Server 2005 Configuration Manager (Local) - SQL Server 2005 Network Configuration - Protocols for SQLEXPRESS. In the pane on the right, right click the TCP/IP item and select Enable. Click OK to dismiss the warning that the changes will not take effect until the SQL Server service is stopped and restarted.
3. In the tree on the left, select SQL Server 2005 Configuration Manager (Local) - SQL Native Client Configuration - Client Protocols. In the tree on the right, make sure the following items are enabled: Shared Memory, TCP/IP, Named Pipes. If any of the items is not enabled, right click it and select Enable.
4. In the tree on the left, select SQL Server Configuration Manager (Local) - SQL Server 2005 Services. In the pane on the right, right click the SQL Server Browser item and select Properties. In the SQL Server Browser Properties dialog, switch to the Service tab, make sure the Start Mode option is set to Automatic, then click OK. Right click the SQL Server Browser item again and select Start. Right click the SQL Server (SQLEXPRESS) item and select Restart.
5. Close SQL Server Configuration Manager.

6. If you have Windows Firewall turned on, turn it off. Alternatively, use the SQL Server Configuration Manager application to configure SQL Server to use specific TCP ports, then launch Control Panel - Windows Firewall, select the **Exceptions** tab, and specify the configured ports as exceptions.

**Allowing other users to connect to and use an instance of SQL Server**

7. Press the **Start** menu button and launch **Command Prompt**.

8. Execute the following command line:

```
SQLCMD -S (local)\SQLEXPRESS -E
```

9. Execute the following commands to create a new database and switch to it:

```
CREATE DATABASE test
GO
USE test
GO
```

10. Execute the following commands to allow users of the domain **MYDOMAIN** to connect to SQL Server and access the new database:

```
CREATE LOGIN [MYDOMAIN\Domain Users] FROM WINDOWS
GO
EXEC sp_grantdbaccess 'MYDOMAIN\Domain Users'
GO
```

11. Execute the following commands to assign one of the users of the domain **MYDOMAIN** as the owner of the new database:

```
EXEC sp_changedbowner 'MYDOMAIN\John'
GO
```

12. Execute the following commands to allow another user of the domain **MYDOMAIN** to write data to the new database:

```
EXEC sp_addrolemember 'db_ddladmin', 'MYDOMAIN\Jane'
EXEC sp_addrolemember 'db_datawriter', 'MYDOMAIN\Jane'
GO
```

13. Execute the following commands to allow all other users of the domain **MYDOMAIN** to read data from the new database:

```
EXEC sp_addrolemember 'db_datareader', 'MYDOMAIN\Domain Users'
GO
```

14. Execute the following command to exit SQL Server console:

```
EXIT
```

After following the above steps it is easy to test that a SQL Server Express installation is functional by using the Database Console in Manifold to quickly connect to SQL Server.

It is possible to connect using either ODBC, OLE DB or ADO .NET. We recommend using OLE DB for read-write connections and for all spatial DBMS work. We also recommend installing SQL Server Native Client on all client
machinges and then using the SQL Native Client provider. If we haven’t installed the SQL Server Native Client we can connect to SQL Server using the default OLE DB Provider for SQL Server.

Connecting to a SQL Server Express Installation:

1. Launch Manifold and launch the Tools - Database Console command.
2. Press the [...] browse button to the right of the Data source box.
3. Follow the instructions in the Create a Data Source for SQL Server Express example section of the Data Source Dialog topic to create a data source for the desired SQL Server Express installation in the Data Source dialog. Double click on that data source to connect to it.

Once a data source for a SQL Server Express installation has been created the Data Source dialog will remember it. It will be available for subsequent uses with Database Console as well as with Administrator Console (if we have Database Administrator Edition installed).

Configuring SQL Server Express as an Enterprise Server

This section is for Manifold Enterprise Edition users. As discussed in the Data Storage Strategies topic, Enterprise Edition allows a simplified “shared” storage strategy that combines the benefits of file-based storage with those of full scale DBMS storage.

After installing SQL Server Express we can configure the SQL Server installation for use as an Enterprise Server.

To read (get) components shared on an Enterprise server, a user account must be allowed to connect to SQL Server, access the database, and be allowed to read data in the MFD_ROOT table that lists available components and data in the data tables for components stored in the server.

To read and write (get, check out, check in, undo check out, share, delete) components shared on an Enterprise server, a user account must be allowed to do all of the above and also to alter data in the MFD_ROOT table and in the data tables, as well as to create and drop tables.

If we install SQL Server Express as given above and if we have followed steps 1 through 14 above given in the section titled Allowing other machines to see an instance of SQL Server then the user accounts MYDOMAIN\John and MYDOMAIN\Jane will be able to use the database Test as an Enterprise server in read/write mode, and all other users of MYDOMAIN will be able to use it as an Enterprise server in read-only mode.

If we had installed SQL Server Express on a machine that is not part of any domain we could get the same result (John and Jane having read/write and everyone else read-only rights) by altering the procedure given above so that commands used in SQLCMD in steps 9 through 14 use BUILTIN instead of the domain name MYDOMAIN.

Using Database Console for Configuration

While it is certainly possible to configure SQL Server Express by using SQLCMD from the Windows Command Prompt on the machine on which it has been installed as illustrated above, as a practical matter it is frequently more convenient to configure it remotely by using Database Console.

Instead of logging in to the machine running an instance of SQL Server Express and launching SQLCMD we could log in to one of the machines that can connect to the server using a user account that has sufficient permissions on the instance of SQL Server Express (for example, a member of the sysadmin server role), launch Manifold, connect to SQL Server Express using Database Console and execute commands by typing them in the query pane and clicking the Run toolbar button. When executing a command in the query pane we do not have to use GO to signal the server that it is time to execute the command, since the Run button does that for us.

A quick and dirty way to allow all users of a particular domain to use a particular database as an Enterprise server in read/write mode is to make them all members of the built-in db_owner role for that database.

To do this via SQLCMD, we can execute the following commands (assuming the configuration above):

\texttt{USE test}
Here are the equivalent commands for an instance of SQL Server on a machine that is not on a domain and with no configuration done previously via SQLCMD:

```
CREATE DATABASE test
GO
USE Test
GO
CREATE LOGIN [BUILTIN\Users] FROM WINDOWS
EXEC sp_grantdbaccess 'BUILTIN\Users'
EXEC sp_addrolemember 'db_owner', 'BUILTIN\Users'
GO
```

Here is how we would do the above using Database Console instead of SQLCMD:

```
CREATE DATABASE test

(click the Run button)

USE Test

(click the Run button)

CREATE LOGIN [BUILTIN\Users] FROM WINDOWS
EXEC sp_grantdbaccess 'BUILTIN\Users'
EXEC sp_addrolemember 'db_owner', 'BUILTIN\Users'

(click the Run button)
```

To remove a database from SQL Server Express, in SQLCMD use:

```
DROP DATABASE test
GO
```

Use with Enterprise Edition

Once SQL Server Express has been installed and a database has been created on the server we can use it as an Enterprise server. We can create an ODBC or OLE DB data source to connect to it as set forth in the Creating an Enterprise Server topic, or we can use shorthand Enterprise Edition syntax provided for a simplified connection to SQL Server databases.

Enterprise dialogs allow a simplified connection string syntax for SQL Server databases as an optional alternative to full ODBC syntax. \"\systemname\" connects to the default database on a given system. \"\systemname:database\" connects to the specified database on the given system. The connection established with a simplified connection string that uses Windows integrated security (suitable for users working in Windows Server 2003, Windows XP and Windows 2000). Using simplified connection strings is a fast way to connect to SQL Server or to SQL Server Express using default options without dealing with the ODBC dialogs.

To connect to a non-default instance of SQL Server Express, expand systemname into systemname\instancename. Thus, connecting to \"\mysystemsqlexpress:test\" will connect to a machine named mysystem, an instance of SQL Server Express on that machine named sqlexpress, and a database on that instance named test.
For example, if we have installed SQL Server on a system called PROJECTS and we have created a database called hydrography to use as our Enterprise server database, we could connect in the Server Console by entering \projects:hydrography into the Server box of the Server Console and then pressing the Refresh button.

Sharing a Component into a SQL Server Express Enterprise server

1. Launch Manifold and open the project containing the component of interest.
2. Right click onto the component and choose Share.
3. Suppose the system hosting the SQL Server Express server is called PROJECTS and the database we created is called manifold. In the Share on box enter \projects:manifold and press OK.

The Enterprise server will be created in the manifold database and the component will be shared into that server. Thereafter, whenever we want to work with that Enterprise server we can open the Server Console and in the Server box enter \projects:manifold to work with the contents of that SQL Server Express server. Of course, if we work with this server on a regular basis Manifold will remember the last-used entries in the Server box for our convenience.

Using an Enterprise server with SQL Server Express

1. Launch Manifold and open a project.
2. Choose Tools - Server Console to launch the Server Console dialog that allows browsing Enterprise servers.
3. In the Server box, the data source connection string or data source name that was last used will appear. To see the contents of any Enterprise server, enter the data source name for that server (such as Example Enterprise server) into the Server box. Press the Refresh button at any time to see the updated contents of that server if you think there have been changes. When working with SQL Server Enterprise servers we can use simplified syntax, as in \systemname:database
4. Click on the component desired and the toolbar buttons to Import or Link will be enabled.
5. Press Import to import the component into the project. This fetches a copy of the component from the Enterprise server into local project storage. Press Link to link the component into the project, leaving it stored within the Enterprise server and under control of the Enterprise server.

Example

Suppose we've just installed SQL Server Express on a machine called PROJECTS. We will create a database called counties and we will grant permissions to all users in our domain to access the database. Our Windows domain is called GISDEPT.

1. Launch Manifold and open Tools - Database Console. The Database Console uses the Data Source dialog to specify connections.
   a. Click the [...] browse button to the right of the Data Source box to open the Data Source dialog, which is similar to the File - Open dialog. In the Files of type box choose OLE DB Data Sources (). This opens the Data Link Properties dialog.
   b. Follow the instructions in the Create a Data Source for SQL Server Express example section of the Data Source Dialog topic to create a data source for the desired SQL Server Express installation in the Data Source dialog, using the Microsoft OLE DB Provider for SQL Server and connecting to the PROJECTS machine. Double click on that data source to connect to it.
2. In the command pane (the lower pane in the Database Console) enter the following command and press the Execute:

   CREATE DATABASE counties

3. In the command pane enter the following four lines. After all four lines have been entered press the Execute button:

   USE counties
   EXEC sp_grantlogin 'GISDEPT\Domain Users'
   EXEC sp_grantdbaccess 'GISDEPT\Domain Users'
   EXEC sp_addrolemember 'db_owner', 'GISDEPT\Domain Users'
4. Close the Database Console. To populate the Enterprise server with components, right click on a component to be shared to the server and choose Share. In the Share dialog, enter the following into the Share on box:

\projects:counties

5. The Enterprise server is now fully operational and populated with the shared component. Use \projects:counties in the Server box of the Server Console to work with that Enterprise server.

Comments

Any machine can host an Enterprise server run on SQL Server Express databases. Although Microsoft refers to it as a "desktop" engine it is actually SQL Server in all its full power and elegance, excepting the limitations of CPU / RAM usage and four gigabytes per database. It has full networking capability as does SQL Server and will appear on the local network as a SQL Server installation. For most practical purposes of interest to Manifold users everything that may be done with SQL Server may be done with SQL Server Express as well.

If we install Enterprise Edition with SQL Server Express on a given machine, that machine can be both a client and a server to other machines on the network. For example, if we have a local area network with ten different machines we can have each of the ten be an Enterprise server for itself and for other machines on the network, even as the machines are simultaneously used as Manifold Enterprise Edition client workstations.

The short examples given above show one database created within a SQL Server Express server. We could create many databases within each SQL Server Express server and use them all simultaneously. Each database is used as a separate Enterprise server.

For example, suppose on the machine called PROJECTS we install a SQL Server Express server and then create databases called hydrography, boundaries, transportation and utilities. We could work with each of these in the Server Console as four different Enterprise servers using the shorthand connection syntax of \projects:hydrography, \projects:boundaries, \projects:transportation and \projects:utilities. We could include shared components from each of these in the same project.

Further Reading

Because SQL Server Express is, in fact, SQL Server there is a massive amount of reading material available to users who wish to learn more. In general, most documentation for SQL Server will apply to SQL Server Express so long as one keeps in mind the minor differences between SQL Server and SQL Server Express.

When searching the microsoft.com site for additional information, search for SQL Server 2008 Express Edition, which has superseded the earlier SQL Server 2005 product.

No Technical Support

Important: Manifold.net does not provide any support whatsoever for installation, administration, management, configuration or use of the DBMS products provided by Microsoft. See the Database Installations topic for details.

Drawings

Drawings

Drawings in Manifold are similar to drawings in a CAD system used to create blueprints. They are made up of points, lines or areas and are often referred to as vector drawings in other mapping programs or CAD systems.

Existing drawings may be imported into a Manifold project using the File - Import - Drawing command. New drawings may be created in Manifold and then exported into common drawing file formats using File - Export. See the Import and Export topic for more information on specific import dialogs used to import drawings from various GIS formats.

Creating a New Drawing

1. Open a project or create a new project with File - New.
2. Choose File - Create - Drawing to create a new drawing.

The File - Create - Drawing dialog takes the projection parameters for the new drawing from whatever window is active at the time the new drawing is created. If the project pane is active, the drawing will be created using the system default projection of Orthographic centered at the 0,0 world latitude/longitude origin. If a map window or other drawing window is active when the new drawing is created, the new drawing will be created using whatever projection is used by that active window. This context-sensitive setting of default projection parameters makes it much easier to create new drawings using projection parameters that are hassle-free by default.

Every drawing has a table associated with that drawing. Creating a drawing will automatically create the table for it.

Drawing Fundamentals

Drawings are fundamentally different from images in several ways:

- Drawings are made up of objects drawn using points, lines and areas that are defined by specific coordinates. In contrast, images have no objects, only a sea of pixels. The "objects" we see in an image appear to be there because our eyes and brains automatically match up pixels of similar colors to interpret that part of the image as being an object.

- The appearance of objects in a drawing is determined by the format of each object and not by the zoom level. A point in a drawing that is formatted to appear as a small circular dot will have the same size and appearance regardless of zoom level. Areas that are formatted so that they appear with a contrasting color on their border will have the same thickness of border line no matter how far one zooms in. Changes in zoom will simply show more or less of the object. In contrast, the appearance of images varies dramatically as one zooms in past the point where individual pixels become visible.

- Drawings use a coordinate system that specifies the precise geometric relationship between different parts of different objects. Drawings intended for use as geographic maps will use a geographic coordinate system so they automatically may be located on the surface of the Earth. In contrast, images have no intrinsic coordinate system except that which is implied by the row and column arrangement of pixels. Images that might be imported into Manifold are rarely bound to geographic coordinates and thus will usually require a quick georegistration before they can be used in geographic maps in a sensible way.

- Because drawings have distinct objects, a drawing can be linked with database information by attaching database records to objects in the drawing. In contrast, because there are no objects in images, databases cannot be attached to images. The only data in images are the color values of the pixels.

- Every drawing has a table associated with that drawing. Each row in the table corresponds to an object in the drawing. A drawing with three points in it will have three rows in its table, for example. The table will have at least one field, an object ID field, that is used to link each row in the table to an object in the drawing.
Points, Lines and Areas

Drawings are created from only three types of objects:

- Points
- Lines
- Areas

No matter how detailed or cleverly formatted a drawing may be, it is ultimately made up of only these three types of objects. Drawings do not have to contain all three types of objects. Many drawings contain only points, only lines or only areas.

**Points** are simply dots at a particular location. Points are formatted by default as small, round dots. Points can be shown as anything from a single pixel to a multicolored icon. In the illustration above, the three points to the left are shown as single pixels whereas the four points to the right are dots formatted with bright green background color.

**Lines** may appear to be straight lines or smooth curves. However, all lines are ultimately made up of straight-line segments drawn between the sequence of coordinates that define the line. Zooming far into even the most smoothly curved line will show that it is made up of straight-line segments. Some CAD and GIS systems call such lines "polylines." In Manifold, we simply say "lines."

**Areas** are like shapes cut out of cardboard. They are objects that actually have some "substance" in their inner region and are often used to show regions such as states or provinces in a map. The illustrations above show a few western states drawn using areas. At left we see the areas drawn in their normal position, and at right drawn separate from each other. The illustration at right has had "shadows" added in a simple way to provide a greater impression of substance, to promote the analogy with shapes cut out of cardboard.
**Historical Note:** Areas were called "polygons" and lines were called "arcs" in some older GIS systems. This terminology may still be used in some organizations that are still using legacy systems. See the Terminology in GIS essay for notes on the difference between older words and modern usage.

**Don’t Confuse Lines with Areas**

Areas are a new concept to users of simple drawing packages. Many graphics arts packages that allow the creation of vector drawings allow use of lines and points, but not areas. Other graphics packages, such as the drawing toolbar in Microsoft Word, uses “shapes” in a manner that is part way between line drawings and the use of areas in more sophisticated packages.

An important difference between areas and lines is that areas have inner substance, like a cardboard cutout, whereas even when lines are drawn in a way that makes a closed figure there is no "substance" inside the white space of the figure. A closed figure drawn using lines is like a figure made up of wire twisted into the desired shape. There’s nothing "inside" the figure.

If we redraw the Western states using lines instead of areas, we can see that when we pull apart the constituent lines there is nothing "inside" the states. It is as if we made a wireframe figure out of pieces of stiff wire twisted into the shape of the state boundaries. When we take the figure apart we see it is just bits and pieces of wire.

The distinction between drawings made up of lines and those made up of areas is important because the appearance of the objects depends on how they are formatted. Only the "substance" of the objects can be formatted. If we wish to draw Western states with different, smooth colors within their interior regions we should use areas to draw the states. We can’t color the interiors of a drawing of Western states made up of lines because there is no "interior" to color.

Imagine, for a moment, the drawing of states using lines as though it were made up of wires and seen in perspective. If we tried to paint the inside of the states with a paint bucket the paint would flow right through the empty spaces between the wires.
If we imagine the drawing made up of areas as though they were shapes cut out of cardboard we can pour paint onto the shape and have it color the interior of the area.

**Advantages of Lines**

It’s a good thing that figures drawn of lines have no interior substance. That makes it easy to use lines to draw linear features like roads in a layer that overlays other objects. One can then see the objects below through the nothingness between the lines.

The image above uses three line drawings stacked up above an image layer. One layer uses lines formatted as thick black lines, while the others use thinner lines. The illustration shows Palo Alto, California, with Highway 101 cutting across from left to right and San Francisquito Creek (the border between Santa Clara and San Mateo counties), shown in blue.

**Don’t Confuse Area Boundaries with Lines**

In a drawing created entirely from areas it could be difficult to see the "joints" between areas if they fit together perfectly.
Suppose we cut out the shapes of Western states from fine paper and fitted them together so carefully the seams between them could not be seen:

That's a less useful drawing than one that clearly shows the seams between the areas so that it's obvious where each area begins and ends:

By default, Manifold will use an area style to draw areas that draws the last pixel at their edges in a contrasting color. This makes it possible to see the seams between areas even when they are perfectly fitted together. When looking at areas drawn using this default area style, we might be tempted to think that we are looking at a map that includes a set of lines drawn in the shape of the areas; however, this is just a different area style. See the Areas and Boundary Lines topic for more discussion on this.

Using Lines to Duplicate Area Boundaries

Sometimes we will want to use both areas and lines to show the same thing, in order to take advantage of greater formatting flexibility.
It's easy in Manifold to create a set of lines that follow the boundaries of area objects using Transform - Boundaries. If we like, we can use this command to create lines that exactly follow the borders of our Western state areas. We can then stack these lines in a layer above the area layer. This gives us greater formatting flexibility than is possible using area styles alone. For example, we can make the lines layer using extra-thick lines in some boundaries to emphasize certain states.

Another reason to create a layer of lines that follow the borders of our state areas is to create a layer of lines that can be overlaid upon an image. Consider the following example:

Suppose we have an image of the US and a drawing that shows US states as areas.

If we stack the areas drawing in a layer above the image the substance of the areas will obscure the image. Although we might use a transparent area effect so that the image could show through the areas in this case we will use lines to get exactly the right visual effect desired.
To create the lines, we use **Boundaries** to create lines in the shape of the area boundaries.

We can create the new lines in a new drawing layer in our map. We can then stack the lines above the image to show boundaries in the image.

Note: this is a small image to fit into the Help documentation and so a very bright color has been used for the boundary lines. In "real life" it is often cooler to use more subdued colors to achieve a more modern look in one’s maps.

**Areas Can be Drawn in Opaque or Transparent Styles**

By default, areas are drawn using an opaque style in gray color. Objects below areas drawn in such style will not be visible. If you can’t see objects that you expect to be in your drawing, make sure that they are not on a layer that is below an opaque area. Move them above the area and they will become visible.

Areas may also be drawn using a variety of transparent hatch patterns or even in a translucent style (by changing the Layer Opacity of the layer they are in). In this case, they are like shapes cut out of transparent plastic or translucent paper.
Areas that overlap each other within the same layer will overlap above or below each other depending on the order in which they were created. When working with areas that overlap, it’s often helpful to use transparent area styles so that the region of overlap is clearly visible in all cases. See the Overlapping Objects and Transparent Area Styles topics for more information.

When drawings are used as layers in a map, the layers can be shown with different Layer Opacity so that different layers can be seen through those that are partially transparent. This is a fine way to show overlapping areas.

Suggestions

- Use lines to draw linear features like roads and streams.
- Use areas to draw regional features such as provinces or lakes.
- When formatting objects, keep in mind the visual analogy that lines are like wires hovering above the drawing and areas are like shapes cut out of cardboard.

Drawings and Maps

Drawings by themselves can only show points, lines or areas. To show other visual elements, such as labels or images, we use other Manifold components such as Images or Labels components. By combining drawings with images and labels layers in a map we can achieve exactly the visual effect desired.

Using the Layers Pane with Drawings

The Layers pane is used to control the appearance of drawings within drawing windows. The layers pane includes checkboxes for two system "layers" - a background color layer and a border layer that shows an enclosing box about the widest extents of objects in the drawing.

Drawings are shown using the checkerboard background Manifold uses to provide a backdrop for any transparent regions. The layers pane is shown to the right of the drawing window.
Checking the Background box in the layers pane will replace the checkerboard background with whatever is the default background color. The default setting for drawings is to show a white background.

Checking the Border box will draw a one-pixel border that represents the minimum enclosing box for all objects in the drawing. When working with drawings that include points, using the Border is a handy way to see if any very small objects exist far away and unnoticed from other objects, since the border will expand to include all objects.

Note that only maps can have true "layers" in Manifold in the sense that they can layer more than one component within the same map window. The border and background "layers" in the Layers pane for are not true layers even though they appear in the Layers pane in the same manner as do layers in maps. These are simply system controls that take advantage of the Layers pane as a conceptually convenient user interface.

Clicking off the Background in the layers pane can resolve visual ambiguities between areas that are white in color and regions that are bordered by lines. With Background on as in the illustration at left above it is not possible to immediately see solid areas that are colored in the same color as the background color. With Background off, white areas will stand out against the default checkerboard pattern.

We can change the background color in Tools - Options. See the Layers topic for an example of how changing background color can radically change the appearance of a drawing or map.

Layouts and the Layers Pane
If a drawing has any Layouts created they will appear as “layers” in the layers pane for that drawing. Checking the box for one of these print layout layers will cause a layout rectangle to appear in the drawing that shows the region covered by the layout.

In the illustration above the drawing has four layouts that show different parts of Mexico. Three of the layouts have been checked in the layers pane causing three layout preview rectangles to appear in the drawing.

Right clicking onto the hatched border of one of the layout rectangles in the drawing will cause a context menu to appear with controls based on that layout rectangle. For example, we can **Zoom** to a given layout rectangle, **Print** it or change its **Properties**. If a layout is empty (for example, if the layout scope is set to **selection** and nothing is selected in the parent component) zooming to the layout will do nothing.

Use **Tools - Options - Colors - Layout Rectangle** to change the color in which layout rectangles are shown. The default color is black.

**See Also**

- Format Toolbar
- View - Properties - Zooms
Drawing Window Menus and Controls

When we click onto a drawing window, Manifold will automatically change menus and toolbars so they contain those menus and controls that work with drawings. The following are commands that appear which are specific to drawings.

**Edit**

- **Cut**  Windows clipboard cut operation. Copy selected objects to the windows clipboard and delete them from the drawing.

- **Copy**  Windows clipboard copy operation. Copy selected objects to the Windows clipboard.

- **Paste**  Windows clipboard paste operation. Paste the contents of the Windows clipboard into the drawing deleting all previously selected objects. Creates new objects in the drawing.

- **Paste Append**  Paste the contents of the Windows clipboard into the drawing without deleting any selected objects. Creates new objects in the drawing.

- **Delete**  Permanently delete selected objects from the drawing.

- **Delete All**  Permanently delete all objects from the drawing.

- **Edit - Change Projection**  Used with components like drawings and images to re-project the component and thus permanently change the data.

- **Edit - Assign Projection**  Used with drawing, image, labels and surface windows to change the interpretation of the data. This is a specialized function that is applied only when manually specifying the projection of a component imported from a format that does not correctly store projection information. To change the native projection of any component other than a map, use the Edit - Change Projection command.

- **Select All**  Select all objects in the drawing.

- **Select None**  Deselect all objects in the drawing.

- **Select Inverse**  Invert selection: those objects that were selected will be deselected while those objects that were not selected will be selected.

- **Select Mode**  Choose the selection mode to be used for mouse selection:
  - **Replace**  - Any selection made with the mouse will replace the previous selection.
  - **Add**  - Any selection made with the mouse will be added to the previous selection.
  - **Subtract**  - Any selection made with the mouse will be subtracted from the previous selection.
  - **Invert**  - Any selection made with the mouse will be inverted with the previous selection.
  - **Intersect**  - Any selection made with the mouse will be intersected with the previous selection.

- **Select Objects**  Choose objects that may be selected by mouse selection:
  - **Areas**  - Any areas within the mouse selection will be selected.
  - **Lines**  - Any lines within the mouse selection will be selected.
selected.

**Points** - Any points within the mouse selection will be selected.

**Select by Type**
Select all objects of the currently enabled Select Object modes, for example, select all points or all lines. See the Selection in Drawings topic and the Edit - Select by Type topic.

**Snap To**
Enable / Disable Snap modes:
- **Graticule** - Snap to graticule intersections if a graticule is displayed.
- **Grid** - Snap to grid intersections if a grid is displayed.
- **Areas** - Snap to coordinates that define areas.
- **Lines** - Snap to coordinates that define lines.
- **Points** - Snap to points.
- **Segments** - Snap to locations within segments.
- **Selection** - Snap only to objects in the selection, if any.

**Instant Data**
Automatically pop up an input dialog after adding a new object to the drawing. Allows rapid data entry when creating new objects.

**Shared Edit**
Toggle shared edit mode.

**Go To**
Go to a particular object or location using a variety of options.

**View**
- **Back**
  Go back one view.
- **Forward**
  Go forward one view.
- **Zoom In / Out**
  Zoom in brings us closer to the drawing while zoom out moves us farther away.
- **Zoom To Fit**
  Zoom so that the drawing fits the existing window size.
- **Zoom To**
  Zoom to a specified zoom level.
- **Graticule**
  Show a graticule (latitude / longitude lines).
- **Grid**
  Show a grid that may be used to measure or to align editing and snap commands.
- **Legend**
  Display a legend showing formats.
- **North Arrow**
  Display a North arrow.
- **Scale Bar**
  Display a scale bar.
- **Structure**
  Display within the drawing window structural items for objects, including:
  - **Object Boxes** - The minimum enclosing rectangle for each object.
  - **Object Centroids** - The coordinate centroid for each object.
  - **Branch Boxes** - The minimum enclosing rectangle for each branch of multi-branched objects.
  - **Branch Centroids** - The coordinate centroid for each branch of a multi-branched object.
  - **Inflection Points** - The coordinates that define each
object.

**Segment Points** - The centroid of each line segment (from coordinate/inflection point to coordinate/inflection point) that defines each line or area.

Points, of course, have only one inflection point or segment point, located at the point's location itself. See the View - Structure topic for examples.

**Panes**

Call a dialog that allows displaying or hiding all panes.

**Full Screen**

Show the drawing over the entire monitor area.

**Refresh Data**

Update a linked drawing with the latest data from the controlling geocoded table.

**Refresh View**

Update the visual appearance of the drawing with any changes made since the last refresh. Enabled only if **Autorefresh View** is off and some change (such as a selection) has been made that might affect the visual appearance of the drawing.

**Autorefresh View**

Automatically update the drawing whenever any changes are made that might affect the visual appearance of the drawing. Turn this option off when working with very large drawings where there is no desire to take the time to show, say, a selection when it is made (repainting a very large drawing on every selection step might take longer than desired). When **Autorefresh View** is off, we can always cause a refresh on demand using the **Refresh View** command.

**Properties**

View the properties dialog for this drawing.

**Drawing**

**Open Table**

Open this drawing's table.

**Align**

Alignment toolbar commands that work with selected objects and the primary selected object (selected with a **CTRL-ALT** click):

- **Left** - Move objects so their left edges are aligned to the left edge of the primary selected object.
- **Top** - Move objects so their top edges are aligned to the top edge of the primary selected object.
- **Right** - Move objects so their right edges are aligned to the right edge of the primary selected object.
- **Bottom** - Move objects so their bottom edges are aligned to the bottom edge of the primary selected object.

**Center**

Alignment toolbar commands that work with selected objects (selected with a **CTRL-ALT** click):

- **Horizontally** - Move objects so that the X coordinate of the center of their bounding box coincides with that of the bounding box of all objects in the drawing.
- **Vertically** - Move objects so that the Y coordinate of the center of their bounding box coincides with that of the bounding box of all objects in the drawing.

**Space**

Alignment toolbar commands that work with selected objects (selected with a **CTRL-ALT** click):

- **Across** - Space objects evenly in horizontal direction across the bounding box of all objects in the drawing.
- **Down** - Space objects evenly in vertical direction across the bounding box of all objects in the drawing.
Resize Full Alignment toolbar commands that work with selected objects (selected with a CTRL-ALT click):
  Width - Increase width of objects to that of the bounding box of all objects in the drawing.
  Height - Increase height of objects to that of the bounding box of all objects in the drawing.
  Both - Increase both width and height of objects to those of the bounding box of all objects in the drawing.

Resize Same Alignment toolbar commands that work with selected objects (selected with a CTRL-ALT click):
  Width - Resize objects so that the width of each is the same as the width of the primary selected object.
  Width (Max) - Resize objects so that the width of each is the same as the width of the widest object.
  Width (Min) - Resize objects so that the width of each is the same as the width of the narrowest object.
  Height - Resize objects so that the height of each is the same as the height of the primary selected object.
  Height (Max) - Resize objects so that the height of each is the same as the height of the tallest object.
  Height (Min) - Resize objects so that the height of each is the same as the height of the shortest object.

Minicharts Create and format minicharts in this drawing.

  Color Color each adjacent area using a different color.
  Applies a thematic format based on a coloring field.

  Dissolve Merge area objects (dissolving away area borders) that have identical values in given data attribute fields.

  Districts Assign areas in the drawing to different districts by writing a district code to a specified data field.

  Orthogonalize Move coordinates to orthogonal grid positions. Used to trim insignificant digits.

  Segmentize Add redundant coordinates to increase the number of coordinates used to define the object. See the Segmentization topic for discussion.

  Simplify Remove coordinates that define the object to simplify the shape of the object.

  Spatial Overlay Transfer data between objects in drawings based upon their spatial relationships.

  Topology Overlay Modifies drawings using Identity, Intersect, Union and Update overlay functions using the areas in a source drawing to guide modifications in a target or results drawing.

  Relink Enabled for a linked drawing only. Relinks (reconnects) the linked drawing to another data source.

  Unlink Enabled for a linked drawing only. Converts the linked drawing to a local drawing with no connection to the originating data source. Linking and then unlinking a drawing is equivalent to importing it.

**Drawing Window Context Menus**

Context menus pop open when we right click on an item in Manifold. They are called “context” menus because what they show depends on the context of where the right click occurred.
Right Click onto an Object

- **Cut**: Windows clipboard cut operation. Copies object to the clipboard and delete it from the drawing.
- **Copy**: Windows clipboard copy operation. Copies object onto the clipboard without deleting it.
- **Paste**: Paste the contents of the Windows clipboard into the drawing. Creates new objects in the drawing, replacing any objects that were selected. New objects will be selected.
- **Paste Append**: Like **Paste**, but does not delete and replace any objects that were previously selected.
- **Delete**: Permanently delete this object.
- **Duplicate**: Duplicate the object. It is wise to immediately move the new object while it is selected. This avoids creating coincident objects that might later cause confusion.
- **Orthogonalize**: Move coordinates to orthogonal grid positions. Used to trim insignificant digits.
- **Segmentize**: Add redundant coordinates to increase the number of coordinates used to define the object. See the Segmentization topic for discussion.
- **Simplify**: Remove coordinates that define the object to simplify the shape of the object.
- **Center**: Pan the view to center this object in the window.
- **Zoom**: Zoom to fit this object.
- **Coordinates**: Launches the Object Coordinates dialog to allow direct editing of the coordinates that comprise the object.
- **Fields**: Launches the Object Fields dialog that shows any table fields associated with this object.

The **Cut**, **Copy** and **Delete** functions within the context menu of a drawing work slightly different than their equivalents found in the **Edit** menu. The **Edit** menu versions work with the selection. The context menu versions work on those that object that has been right clicked.

**Double Click Short Cuts**

Double-clicking on legends, north arrows and scale bars will open the **Properties** dialog for those items.

Double-clicking on an object in a drawing will launch your Internet browser using the contents of a **URL** field, if any, in the drawing's table for that object. If there is no **URL** field or if it is not of type "URL" or if it is empty the **Fields** dialog will be popped open.

**CTRL**-double-clicking on an object in a drawing will launch the **Fields** dialog.

**Minicharts**

Minicharts are small charts that hover above objects in a drawing. See the Minicharts topic for details.

**Frequently Used Panes**

Panes are launched from either the **View - Panes** menu or by **ALT-SHIFT** keyboard shortcuts listed in the **View - Panes** menu.
**Control Points**  Assign control points for geregistration.

**Info**  Display data attributes for objects in the drawing.

**Layers**  Turn background and border on/off, show coverage of any print layouts using this drawing.

**Selections**  Saved selections for this drawing.

**ViewBots**  Assign 'bots to watch this drawing and report an analysis.

**Views**  Save and return to particular pan and zoom view.
Selection in Drawings

Please read the main Selection topic before reading this topic. The Selection topic explains selection modes and the use of select object buttons.

Selection in drawings is the same as selection in drawing layers in maps. Since maps are the preferred user interface for most interactive work, selection is less often done directly within a drawing window. However, it works the same way in both cases.

Objects in drawings may be selected in several ways:

- Mouse moves such as Select Box or SHIFT Select Box
- Selection using mouse moves within any Tables linked to the drawing.
- Selection using the Query toolbar.
- Selection using SQL queries.
- Objects created by the Transform toolbar are automatically selected after they are created.
- Some transform toolbar operators (such as the Select Adjacent to operator) may select objects in the drawing.
- Scripts may select objects in drawings.
- A selection in a drawing or image can be used to create a selection in a drawing using the Transfer Selection command.

Selection using Mouse Moves

The key to selection using mouse moves is to choose the right selection mode and the desired combination of select object filter buttons. The select object filter buttons used with drawings are:

- **Select Areas** - Enable selection of areas by mouse selection tools.
- **Select Lines** - Enable selection of lines by mouse selection tools.
- **Select Points** - Enable selection of points by mouse selection tools.

Choose the type of items that are to be selected by pushing the selection filter buttons for the desired types. When working in drawing windows, the Select Pixels and Select Text buttons will not be visible since there are no pixels or text labels in drawing windows.

Examples

In the following sequence of illustrations we will make a Select Box mouse selection with various combinations of select objects filter buttons enabled. The Select Box command selects objects that are entirely within the rectangular mouse cursor. We use Replace Selection mode so that every time we make a selection it replaces any previous selection.

The example uses a map with several drawings as layers. It shows land areas in the San Francisco Bay region together with major roads as lines and the centers of named cities as points. The blue water region is not an area but is just the blue background color used for this map that is seen through "empty" space between the land area objects. The task now is to selectively grab just areas, lines or points in various combinations without selecting undesired types of objects.

Each illustration shows the mouse selection box drawn with the Select Box tool overlaid upon the results of the selection to make clear the action of each selection. In real life, the selection would not appear highlighted in red selection color until after we release the mouse button at the end of the selection click and drag.
If none of the three select object filter buttons are pushed in then no objects will be selected.

When all three select object filter buttons are pushed in all areas, lines and points entirely within the cursor box will be selected. Note that only those land areas (representing Angel Island, Treasure Island and Alameda Island) that are entirely within the selection box are selected. The other, larger areas representing the mainland were not selected because they are partially outside the selection box.
If only the **Select Points** button is pushed in only points within the mouse cursor box will be selected. Note that selected points are shown with red color used for their foreground color, the normally black outline of the dots.

If only the **Select Lines** button is pushed in only lines within the mouse cursor box will be selected. Note that only those line objects that are entirely within the selection box are selected. If we wished to select all lines that are touched by the selection box, we could have used **SHIFT - Select Box** for an "open" selection tool.
Poets, artists and those readers with advanced math degrees will have already begun to see a pattern in this example and will have successfully thought ahead to realize that if only the Select Areas button is pushed in then only areas within the mouse cursor box will be selected.

Any combination of the select object filter buttons works to select what we want. If we want just lines and points we push in the Select Lines and Select Points buttons.

A reminder: The illustrations above show both the mouse cursor box as well as the resultant selection at the same time. In real life, the selection appears in red color momentarily after the mouse cursor box is drawn and released.

Select by Type
When a drawing window is active, choosing **Edit - Select by Type** or **CTRL-T** will select all objects of the currently enabled select object modes. This is a quick way to select all lines in a drawing, or all points or all areas. See the **Edit - Select by Type** topic.

### Selections in Drawings Select Records in Tables

If a drawing is linked to a table making any selection in the drawing will also select the records for those objects in the table. When a drawing and a table are linked there is only one selection within either of them because there is a one to one association between records and objects in linked tables and drawings. Selecting an object in a drawing will select (that is, highlight) the associated record in the table and vice versa.

A very important adjunct to making selections in any drawing or drawing layer in a map is using selection within tables at the same time we are looking at the same data in a drawing. It is very important to read the Selection in Tables topic to learn about selection methods in tables.

### Selections Pane

The most frequently used pane when making selections in drawings is the **Selections pane**. We often will use the Selections pane to save selections made in drawings for later use. Each drawing or drawing layer can have up to seven saved selections in the Selections pane. See examples using the Selections pane in the introductory Selection topic.

### Smart Mouse Selection

**Smart Mouse** selection is used to select objects for editing. An object selected with smart mouse selection will appear with edit handles that can be used to move or reshape the object. An object chosen for editing is also called the **primary selected** object.

Commands involving the mouse are normally controlled by whatever toolbar button is engaged. To use **Select Box** for example, we push the **Select Box** button in and then use the mouse in this mode. To provide fast operations when the mouse is not engaged in any other command, Manifold allows "smart mouse" selection in a way that mimics ordinary Windows point and click mouse highlighting and motion methodology as is used in Word and other applications.

### Smart Mouse Touch Selection

The simplest form of smart mouse selection is to click on an object to select it. This is a smart mouse version of **Select Touch**. For example, clicking on an area object in a drawing will select it for editing. Clicking on an object

See the **Editing Objects** topic for examples and more information on interactive editing with smart mouse selection.

### Keyboard Modifiers with Smart Mouse Touch Selection

Because a selection may already exist in the drawing when we wish to select an object for editing, smart mouse selection uses keyboard modifiers to allow a richer set of commands.

**Click** Equivalent to **Select Touch** in **Replace** mode. Click on an object to select it as the primary selected object. All other objects are deselected.

Clicking into an empty part of the drawing deselects all objects.
(with confirmation dialog).

**CTRL**  
Invert the selection state of the object without changing the selection state of any other object. Equivalent to **Invert** mode.

**SHIFT**  
Select the object if it is not yet selected and make it the primary selected object. Does not change the selection state of other objects. Equivalent to **Add** mode.

### Smart Mouse Box Selection

When clicked on an empty region and dragged the mouse automatically makes a box selection analogous to using the **Select Box** selection tool in **Replace Selection** mode. This is a general shortcut for selection. To select an object as the primary selected object for editing, either click on it or **SHIFT** click on it.

### Keyboard Modifiers with Smart Mouse Box Selection

The following keyboard modifiers may be used with smart mouse box selection:

**Click and drag**  
Click on an empty region and drag to make a box selection in **Replace Selection** mode. Selects all objects that are entirely within the selection box.

**CTRL**  
Click on an empty region and drag to make a box selection in **Invert Selection** mode.

**SHIFT**  
Use an open box selection to select all objects any part of which are within the selection box.

### Notes

Why is it called "smart mouse" selection? This is based on the idea that to support this type of selection the mouse cursor in its default mode must understand a lot about its environment. For example, it must be able to keep track of and know when it is clicked on a drawing object (and, for that matter, when the object is in the active layer if the mouse hovers in a map window) and much more. This requires considerably more thought for the cursor than merely being a default Windows cursor, so it is said to be a "smart mouse" cursor.

Note that the default action of the mouse in "smart mouse" action depends on the context of where it is clicked and how it is moved. For example, clicking on an empty region and dragging creates a box selection mouse move. Clicking on an object and dragging is a drag-n-drop operation.

### Tech Tip

When objects in drawings are selected the associated records in the drawing's table will also be selected. One way to browse the data contents of objects is to open both the drawing and the drawing's table.

Click the table window and press the **Filter Selected** button so the table window shows only selected records. We can then select objects in the drawing and see their data contents in the table window.

Linked Drawings

Linked drawings are drawings that are created dynamically from geometry data stored in tables or created by queries. The table or query may be in the Manifold project or it may be a table or query in an external database provider. Linked drawings are shown in the project pane using an icon that include a yellow "database" cylinder to show they are created from a database table or query.

There are two types of drawings in Manifold:

- **Regular drawings** - These are static components in which all geometry (the information that defines the shape, size and location of objects) is stored in the drawing component with data associated with each object saved in the drawing's table component. Such drawings are also called local drawings.

- **Linked drawings** - Linked drawings are created from geometry data stored in database tables or generated from database tables by queries. Such databases and queries can reside within the Manifold project or, as is more frequently the case, they can reside in external database servers, so that even though the linked drawing appears to be a component in the Manifold project the actual data to create that drawing comes from the external database.

Linked drawings have characteristics depending on their source of geometry data:

- **Linked drawings from geometry data** - These are fully editable, read/write drawings containing points, lines or areas that are created dynamically from geometric columns in tables. Linked drawings can be linked from a variety of database technologies using a variety of different methods of storing geometry data. For example, drawings can be linked from geometry data saved in OpenGIS style Geometry(WKB) form, ESRI style Geometry(SHP) form or Manifold Geometry form in a very wide range of database products, such as Microsoft SQL Server, Oracle, IBM DB2, MySQL or even within ordinary Microsoft Access .mdb databases. Manifold also supports Oracle Spatial and Locator native databases saving geometry as SDO_GEOMETRY data. See the Geometry in Tables topic.

- **Linked drawings created from queries** - When linked drawings are created from queries, if the query creates geometry data on the fly then the resultant linked drawing will be read-only regarding spatial data such as the shapes and positions of objects (points, lines, areas).

- **Linked drawings created from geocoded tables** - This is a special case of linked drawing provided for the convenience of users when dealing with simple geocoded data in tables. When a geocoded linked drawing is created from a geocoded table, Manifold will automatically create an intermediate query that takes the simple, non-geometry data from the table's coordinate columns and then on the fly will create geometry data from which a linked drawing may be created. Geocoded linked drawings contain only points or lines that are created from X and Y (Longitude and Latitude) values saved in coordinate columns in database tables, that is, so-called geocoded tables. Linked drawings created from geocoded tables using coordinate columns are read-only and are provided as a convenience to simplify the acquisition and display of geocoded data in a variety of common applications. See the Creating Drawings from Geocoded Tables topic and the Linked Drawings from Geocoded Tables topic for details.

The above guidelines show the tremendous flexibility of linked drawings. However, even with such flexibility we should keep an eye out for logical limitations of various data sources from which drawings may be linked.

For example, linked drawings support adding or removing objects, provided the data source supports adding or removing table records. Suppose we have a table in our project that contains a geometry column. We can link a drawing to that table and it would be possible to add or remove objects in that linked drawing. Suppose now we create a SELECT query in that same project that takes geometry data and other columns from the table. We could also create a linked drawing from that query, but we would not be able to add or remove objects from that linked drawing because it is created from a query, which is a "one way" generator of geometry data.

**Projections**

The projection of a linked drawing is specified by its data source. Attempting to re-project a linked drawing will reload its data from the data source.

**Properties**

The View - Properties dialog for components shows the data source of a linked component (such as a linked drawing) and other relevant information.
The Link / Share dialog accessed from the [...] browse button for linked or shared components accessed from the View - Properties dialog will provide a summary of the link or share properties. This will show the status of a shared component and whether or not changes in a linked component will propagate back to the data source.

**Linked Tables in Linked Drawings**

Like any drawing, a linked drawing also has its own table, which in the case of a linked drawing is a linked table. Such linked tables are just like regular, standalone linked tables and can be used just like standalone linked tables.

For example, we can make changes in the linked table and those changes will be implemented back to the data source from which the table is linked. In particular:

- A linked table allows adding or paste-appending a new column, renaming an existing column, and changing the type of an existing column.
- We can change the design of a linked table.
- It is possible to geocode records in a linked table.

All of the above capabilities apply to both standalone linked tables and tables bound to linked drawings.

Manifold will also try to exploit the capabilities of the remote data source whenever possible in the case of the linked tables associated with linked drawings. For example, if new columns must be created in such tables because objects are being pasted from other drawings Manifold will try to create such new columns as NULL-able (that is, able to contain NULLs).

**Tech Tip**

Importing or linking a drawing from another drawing in the same .map project using the Geom (i) intrinsic field will inherit both the coordinate system as well as the location precision of the source drawing.

Linked Drawings from Geocoded Tables

For a general introduction to geocoded tables, see the Creating Drawings from Geocoded Tables topic.

Manifold can create linked drawings from geometry data in tables or from geometry data fetched or created by queries. Using geometry data in tables and then creating linked drawings from that data allows storing drawings within tables in a fully read/write and editable way. However, at times we deal with simple, non-geometry data in tables and would like a simpler way of displaying such data in drawings.

For example, a **geocoded table** contains two coordinate columns that for each record give the longitude and latitude (or X and Y) position of that record. A classic example might be a table downloaded from a GPS device that provides a list of waypoints with the longitude and latitude of each waypoint. Such a table, because it provides a location for each record in the longitude and latitude columns, is called a **geocoded table**.

For the convenience of users, Manifold provides a simple way of displaying data from geocoded tables within linked drawings. We can create a linked drawing based on a geocoded table, and when we do so Manifold will automatically create an intermediate query that takes the simple, longitude and latitude data from the table's coordinate columns and then on the fly creates geometry data from which a linked drawing is created. Like all linked drawings, the linked drawing is created from geometry data; however, in this case the geometry data from which the linked drawing is created comes from the intermediate query. The automatically-created query takes data from the coordinate columns in the table and creates geometry data necessary for a linked drawing. There is nothing special about this process that could not be done manually, if we were so inclined.

The only magic in this process is that if we try to link a drawing from a table that contains no geometry data (Manifold can see right away if a table contains geometry data or not), then Manifold assumes we want to create a linked drawing from a geocoded table and so it launches the appropriate dialog. When we use that dialog to specify which columns are to be used as coordinate columns (that is, for the longitude and latitude columns or X and Y columns), then Manifold knows what columns to use in the query it writes for us.

If we had good knowledge of spatial SQL we could have written the query manually and then manually linked a drawing from that query. When Manifold does this for us automatically it saves time and requires less thought.

**To create a linked drawing from a geocoded table:**

1. Choose **File - Link - Drawing** and open the desired database file or connect to the desired data source.
2. Choose the table desired and check the desired fields. Specify the fields that contain latitude and longitude values (by default, the system will guess that any fields named "Latitude" and "Longitude" are the fields to use. Press **OK**.

Four new components will appear in the project:

- A linked table - This linked table is a way of linking the table data from the geocoded table that will provide the data for the linked drawing.
- A query - This query transforms the ordinary, geocoded data in the coordinate columns into geometry data from which the linked drawing will be created.
- A linked drawing and the linked drawing's table - The linked drawing is like any drawing, except it is created dynamically from the data within the geocoded table.

For example, if the table below were located in some database provider (such as SQL Server or Oracle) or was saved in a database file such as an .mdb file it could be used to create a linked drawing.

<table>
<thead>
<tr>
<th>X</th>
<th>Y</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.0</td>
<td>1.1</td>
<td>Oil Well</td>
</tr>
<tr>
<td>1</td>
<td>2</td>
<td>Oil Well</td>
</tr>
<tr>
<td>2</td>
<td>4</td>
<td>Oil Well</td>
</tr>
<tr>
<td>3</td>
<td>8</td>
<td>Oil Well</td>
</tr>
<tr>
<td>3</td>
<td>9</td>
<td>Oil Well</td>
</tr>
<tr>
<td>6</td>
<td>2</td>
<td>Gas Well</td>
</tr>
</tbody>
</table>
If we created a linked drawing from the table above using the X field for Longitude / X and the Y field for Latitude / Y we could create a drawing of points like that seen below.

For each record in the table, a point has been created. If we add a new record to the table, delete a record or change an X or Y value then the corresponding point will be added to the drawing, or deleted from the drawing or moved within the drawing.

For a step-by-step example, see the Create a Linked Drawing from a Geocoded Table example topic.

**Uses for Linked Drawings**

Linked drawings allow us to create drawings from data that is changeable and most conveniently stored within geocoded tables or queries. The classic use for a linked drawing is within a Manifold IMS application such as a vehicle tracking web site. Suppose we have a fleet of trucks or ships or other vehicles and we would like to display the location of each vehicle on a web site map. Suppose we can acquire the location of each vehicle through some other application that receives location data from a GPS in each vehicle and places it into a table in our database. Showing the location of each vehicle in Manifold is as easy as creating a linked drawing using that table.

Because most data acquisition software for vehicle tracking applications is already programmed to update a database table, using linked drawings completely eliminates the need to teach the tracking software package how to interact with a GIS system. All the tracking software need do is update a table, as it already knows how to do.

Linked drawings are also very useful in situations where the number of objects to be displayed is changeable. For example, suppose we work for an insurance company that sells its insurance products through independent agents. The list of approved agents might change every few weeks as new agents are added and as poorly performing agents are dropped. We want to create a web site that a prospective customer can use to find the nearest agent offering our insurance products. It would be very convenient to use a linked drawing in the web site so that the list of approved agents can be kept in the form of a geocoded database table.

This reduces the task of updating the list of agents to an interaction with the database table, which allows greater flexibility in software that can be used to update the status of each agent, what products he or she offers from our company and so forth. There will always be many more software packages and programmers who know how to interact with a popular DBMS product than will know how to interact with GIS software. Therefore, using linked drawings is a good way to add dynamic updating of data to Manifold projects and to Manifold IMS web sites without requiring a lot of GIS expertise on the part of accessory software or web site programmers.

**Lines in Linked Drawings**

Although there is no standard GIS method for representing lines in geocoded tables, Manifold uses a simple convention that can be used to create lines in linked drawings from tables. When importing or linking a drawing...
from a geocoded table, we may optionally specify a LineID column that will be used to identify which points will be used to draw lines.

As Manifold scans through the table it will draw lines through all contiguous sequences of two or more records for which the LineID value is the same. When the LineID value changes Manifold will start a new line. If the LineID value is the same for only one record the record will be treated as a point and no line will be drawn. The column used for LineID may be of any type, for example, it could be a numeric or a text column. Newly-created lines will inherit the LineID values of the points used to create them.

<table>
<thead>
<tr>
<th>X</th>
<th>Y</th>
<th>Comments</th>
<th>Line Number</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.0</td>
<td>1.1</td>
<td>line 1</td>
<td>1</td>
</tr>
<tr>
<td>2</td>
<td>4</td>
<td>line 1</td>
<td>1</td>
</tr>
<tr>
<td>3</td>
<td>8</td>
<td>line 2</td>
<td>2</td>
</tr>
<tr>
<td>3</td>
<td>9</td>
<td>line 2</td>
<td>2</td>

<td>6</td>
</tr>
<tr>
<td>2</td>
<td>3</td>
<td>line 3</td>
<td>6</td>
</tr>
<tr>
<td>6</td>
<td>3</td>
<td>line 4</td>
<td>5</td>
</tr>
<tr>
<td>6</td>
<td>4</td>
<td>line 4</td>
<td>5</td>
</tr>
<tr>
<td>6.2</td>
<td>5.2</td>
<td>line 4</td>
<td>5</td>
</tr>
<tr>
<td>6.2</td>
<td>5.8</td>
<td>line 4</td>
<td>5</td>
</tr>
</tbody>
</table>

For example, consider the table above. If the Line Number field is specified as the field to use for LineID then Manifold will use the first three records to draw a line through three coordinate points because the value of 1 is the same in the given LineID field. Next, the system will draw a line through two points corresponding to the records with LineID values of 2. The next record has a LineID value of 5 but because the LineID value changes immediately to the next record it is ignored.

The system then encounters two records with LineID of 6 so it creates a third line through two points. Finally, Manifold reads four records with a Line ID of 5 so it creates a fourth line through four coordinate points.

From the above example note there are two key characteristics of this simple format for representing lines in tables:

- Lines are created from records taken in order. The geocoded table must list the coordinate records in the order that the line is to be built, from beginning to end.
- Lines are denoted by a change of value in the LineID field and are not tied to unique values. In the example above the 5 value was used twice in the table. Once it was used for a single record and thus ignored and the second time it was used for a line consisting of a sequence of four points.

To amplify the second point, the table below would have the same effect in creating lines as the table above.

<table>
<thead>
<tr>
<th>X</th>
<th>Y</th>
<th>Comments</th>
<th>Line Number</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.0</td>
<td>1.1</td>
<td>line 1</td>
<td>1</td>
</tr>
<tr>
<td>2</td>
<td>4</td>
<td>line 1</td>
<td>1</td>
</tr>
<tr>
<td>3</td>
<td>8</td>
<td>line 2</td>
<td>0</td>
</tr>
<tr>
<td>3</td>
<td>9</td>
<td>line 2</td>
<td>0</td>

<td>4</td>
<td>line 4</td>
<td>1</td>
</tr>
<tr>
<td>6.2</td>
<td>5.2</td>
<td>line 4</td>
<td>1</td>
</tr>
<tr>
<td>6.2</td>
<td>5.8</td>
<td>line 4</td>
<td>1</td>
</tr>
</tbody>
</table>
A new line would be created whenever the field used as the LineID field changed from a 0 to a 1 or back to a 0. For legibility reasons, though, most applications will use a field for LineID that more naturally identifies the lines to be created than a pattern of changing from 1's to 0's.

For example, if our application is a vessel tracking application that shows where ships are currently located and where they have been an easy way to show the tracks of ships where each ship has a unique ship number is to use the Ship Number as the LineID field.

<table>
<thead>
<tr>
<th>X</th>

<td>5.2</td>
<td>line 4</td>
<td>5</td>
</tr>
<tr>
<td>6.2</td>
<td>5.8</td>
<td>line 4</td>
<td>5</td>
</tr>
</tbody>
</table>

We would set up our database so that the table used for the linked drawing is first sorted by Ship Number and then sub-sorted by a date/time field (not shown in the example above) that gives the time each location was acquired. Using the Ship Number field in that case as the LineID field will automatically result in lines that show the ship's track. If we like, we can even format the linked drawing so that lines use directional arrowhead styles so we can see the direction the ship is headed.

For convenience, if we import or link a drawing from a geocoded table and we build lines using a LineID column Manifold will propagate that LineID column to the created line drawing.

**Controls**
When creating a linked drawing the typical dialog seen when connecting to a database file or data source is seen above. The illustration shows a connection to an Access .mdb file data source that was created in the Data Source dialog (as in the example below in this topic). This dialog allows us to specify how the linked drawing should be created from the table.

**Data source**  The source used from the Data Source dialog.

**Type**  The type of geometry source. In the above example it is a Table with coordinate columns, that is, a geocoded table. In more advanced usage we might link a drawing from a table that contained geometry data in various forms, such as with a spatial DBMS or a table containing geom types.

**Source**  The table to use, if there is more than one table in the data source.

- **Select All** - Check all columns.
- **Select None** - Do not check any columns.
- **Select Inverse** - Uncheck all currently checked columns and check all other columns. A fast way to use all but one column: click Select None, check the one column not desired and then click Select Inverse.

(Columns pane) Check columns that are to appear for each point in the linked drawing.

- **X**  Choose a field to use for X coordinate or longitude.
Choose a field to use for Y coordinate or latitude.

**Latitude / longitude coordinates**
If checked, interpret the X / longitude and Y / latitude coordinates as unprojected latitudes and longitudes using decimal degrees. Checked by default. Uncheck if the table coordinates contain projected coordinates.

**LineID**
 Optionally specify a field to use to determine points that are to be used to guide the creation of lines. A line will be drawn through all points having the same value in the LineID field. A new line will be started for each new value in the LineID field. Single-point lines are ignored. The LineID column may be of any type.

**Coordinate order**
 Only enabled if a LineID field is selected. Specify a field to use to determine the order in which records are taken to construct a line.

**Coordinate Order**

When building lines using some LineID column, Manifold by default will take records as they come in whatever order they are presented by the data source for the table. That is risky, because the order in which records are presented might be varied by sorting, compaction or other activities with tables and databases.

Specifying some field that gives the order in which records are taken for lines will guarantee the line is assembled in correct order.

</tbody>
</table>

For example, the sample table used above could have a Line Order column added to it that has numbers in ascending order for each of the coordinates of a line. Even if the table is resorted into random order the lines will still be assembled correctly if the Line Order field is specified in the Coordinate order box.

**Refresh Data**

The data in an external table from which a linked drawing is created controls the contents of a linked drawing. When a record is added to or deleted from the table a corresponding point in the linked drawing will be added or deleted. If the coordinates of a record are changed in the table the corresponding point in the linked drawing will move.

When Manifold is used interactively, linked drawings are updated whenever they are opened or whenever we press the View - Refresh Data command. When Manifold is used in Internet Map Server mode, linked drawings will automatically be refreshed on whatever interval has been specified.

Refreshing a linked drawing will fail gracefully in case of a connection error, for example, as might be caused by a network failure if the drawing is linked from a data source accessed over a network. In general, whenever an update fails for a component linked from an external table Manifold will report any detailed error data returned by the data source.
Note that unlike map server mode, in interactive usage linked drawings are not automatically refreshed. They are only refreshed (updated to any changes in the controlling table) when the drawing is opened or when the Refresh Data command is issued. The reason for this behavior is to guard against situations where the linked drawing suddenly changes while we are in the middle of an editing command or a transform operation.

Because external tables can be edited independently of what we are doing in Manifold, if linked drawings were automatically refreshed in interactive mode we could easily encounter a situation where we are doing something and suddenly points might appear or disappear or move about. Suppose we were in the middle of transferring a selection from the linked drawing to an image: in that case the sudden change would wipe out the operation.

Relinking a Drawing Linked from a Geocoded Table

Drawings linked from coordinate columns in geocoded tables cannot be relinked if a connection is lost using the Relink command: attempting to relink such a drawing using the Relink command can only reconnect the drawing to the intermediate query. If the connection to an external data source is lost, the linked table within the project upon which the intermediate query operates is the component that must be relinked. In such cases it is usually easier to simply re-create the linked drawing directly from the external data source using the File - Link - Drawing command.

Cascading Links and Refresh Data

Manifold allows cascading links, where one linked component is created from another linked component. Circular links are resolved automatically. For example, suppose we create a linked table called Table A in a project that is linked from a geocoded table called Table X in an external data source, such as a table in a SQL Server or Oracle database. We could then create a linked drawing in the project that is linked from that linked table. Let's say we call that linked drawing Drawing A.

However, when a cascading link is created in this way, refreshing the linked drawing will update the drawing to any changes made in the linked table, but it will not cause a cascading refresh backwards out of Manifold to the external database. That is, if we make any changes in Table A and we then refresh Drawing A, the drawing will show those changes. However, if we make any changes in the external Table X and then we refresh Drawing A, the changes will not appear in the drawing. We must first refresh Table A so that it incorporates the latest changes in the external Table X and then we can refresh Drawing A.

Properties

We can get useful information on a linked drawing by right clicking on it in the project pane and choosing Properties to see the View - Properties dialog. Clicking the [...] browse button to the right of the Status information line opens a very useful dialog that shows the data source of a linked component, the link technology and the name of the rowset, if the component is linked from a table or query and the behavior of the data in multi-user editing scenarios.

Caching

Linked drawings are automatically cached locally using techniques similar to those employed in Manifold Enterprise Edition to cache shared components that are linked from an Enterprise server. If a connection to an external database table is lost during a work session Manifold will continue to operate the linked drawing using the local cache. When a project containing a linked drawing is saved, the local cache will be saved into that project.map file. When the project is opened again, the cached image will be synchronized with the current version of the database table so when the drawing is opened it will show the latest data in the table.

Use with IMS

Linked drawings work very well with IMS (Internet Map Server) applications. There are three main considerations to keep in mind when using linked drawings within a map server project:

- Choose a suitable refresh interval. The Refresh linked components every ... minutes control in the Export Web Page dialog allows choice of refresh interval. Choosing a value of 0 will force a refresh with every browser session served. With a large number of users, this is a guaranteed way of achieving unacceptably poor performance. A better idea is to choose a low value such as one or two minutes, if a linked drawing must be kept reasonably up to date as, for example, in vehicle tracking applications.

The Internet user login (IUSR_systemname) for the machine running IMS must have access permissions to read the database table used to control the linked drawing. When Manifold runs in IMS mode it runs with the Internet user's permission and so must have the ability to at least read the table.

The path to the table must be preserved, or IMS will not be able to find the data source and open the table.

**Absolute Paths**

When specifying a database table to control a linked drawing the path to the data source is often normalized by Microsoft OLE DB or ODBC drivers to an absolute path. Therefore, when moving projects and any tables used by linked drawings to a different machine, try to preserve the absolute path to the table. For example, if the table is located at C:\Manifold Projects\mytable.mdb on one machine then place it in the same location on the other machine. This is obviously an important consideration when moving files from a development machine to a production IIS machine for use with Manifold IMS in a map server application.

If we would like to exchange data with other users we should employ linked drawings with care if the linked drawing is created from a table or query outside the Manifold project. If the table controlling a linked drawing is outside of Manifold it will not stored within the Manifold.map project file. Sending a colleague a copy of our .map file will not also send them the database table from which the linked drawing is created.

**Re-attaching a Linked Drawing to a Data Source**

If a linked drawing is disconnected from its data source, it may be reconnected using the Relink command. See the Drawing - Relink / Unlink topic.

Linked drawings are deliberately designed to have a very damage-resistant connection to their originating tables. We can even delete the table and the drawing will still function from cache if at all possible, ready to be relinked. Renaming or removing the table or query (or renaming or removing the coordinate columns in the table or query) harms the link between the drawing and the table, but linked drawings are designed to survive such scenarios and can even be relinked to modified data with the Relink command.

While it is not a good idea to tempt fate by deleting tables or otherwise removing data upon which linked drawings depend the robust nature of the connection combined with use of the Relink command will often allow linked drawings to survive significant damage.

**Converting a Linked Drawing to an Ordinary Drawing**

Convert a linked drawing to an ordinary drawing by right clicking on the linked drawing in the project pane and choose Unlink. This will cut links to the controlling table or query and recreate the drawing as an independent, ordinary drawing. See the Drawing - Relink / Unlink topic.

**Importing an Ordinary Drawing from a Geocoded Table**

Drawings may also be created from geocoded tables by using File - Import - Drawing and selecting a database table file or data source in the Files of type box. In this case a drawing of points will be created from the geocoded table but it will not be linked to the table.

**Editing Linked Drawings**

Although a linked drawing that appears in the project pane is normally read-only, it is usually possible to edit that linked drawing by editing the linked table within the project from which it is created, which will end up editing the table in the data source as well. We could also edit the original data source. For example, suppose we have a linked drawing created from a query that grabs data from a table in an external database file. We could change that linked drawing by editing either the external table or by editing the query.

Linked drawings normally are used not for the purpose of interactive editing through the Manifold console graphical user interface but rather to display visually data from some database table. The assumption is that the database table from which the drawing is created will be edited through the database management system or by other programs which will change the data in the table.

**Open Data Source Command**
Right clicking a component that is linked from an external data source in the Project pane and then choosing **Open Data Source** will open the Database Console and connect to the component data source.

Opening a component linked from an external data source in its own window, and then choosing the **Open Data Source** command in the component menu (for example, choosing **Drawing - Open Data Source** when a linked drawing window is open) does the same thing.

**Creating a "Lines-only" Display**

When creating lines in a linked drawing using the **LineID** option Manifold will draw all points as well as lines in the drawing.

This can result in a cluttered display, like that seen above created from the tables used as examples earlier in this topic. The lines have been formatted using a directional line style to show their beginnings and ends. Since points are also drawn they appear above the lines in the same drawing and depending on placement can clutter the drawing.

In interactive work we can easily remove the points, if desired. When working with IMS we cannot interactively delete the points, but we can use a convenient formatting trick to prevent them from appearing. We simply format the drawing so that points are drawn using transparent color for the foreground color.

This causes the entire point to disappear so no points appear in the drawing, resulting in a lines-only drawing. If we need to create an IMS display that has a combination of some lines and some points we can create two linked drawings in our project from the same table, one of which uses the **LineID** option and has foreground formatting for points set to transparent color so there are no points and the second drawing of which does not use the **LineID** option so there are no lines. By using the two drawings in a map with the lines-only drawing appearing in a layer above the other drawing we can cause points to appear below the lines.
The appearance in IMS will be the same except that the points will appear to be drawn below the lines.

There are many possibilities to create exactly the display desired. For example, if a display is desired that shows lines for all points but which draws points only for single points or only for the last point in a line sequence we can use SQL to help create such a display. We begin by creating a lines-only display in one linked drawing. Next, assuming that points have fields that can be used to distinguish one point from another we can use a SQL query in our database to create a table that has only single points or terminal points (through clever use of fields that distinguish one point from another) and then create a linked drawing from the query.

Combining the two drawings in a map will result in a display that shows lines for all points but draws only those points that are single points or that are terminal points. The exact SQL expression that creates a table of only single points or terminal points will, of course, be dependent on what fields are available and how the geocoded table is written in the first place. For example, if we have a vehicle tracking application the code that updates the table with the latest position point may write a flag field that marks this record as the latest in the sequence for that vehicle.

Example

In this example we take a geocoded table of restaurant locations and we create a linked drawing. We then create a query using the table and create a linked drawing from that query.
The table seen above in Microsoft Access shows sushi restaurants in Palo Alto and Menlo Park near the Northern California USGS facility in Menlo Park. The table is similar to the geocoded table created in the Street Address Geocoding topic example.

To create a linked drawing using this table we choose **File - Link - Drawing** and then in the resulting Data Source dialog we must add a new data source for the Access .mdb file in which the table is stored.

Click on the **Add Data Source** button.
In the resulting Connect To dialog we navigate to the folder in which the .mdb file is stored and choose MDB Files in the Files of type box. We can then click on the desired .mdb file to highlight it and then press Open (or, simply double-click on the desired .mdb file).

This adds the file as a data source. We enter a memorable name into the Name field for the data source, in this case, Sushi Restaurants and press OK.
In the resulting Link Drawing dialog we can accept defaults, since the table already has fields named Latitude and Longitude and Manifold will know to use them by default as the Y and X fields. Press OK.

The result is that several new components appear in our drawing, including a new linked table, an intermediate query and a new linked drawing and its table.
If we open the linked table we see it is simply a table linked to the external Access .mdb table. If we change anything in that external table the changes will appear in this linked table and vice versa.

If we open the drawing we see that it contains a point at the location of each restaurant. This drawing has been created from the table via an intermediate query that creates, on the fly, geometry data from the geocoded table.

There are many things we can do with geometry data. However, even though our new linked table (seen above) has been created automatically by Manifold to make it more convenient for us to create linked drawings from external geocoded tables, it is still a Manifold table just like any other. We can use it just as we might any other table.

In fact, we can create queries from that table in addition to the intermediate query already automatically created for us by Manifold. If we would like to customize the data taken from that table we can easily do so with a query.

Suppose that we would like to create a linked drawing that shows only sushi restaurants in Menlo Park. We can do that by writing a query and then creating a linked drawing from that query.

We create a query with the text above. If all we are interested in are the locations of the sushi restaurants we don't need to select everything (using Select *) but we must select at least the Latitude and Longitude fields. In this case, we select everything so that the linked drawing's table will have all the fields that were in the original table.
If we are curious to get a tabular view of the query's results, we can highlight the query in the project pane and press the **Run** button to see the above. Note that records from Menlo Park have been selected.

Manifold allows us to use the results of queries like tables. If we like, since the above results provide geocoded table data, we can create a linked drawing from them. In this case, instead of linking a drawing to an external geocoded table we will link it to a query within the same project.

We once more we launch the **File - Link - Drawing** dialog and choose **This Project** in the **Data Source** dialog. This data source is "built into" the Data Source dialog when linking a drawing. It allows us to create linked drawings from the Manifold project with which we are working.
In the **Source** box in the **Link Drawing** dialog we choose **Menlo Park Restaurants**, the name we used for our query. We accept all other defaults and press **OK**.

Several additional components are created in the project pane: a new linked table called **Menlo Park Restaurants 2** that is linked from the query, an intermediate query, and a linked drawing and its table.

It may seem to be somewhat extravagant of Manifold to create these new components, but doing so provides a very systematic, regular approach to the matter that is the same whether we link a drawing from a geocoded table from outside the project or from inside the project: in both cases, the first thing Manifold does is create a linked table to the data, and then an intermediate query and finally the linked drawing and its table.
When we open the new linked drawing and pan and zoom it to the same location as the other linked drawing, we can see that it shows only those restaurants that are in Menlo Park (which is slightly North and West of Palo Alto).

Now let's do something interesting and show the nature of the linkage between the original linked Sushi Restaurants table and the drawing linked from the Menlo Park Restaurants query. This will show how Manifold can have cascading links within the same project, where one linked component is created from another linked component.

Let's select two of the sushi restaurants in the original table and delete them.

Selecting the two records and pressing Edit - Delete will delete the records for Mikasa and Toshi's Sushiya.
If we click on the Menlo Park Restaurants 2 Points drawing (the linked drawing created from the query) and choose Edit - Refresh Data the linked drawing will refresh back through the query and cause the query to refresh itself from the (now altered) table. The result is that two points, those representing Mikasa and Toshi's restaurants, disappear.

We can bring the records back by clicking onto the original Sushi Restaurants table and choosing Edit - Undo. This restores the records, which has the same effect as if we added two new records.

If we click onto the Menlo Park Restaurants 2 Points drawing and choose Edit - Refresh Data once more we see two new points appear for the restored records. If only it was that easy to bring a good sushi restaurant back into business!
Drawings

The point of the example above is to show how linked drawings are created on the fly from geocoded tables or queries that contain geocoded data. As records are edited, added to or deleted from the original tables or queries, points corresponding to those records will move, appear and disappear as the drawings linked to those tables or queries are refreshed.

Note that when linked drawings are created using cascading links that ultimately arise from data sources outside of the Manifold project, a refresh of the drawing will cause a refresh all the way back to the original, external data source, to update the drawing using the latest data available.

Read / Write Linkage to Databases

Keep in mind that when Manifold links a table from a database that unless something about the connection makes it read-only (not a typical situation), the connection will be read / write. Changes we make in the linked table are changes in the database from which it is linked.

Consider the Sushi Restaurants linked table as it is at the end of the above example.

If we opened the originating .mdb file in Access we could see the same table in Access, as seen above. [We can have the same table open both in Access and also have Manifold running with the linked table opened in Manifold as well.]
Suppose that back in Manifold we highlight two of the records...

<table>
<thead>
<tr>
<th>Latitude</th>
<th>Longitude</th>
<th>Name</th>
<th>Address</th>
<th>City</th>
<th>State</th>
<th>Zip</th>
</tr>
</thead>
<tbody>
<tr>

</tr>
</tbody>
</table>

Suppose that back in Manifold we issue an **Undo** command to restore the two deleted records to the table. Not only will they re-appear in the linked table in Manifold...
...but will also appear back in the table in Access as well.

Example Scenario

Linked drawings created from tables or queries have great flexibility. In addition to the above example, consider this scenario in which a linked drawing is used to create a particular display:

For example, we might have a table of populated places linked from an SQL Server database. We want to label the places so that labels for larger places appear on top of labels for smaller places.

We create a query for each population range such as...

```
SELECT [Latitude (I)], [Longitude (I)], [Pop]
FROM [Places] WHERE [Pop] BETWEEN 10000 AND 50000;
```

... and we link a drawing from each query.

We then create a label component for each linked drawing and place all the label components in a map so that the label layers for larger places are higher on the display stack than those for smaller places. Each time the project is opened, the system will connect to the table on the SQL Server, re-compute the queries, update the drawings linked to the queries and update the labels bound to the drawings.

Important Note when Using 64-bit Manifold Editions

Due to a lack of required Microsoft facilities in 64-bit Windows systems, Manifold in 64-bit mode cannot export, import, export or link to DB, HTML, MDB, XLS or WKx format files. This includes no access to the MDB parts of Manifold MFD and MapInfo TAB imports. The workaround for importing or exporting such files is to launch Manifold in 32-bit mode by using the Manifold System 7x (32-bit) shortcut, perform the export from or import into a .map project file and then re-launch Manifold in 64-bit mode using the Manifold System 7x (64-bit) shortcut. Linking is more complex: the data must be in some format usable in 64-bit mode within 64-bit Windows systems, such as a SQL Server database. Alternatively, the data can be kept within a Manifold .map project file and linked using the Manifold ODBC driver.

Tech Tip

Master the use of linked drawings with geocoded tables that use straightforward, unprojected longitude and latitude coordinates before attempting to work with geocoded tables that use projected coordinate systems for their X and Y coordinates.

Notes

Refreshing a linked drawing created from a table that resides in an external data source will refresh the table. Refreshing a drawing linked from a query will recompute the query.
Refreshing a query will refresh all linked drawings descended from that query.

Although this documentation is written to require decimal degrees notation, in fact if coordinate columns in a geocoded table use degree - minute - seconds notation Manifold will try to parse the notation used to extract valid longitude and latitude values. manifold.net strongly recommends using decimal notation to avoid any possible ambiguity.

Multi-User Editing of Linked Drawings

Manifold Enterprise Edition and higher versions support concurrent, multi-user editing of linked drawings that are created from geometry columns in tables. A drawing can be edited by more than one person at the same time by storing that drawing as a table in a database and then working with it in Manifold as a linked drawing. Each user who needs to edit the drawing can link it into his or her project. It may then be edited by multiple users simultaneously, whether the drawing appears in a drawing window or as a layer in a map window.

For example, a drawing may be linked from an Oracle Spatial database into a project on our machine and we could edit that drawing at the same time that a colleague is also editing it on a different machine. If any editing conflicts arise with other users, say if we delete a particular area while our colleague is moving it to a different location, we can resolve such editing conflicts using the Review pane.

Resolution of editing conflicts is important because when potentially many people are editing the same drawing at the same time it is possible that more than one person might edit the same object (that is, the same point, line or area) differently. Manifold uses a version column in the database table to keep track of which objects have been changed.

If we do not have Enterprise Edition or if we do not create and use a version column, we can still use linked drawings in multi-user environments. However, if no version column is in use then any changes made to objects made by any one user will immediately apply to the data source without notice to other users. Other users will only become aware of such conflicting changes when they refresh their linked drawings and see that someone else's edits have been applied instead of theirs.

Manifold Database Administrator Edition provides the Administrator Console to make it easy to prepare drawings stored on database servers for multi-user editing. Administrator Console allows DBMS administrators to designate friendly names for components, to enable storage of formatting with drawings within the database and to specify defaults to be used when importing and linking drawings, such as automatic use of version columns.

Linked Drawings and Refresh Data

Whenever we edit a linked drawing the objects displayed arise from data fetched from the originating data source to which the drawing is linked. The drawing objects we see and edit are cached locally and will not reflect changes in the originating data source until the drawing is refreshed.

Refreshing a drawing using View - Refresh Data or the equivalent keyboard shortcut ALT F5 re-synchronizes the drawing with the originating data source and updates the Review pane with editing conflicts, if any.

Drawings are refreshed automatically when a project is opened (the default setting in the Tools - Options dialog) but otherwise we can work a long time, if desired, on a drawing without doing a refresh. Whenever we do a refresh, our drawing will be synchronized with the data source so that the drawing contains all of the changes made to the data source (by anyone) since the last refresh, and the data source will be updated with our changes. If our changes conflict with any others, we can resolve them using the Review pane.

For this reason, it is wise to Refresh Data or do an ALT F5 when commencing an editing session and then on a regular basis throughout an editing session.

Multi-User Editing Overview

The following guidelines apply to multi-user editing of drawings linked from enterprise-class DBMS products such as Oracle or SQL Server:

- Drawings linked from geometry data support concurrent multi-user editing. Multi-user editing is not supported with linked images, with linked surfaces or with drawings linked from geocoded tables.
- The table from which the drawing is linked must have a writeable version column that is a numeric column. The version column is normally created by the drawing's author when the drawing is exported into the database. Drawings exported to Oracle spatial data will have a version column created automatically.
- We must specify a column to use as the version column version when we link the drawing into our project if we want to be able to cleanly resolve editing conflicts between users. If we do not specify a version column to use, we can still edit the drawing with multiple users at the same time, but Manifold will not be able to resolve multi-user editing conflicts for us. Therefore, it is wise to always use a version column.
• To enable versioned editing (that is, edits using a version column to resolve conflicts) we must include the drawing's ID column (the default setting) when exporting the drawing into the database. Versioned editing uses the ID column as a key column in the database for faster performance. See the discussion below on key columns.

• Manifold provides two modes to use for resolving editing conflicts. The default mode used when a version column has been specified is to interactively review any editing conflicts with changes made by other users. If a version column has not been specified (or, if we simply choose to be authoritative), we can use an edit mode specifying that any changes made by us will overwrite changes made by others without review. The mode in use may be viewed and specified in the View - Properties - Link / Share Status dialog reached from the View - Properties dialog of the drawing.

• We use the Review pane to see the changes we have made as well as the changes made by other users and to choose which version we prefer to use to resolve any conflict.

• Drawings that have had formatting storage enabled on the database by Administrator Console may be linked with formatting from the server. Any formatting changes made by different users will be automatically managed and resolved by the Review pane.

• Most organizations using Manifold for multiuser editing of linked drawings will install some Database Administrator licenses to enable use of Administrator Console to prepare drawings for fast and easy use by all users and to enable formatting storage within database servers.

Version Columns

To make multi-user editing possible we must have a version column in the table from which the drawing is linked. The version column must be a numeric column and it must be writeable. This column may use any name and does not need literally to be called "version," although it is normally it is given a name similar to that. Most organizations using Manifold extensively will also standardize on using a particular name so that everyone knows that a column of that name is intended for use as the Manifold multi-user editing version column. The version column need not be displayed or linked into the drawing's table: when the drawing is linked from the table we do not have to check this column for inclusion in the drawing's attributes.

If we think that a drawing may be edited by multiple users we normally create a version column in the drawing before exporting it into a database system. If a drawing has already been exported into geometry storage in a database table and does not have a version column, we can easily add a version column to that table. To do so, simply link the table into a Manifold project to create a linked table. Open the linked table and right click onto the column heads to add a new numeric column or use the Table - Design command to add a numeric column. Any numeric data type will be fine for the column: most users will employ the 32-bit integer data type used by default to create numeric columns.

Drawings exported into Oracle spatial databases do not need to have a version column created as this will be done automatically during export into Oracle. The name of the version column so created may be customized, if so desired.

Every time an object is changed by someone, the version value for that object in the version column will change. Manifold can compare the version values for any object as stored in the local cache used for editing with the version value stored in the originating table to tell who has changed that object and if any editing conflicts have arisen. Manifold can then apply the edit mode rule specified by the user (by default, to review conflicts) to resolve any conflicts. Conflicts are viewed and resolved using the Review pane.

Specifying Edit Modes

The method used for resolving editing conflicts between users is specified in the View - Properties - Link / Share Status dialog reached from the View - Properties dialog of the drawing. There are two settings:

• Review changes made by others when resolving conflicts. This mode detects changes made by others to drawing objects and allows us to review editing conflicts using the Review pane. We can then decide whether we prefer our changes or changes made by someone else. This is the default mode whenever we use Enterprise edition or above and have specified a version column. This choice enables orderly, concurrent multi-user editing of geometry in drawings.

• Overwrite changes made by others without review. This mode does not detect changes made in drawing objects by others but simply applies any local changes made, overwriting any changes made by others. This is the only choice if we are not using Enterprise edition or if we have not specified a version column. We can still edit geometry in drawings with this choice, but any changes we make will be immediately applied regardless of what someone else may have done to that same object since our last refresh.
The Edit mode applies to geometry editing only: as is the case with any table attribute editing, any edits of non-geometry fields in a linked drawing’s table will always be immediately applied, overwriting any changes made by another user.

**Example**

In this example we will first export the US_Main sample drawing of the United States into an Oracle 10g Express Edition database. We will then simultaneously edit it by two users from two different sessions of Manifold, deliberately introducing an editing conflict. We will then resolve the conflict using the Review pane.

**Step 1: Export a Drawing to Oracle**

We begin by creating a project that has the US_Main example drawing in it, as set forth in many of the topics in the Examples chapter. We will export this drawing to an Oracle Express server, so there is no mystery as to what the drawing is or how it got into Oracle.

**Note:** Depending on the version of US_Main in use the drawing’s table may have more than one field as variable length ASCII type. A limitation in Oracle requires us to change the type of such fields (right click on the column header and choose Change type) to a fixed length field of sufficient length to hold the data so that no more than one field is variable length.

We right-click on the drawing in the project pane and choose Export, specifying Data Sources in the Save as type box to launch the Data Source dialog. In the Data Source dialog we create a data source for the Oracle Express server we choose to use. We then double-click that Oracle Express server data source.
In the resulting Export Drawing dialog we choose defaults as seen above.

Note that the Version column box is already filled in for us since Manifold will automatically create a version column when using an Oracle database. Press OK. Close the project.

**Step 2: Link a Drawing from the Database**

Let us now go to a different machine, launch Manifold and link in the US_Main drawing from the Oracle database.

Since this example will use two different sessions on two different computers to illustrate the resolution of multi-user editing conflicts, we will choose a different color Windows color scheme on each computer. One computer will use the default blue Windows color scheme and the other will use a green color scheme. We will refer to the different computers as the Blue computer and the Green computer.

**On the Blue Computer:**

We launch Manifold with a new project.
We launch the Database Console and connect to the Oracle server using the Data Source dialog. We highlight the US_Main drawing just exported and press the Link button. The Database Console is almost always used to link drawings from big databases because (unlike the File - Link - Drawing dialog) it has good facilities to make it easy to find the one drawing, possibly among very many items in the database, we would like to use.

The Import / Link Options dialog opens up. We will use the entire drawing (and not just some subset area of interest). Linking a drawing from Oracle will automatically choose the VERSION field in Oracle to use as our version field.

If we open the linked drawing and zoom into the Southeastern portion of the US we see it is indeed the US_Main example drawing in play. Note that we have the Review pane opened and undocked so that it is conveniently near the drawing window when we make screenshots.

On the Green Computer:

Let's now move to the green computer and launch another Manifold session. We can repeat the above procedure to link the same drawing from the same Oracle server into this second session.
If we open the drawing on the second server, we can see that it is also the same, US_Main, drawing. We have also opened the Review pane on the green computer.

On the Blue Computer:

Moving to the blue computer, we **CTRL-ALT** click on one of the areas (South Carolina) to select it for editing.

We can then **SHIFT** click and drag one of the editing handles to move the entire state. We will drag South Carolina out into the Atlantic.
We then click on any open space in the drawing to deselect the area from editing.

**On the Green Computer:**

When we switch over to the green computer, the first thing we notice is that South Carolina has not moved. Manifold won’t move objects about in real time as people on different machines edit them, because if Manifold did so it would be impossible to reliably edit drawings in an orderly way. If it did so we could be in the middle of an edit and suddenly the object might be teleported out from under our mouse to a different location.

Instead, Manifold only updates objects when we do a **Refresh Data** command (or **ALT-F5** keyboard shortcut) on the drawing. If we don’t **Refresh Data** on the green computer, the drawing on the green computer will not be refreshed and will not show the changes made on the blue computer. Instead, the drawing will continue to display based upon locally-cached data brought into the green computer from the database to create and display the linked drawing.

In the usual course of events, before we set out to edit an object we would do a quick **ALT-F5** to refresh the drawing to see if anyone already has altered an object of interest before we start editing it. However, because we are trying to simulate a situation where two users on two different machines simultaneously edit the same object in different ways, we will not refresh the drawing. Instead we will proceed to edit it.

Because we have not refreshed, the drawing still looks as though no edits have occurred. The Review pane also reports **No editing conflicts**. We begin by **CTRL-ALT** clicking on South Carolina to select that area for editing.
We then **SHIFT** click and drag the state out to the Atlantic again, but this time to a more northerly position.

The moment we release the **SHIFT** click and drag, South Carolina instantly snaps to the new position, still selected for editing. The moment the area moves, a conflict appears in the Review pane and the pane reports 1 editing conflict.
We can click on the conflict in the Review pane to highlight it. When we do so, Manifold shows us the local edit we have made in blue and the remote edit made by another user in an alarming red color. Colors used for local and remote preview can be set in the Tools - Options dialog; however, the default colors play on the psychology of being easy to remember in that it's natural to assume we are always right and that changes made by other users should be shown in red, "error" color.

Since the same object has been edited in different ways by two different users, we must decide whether to use our local version or to use the remote version. We can choose our local version by pressing the Use Local button.
The conflict disappears from the Review pane and the area we have moved appears without any previews, still selected for editing.

We can click on any open portion of the drawing to deselect the area from editing.

**On the Blue Computer:**

Back on the blue computer we can see there has been no change in the display.
Until we either do a Refresh Data or attempt a different edit, the drawing will not be updated and no editing conflicts will be indicated by the Review pane.

If we choose Refresh Data or do the ALT-F5 shortcut, the drawing will refresh and the area will move to the position given it on the green computer, as indicated by the red arrow. [Manifold does not actually show red arrows when an object moves as part of the refresh. The red arrow was added to the illustration to show how the object moved.]

**Note:** The above example assumes Administrator Console has not been used to prepare drawings for simplified linking by setting default properties using the Database Object Properties dialog. When so prepared, drawings may be linked with a simple click of the Link button in Database Console with no need to specify options such as the version column to use.

**Disconnected Links and Editing Conflicts**

Editing conflicts in a linked drawing are stored locally in the .map project file. If not resolved via the Review pane, they will still be available even if the project is closed and then later opened. This allows deferring resolution of a large number of editing conflicts to a convenient time.

When a project that contains a linked drawing is opened, the linked drawing may or may not be automatically connected to the data source for the drawing. Normally, a linked drawing is automatically connected to its data source when the project is opened as this is the default setting for the Refresh linked components after opening file option in the Tools - Options dialog. However, it is possible that the data source is temporarily unavailable (such as, perhaps, during a network failure) or it is possible that the Refresh linked components after opening file option was turned off for some reason.

If a linked drawing in a project cannot be connected to the data source when the project is opened, any editing conflicts for that linked drawing will be inactive until the drawing is connected to the data source. The Review pane will still report inactive editing conflicts in the total number of conflicts reported in the Review pane's status bar, but inactive conflicts will not appear in the pane's list of editing conflicts. The Review pane will still allow discarding all local changes by using the Use All Remote toolbar button.
Connecting a drawing to the data source by using a **Refresh Data** or **Relink** command will refresh conflict data and will make any editing conflicts active again.

When using a data source to create a linked drawing, Manifold will create a **signature** for that data source which contains a description of the data source's key columns. Manifold can then use the signature to tell if the data source has changed substantially or has been replaced with a similar, but different, data source when a linked drawing is refreshed or relinked. When a linked drawing is refreshed or relinked, Manifold will validate the signature of the data source and will throw away all editing conflicts if the signature has changed, logging a message to that effect in the History pane.

**Usage Scenarios**

Conflicts created by concurrent multi-user editing can become intricate. For example, just because we pause to review an existing conflict in the **Review** pane doesn't mean that other people stop working. While we are considering an editing conflict in the **Review** pane some other person might change the object under review yet again, so that whichever way we decide to resolve the conflict there will still be a conflict with that object that will require a second review.

**Example**

Editing conflicts are detected by storing the current local version of each drawing object and comparing that version to the version stored in the data source every time the object gets changed. Whenever the local version of the changed object is not the same as the remote version, Manifold records an editing conflict.

There are two users, Andy and Bill, who edit the same linked drawing from different machines. The linked drawing contains two areas, Thing1 and Thing2. The version number for each area starts with 10. Andy launches Manifold and opens a `.map` project file containing the linked drawing, which refreshes the data for all linked components in the project. Bill does the same.

Andy changes Thing1, which increments its version number to 11. Bill changes Thing2, which increments its version to 11.

Bill now also changes Thing1. This creates an editing conflict, since the local version of Thing1 on Bill's machine is 10 but the remote version of Thing1 is already 11 because Thing1 has already been changed by Andy. If Bill doesn't have the **Review** pane open, he might not notice the conflict or he might not care, preferring to resolve all editing conflicts later on in his work.

Bill changes Thing2 again, which increments its version to 12. There is no editing conflict, since the local version of Thing2 on Bill's machine was 11 and the remote version of Thing2 was still 11.

**Example**

There can be situations where the object participating in the editing conflict is being changed while the person reviewing changes to the object decides how to resolve the conflict. In this case, committing local changes to the object will fail to resolve the conflict. Instead, Manifold will fetch the latest remote version of the object from the data source for comparison with local edits, to allow a decision on which version to use based on the latest remote and local changes.

There are two users, Andy and Bill, who edit the same linked drawing from different machines. The linked drawing contains two areas, Thing1 and Thing2. The version number for each area starts with 10. Andy launches Manifold and opens a `.map` project file containing the linked drawing, which refreshes the data for all linked components in the project. Bill does the same.

Andy changes both Thing1 and Thing2, which increments their versions to 11. Bill changes both Thing1 and Thing2 as well. This created two editing conflicts.

Bill chooses to use his local version of Thing1 in spite of the changes made by Andy. Bill selects Thing1 and presses the **Use Local** toolbar button. This sends Bill's version of Thing1 to the data source and increments its version to 12.
In the meantime, Andy changes Thing2 one more time, which increments its version to 12 as well. Bill is unaware of that change and reviews the outdated version of Thing2. He chooses to use his local version of Thing2. He selects Thing2 and presses the Use Local toolbar button.

Manifold detects that the version of Thing2, version 11, seen by Bill in the Review pane when he decided to use the local version is not the latest remote version of that object in the data source, version 12. Manifold will not blindly honor the Use Local command issued by Bill without giving Bill a chance to compare his local edits to the latest remote version of Thing2. So instead of applying the Use Local command Manifold will refresh the Review pane on Bill's machine with the latest remote version of the object and will keep the editing conflict open. Bill now has a choice between his local edits and the latest remote version of the object.

As seen in the above example, the Use Local command is not a blind, "crush the remote version no matter what" command. It is a more nuanced command meaning "use my local version if what I see in the Review pane accurately reflects the latest status of the remote version at the time I issue the Use Local command and if not, get the latest remote version and show me the conflict again so I can make up my mind."

Multiuser Editing and Formatting

If we have a Manifold Database Administrator Edition license we can use Administrator Console to enable storage of formatting for drawings in databases. Database Administrator Edition must first be used to enable storage of formatting for a drawing saved in the database. Once storage of formatting is enabled then other Manifold instances, for example, an Enterprise Edition license used by some other user can take advantage of formatting storage in the data source for that drawing. However, if Database Administrator Edition has not been used to configure storage of formatting for a particular drawing in the database, then if we link that drawing into a Manifold project we will not be able to change formatting from the default format settings.

When a drawing saved in a database has had formatting storage for it enabled in the data source, more than one user at a time can link that drawing into a project and change that drawing's formatting. Concurrent multi-user editing of linked drawings that involves changes to formatting by different users is similar to how concurrent, multi-user object editing works:

- Refreshing a linked drawing fetches the latest formatting for that drawing stored in the data source.
- Changing the formatting of a linked drawing uploads those formatting changes back to the data source.
- Editing conflicts when two different users change the formatting in different ways is resolved using the Review pane.
- If the data source becomes unavailable in the process of uploading updated formatting data, the changes are saved in the local component and appear as an editing conflict.

See the View - Panes - Review topic for a visual example of multiuser editing with formatting changes.

Supported Database Systems

Manifold's support for concurrent multi-user editing works with drawings linked from any database in which geometry columns can be stored, so long as that database allows multi-user access and the version column used to keep track of changes in the multiuser environment is writeable. Obviously, if the drawing is being edited the geometry column and any attribute columns involved in the editing must also be writeable.

Versioned editing uses the ID column as a key column in the database for faster performance. Therefore, the database must be able to handle key columns. All modern enterprise-class DBMS products and even most consumer-class DBMS drivers likely to be used with Manifold have this capability.

Although Manifold supports concurrent multi-user editing of drawings linked from a wide range of DBMS products, there is no reason not to use an enterprise-quality DBMS like IBM DB2, Oracle or SQL Server. The Express versions of these database products are free and are vastly superior to consumer-grade free data sources such as Access .mdb. Complete, licensed installations of these three DBMS products may be downloaded for free.

This example happens to use Oracle, but all three of the major DBMS products are superb, well-engineered software and will work well with Manifold. All three have a host of features with many sophisticated and subtle distinctions in their approach to enterprise DBMS with extensive documentation and far-reaching user communities in their support.
Users tend to have very strong opinions on which DBMS they prefer, opinions so strong that at times they make political or religious controversy seem pallid in comparison. Therefore, other than choosing the "Big 3" as examples for technical support, Manifold does not take sides over which DBMS is the "best." The best one is the one you decide is right for your needs.

If you would like advice in choosing which DBMS to use for your work with Manifold, consider asking the advice of your colleagues in the Manifold Online Community.

**Limitations with IBM DB2**

IBM DB2 Express-C Edition may be used for Enterprise Edition Enterprise Servers without any technical limitations. However, two small usage limitations apply when DB2 Express-C is used for storing geometry in tables in the database to support subsequent concurrent, multiuser editing. When a drawing is linked from a DB2 Express-C data source the following limitations apply:

- Adding a new object and immediately editing it without refreshing the drawing creates an editing conflict.
- Adding a new object and immediately deleting it without refreshing the drawing will fail.

Therefore, whenever editing drawings linked from a DB2 Express-C data source make sure to refresh the drawing after adding a new object before attempting to edit that object or to delete that object.

**Key Columns**

Whenever we use a version column to help resolve editing conflicts Manifold must rapidly identify any changes caused by different users within the geometry data in the originating table. That requires high speed access using key relationships supported by the DBMS in which the table is stored. If a data source does not have a key, which can be one column or a combination of columns, versioned editing will not work.

The ID column in any Manifold drawing's table is guaranteed to be unique, since the ID field provides a unique numeric identifier for each object. Exporting drawings to data sources such as Oracle therefore automatically designates the ID column as the key column. This works automatically provided the data source supports key columns and the ID column is included in the list of columns to export.

Virtually all enterprise class DBMS products like IBM DB2, Oracle and SQL Server support key columns, as do many consumer class DBMS products. However, certain database drivers, like those for CSV and DBF files do not support key columns. These formats therefore do not support versioned editing within Manifold System.

Although the ID column will be automatically designated by Manifold on export of a drawing to a data source, if we do not export the ID column or if geometry has been sent to a table (perhaps programmatically or as the result of some manual process other than export) we will have to designate a key column to enable versioned editing. Different DBMS products have different ways of specifying a key column.

If we don't have a key column in such data sources we can still edit the drawing if we do not designate a version column when linking the drawing. In that case the drawing will be fully editable but we will lose the protection of editing conflict resolution given by the version column.

However, failing to have a key field in a data source but designating a version column can have some odd consequences. For example, suppose we link a drawing from an Access .mdb file that stores geometry, that had a version column designated when linking the drawing but which does not have a primary key column in the originating table. In that case we will be able to select items and we will be able to edit attribute values but we will not be able to select an object for editing in the drawing.

The solution to avoiding such oddball situations is to always use a DBMS that supports key columns and to always designate a version column. That's easy enough to do whether we are using consumer grade data sources such as Access .mdb files or have everything done automatically for us with an enterprise-class DBMS like Oracle.

To create a primary key in an .mdb table, link the table into Manifold as a linked table and open the linked table. Choose Table - Design to see and alter the design of the table. Add a new field to be the key field using a default 32-bit integer type. In the Table Design dialog toolbar press in the View Extended Properties mode button. In the Unique column that thus appears for the key field, choose primary key as the value. Press OK.
Tech Tips

Remember, ADO.NET connections are read-only. If we are link a drawing from a DBMS table using ADO.NET, we will not be able to edit the drawing. To link a drawing so it is editable we must use some read/write connection technology such as OLE DB or ODBC or, in the case of Oracle, the automatic use of Oracle's OCI.

Projects may contain many linked drawings, which could be linked from different data sources. The Review pane will show conflicts for whatever drawing window or drawing layer has the focus.

FAQ: Why not Auto-refresh Drawings?

Novice users sometimes wonder why drawings are not refreshed in real time in Manifold, with the drawing objects they contain being changed instantly whenever some other user changes them. That's not done with interactive Manifold sessions to preserve the ability of users to organize their work using conceptually unambiguous beginning and end points to tasks, and to preserve the integrity of data against bizarre modifications caused by the unpredictable overlap of complex editing operations launched by different users at the same time.

Keep in mind that Manifold has profoundly greater editing capabilities than simply moving a dot on a map from one location to another, or simply changing the shape of a line or an area. Manifold operations include commands of awesome complexity and power that can change large numbers of objects at once, dramatically alter the topology of objects or their metrics, create or eliminate objects and so on. Consider, for example, what could happen in a sophisticated Topology Overlay command or a Clip with (Intersect) transform if part-way through the operation a different user changed something about the objects that were being used to "cookie cut" through large numbers of other objects in a different drawing layer. The result could be chaos.

It's true that Manifold could provide extensions to the user interface that equipped such commands with accessory dialogs to deal with the many varieties of chaos that might be induced by such interleaved, real-time edits. But that would greatly complicate the user interface that users would have to learn with a host of special cases and complex dialogs. Instead, the current system provides a simple, clear firewall between changes we make and changes others might make.

In all cases with Manifold, "what you see is what you get." What users see in their linked drawing windows is exactly the local data upon which commands operate. To synchronize our local project with the data source from which the drawing is linked we do a Refresh Data or an ALT F5. Each such refresh brings us up to date and also brings the data source up to date with our changes. If any changes we have made since the last such refresh conflict with edits done by other users, we can see such conflicts in the Review pane and in an orderly way deal with them.

However, in all such cases because the various edits have each in their own projects been "firewalled," so to speak, between refreshes done by their users, each such editing change stands as an organic, coherent whole. When we resolve editing conflicts in the Review pane we can have confidence that whether we pick our local edits or those made by someone else they will be applied to the project in an orderly way, without the chaos of partial combinations between something we did and something someone else did.

Note that in Internet Map Server web sites, we can force a refresh of all linked components on a desired time interval. Such applications are either view-only or permit editing only under the fully-custom control of the application developer. That's a very different situation than the sweeping editing commands available as part of the Manifold user interface.

Advanced users might note there is a philosophical conflict between the rationale described above for avoiding auto-refresh of drawing objects and the immediate propagation back to the data source of changes made in ordinary data attributes in linked tables. That's certainly a breach of perfect philosophical orthogonality, but one rooted in long tradition in multi-user databases. DBMS operators and software vendors have long ago evolved mechanisms for dealing effectively with multi-user attribute editing, which still will be in play in the host DBMS whether an attribute is changed by a Manifold session or some other client of the DBMS server.

It's true that in a GIS environment, where attributes can affect the operation of spatial commands such as the Dissolve command, allowing instant propagation of attribute changes does indeed raise the risk of chaotic interleaved edits of drawing objects. However, even in this case the use of the Review pane will alert users to such conflicts because the object modifications caused by such attribute-dependent commands will result in different objects that will be identified as editing conflicts in object geometry.

Using Administrator Console
Hyperlinks

Hyperlinks are URLs (Internet hyperlinks) that are embedded into objects in a drawing. If an object has a hyperlink, double clicking on the object will launch an Internet browser using the object’s URL. If an object does not have a hyperlink, double clicking on it will launch the Fields dialog.

Adding hyperlinks to objects:

1. Open the drawing's table.
2. Create a new field called URL that is of type URL or any text type (fixed or variable length ANSI or Unicode text).
3. For each object that is to have a hyperlink, enter the desired hyperlink into the object’s record in the URL column.

When the mouse is double-clicked on an object in a drawing, Manifold goes to the URL field of the table, fetches the hyperlink stored there for that object and launches an Internet browser using that link. If the URL field is empty, or if it is not of database type “URL,” Manifold will launch the Fields dialog for the object.

This provides a fast meaning for double clicking on an object in most cases. If the object has a URL an Internet browser is launched. If it does not have a URL, the Fields dialog pops open.

Example

We would like to use the Congress.map example provided on the Manifold CD to look up the web pages of each US congressional representative by double clicking on their district in a map.

Open the Congress Table associated with the Congress drawing. The table has a column called Web page that contains the URL of each congressional representative’s web page. This Web page field is an ANSI Text field.

First we will rename the field to URL. Right-click on the Web page column head and choose Rename. Change the name to URL.
Next, we will change the field type to **URL**. Right click on the column head and choose **Change Type**. In the **Column Type** dialog, change the field type to **URL**. Press **OK**. Close the table window.

We can now open the **Congress** drawing window. Whenever we double-click on a congressional district in the drawing, Manifold will launch a browser window loaded with that representative’s web page taken from the **URL** field. For example, we can double-click on Nevada (which has only one congressman for the entire state outside of Las Vegas).

Like magic, a browser window pops open with Congressman Jim Gibbon’s web page in it.

If we wanted to see the fields associated with that district, we could have **CTRL**-double-clicked onto Nevada.
That will open the **Object Fields** dialog for that object.

**More sophisticated uses**

The example above shows URLs in use to open a very simple web page. We can also use URLs that are local references to files on our local hard disk. If such files are image files in a format that can be displayed in browsers (such as `.jpg`, `.png` or `.gif`) we can URLs to show pictures associated with objects.

Because web pages can be very rich and browsers can display all sorts of things automatically, we can use the general mechanism of specifying a hyperlink via a URL to display all sorts of things. For example, we could have a drawing that shows a factory floor plan with locations of different machines. For each machine we could have a URL pointing to a PDF document or other document that provides its user manual. Double clicking on the machine in the drawing will open its manual.

More dynamic information can be achieved by linking a table into the Manifold project from an external database and then forming a relation between the linked table and our drawing's table. If the linked table contains a URL field called "URL" and that column is brought in via a relation it will be used for the hyperlink. We could therefore keep a database of sites, documents, images or other information that dynamically changes so that whenever we double-click onto an object in the drawing the URL field to which the browser jumps will be taken from the external database provider's table.

**Tech Tips**

Since most drawings in GIS aren't used for Internet hyperlinks the fallback behavior of hyperlinks to launch the **Fields** dialog is a useful way of preserving double-click functionality for a quick look at object fields. However, in the case of drawings that are used for Internet hyperlinks if a particular object has an empty URL field the **Fields** dialog will also be launched. That may not be desired. To avoid this situation, create a simple web page that reports something like "This item does not have a web site" and save it on the local disk. In the table window select all records with an empty URL field and fill it with the local path to that web site.

For example, if we created an empty.html web page in the C:\tmp folder we would fill all empty URL fields in the table with C:\tmp\empty.html. When someone clicked on an object that did not have a web site the browser would launch using our empty.html web page.

Whether double-clicking an object launches a new browser window or appears within a previous browser window is set by your browser options. In Microsoft Internet Explorer, see **Tools - Internet Options - Advanced** and uncheck the **Reuse windows for launching shortcuts** box if you would like each URL to launch a new browser window.

When using drawings that contain hyperlinks within Manifold IMS applications we will probably also want to use **layer restrictions**
Formatting

Formatting Drawings

Drawings are made up of points, lines and areas that are drawn in a "connect the dots" fashion between exact coordinates. The appearance of drawings is highly dependent on the formatting choices used to draw the points, lines and areas. Drawings may be formatted to provide a particular appearance, or a theme can be created for a drawing that shows that drawing using desired formatting.

The main formatting choices are:

- **Foreground Color**: The color of solid points and lines and the foreground color of two-color area styles or of two-color area border styles. Choosing a transparent color for foreground color for an area will turn off display of that area. This is a short-cut way of turning off areas when desired.

- **Background Color**: The fill color in most styles used for points, lines, areas and area borders.

- **Style**: The pattern or icon used to draw points, lines, areas or area borders.

- **Size**: The relative size to use for patterns used to draw points, lines, areas and area borders. Does not apply to bitmapped images used for points.

- **Rotation Angle**: Allows rotating the symbols used for points to a given angle.

The Format toolbar for drawings shows the basic formatting choices in use for the active drawing or drawing layer in a map.

![Format Toolbar](image)

It shows **foreground** color, **background** color, **style** and **size** currently in use for areas, area borders, lines and points as well as the **point rotation angle** button for points. Default formatting uses light gray for background colors with black used for foreground color for lines and points and dark gray used as the foreground color for areas. Changes made in this toolbar will immediately be applied to the drawing. Drawings (and thus drawing layers in maps) have one set of formats for all areas, lines and points in that drawing. The format toolbar always shows the formats in use for the active layer or drawing.

**To Change Formatting**

1. Click on the layer tab that contains the objects.
2. Click on the format control to be changed (colors, style or size) for the type of object to be changed (areas, lines or points).

**Color Wells**

Click on the foreground or background color wells in the format toolbar to change color.
The color wells display knows what the current color is and will display a sample of color wells that Manifold reckons will be helpful. The screen shot above shows that the current color is a bright blue (indented well). The top line will always show lightness variations of the current color. The second line in the color wells display will show grayscale variations. The X color well in the upper right is **transparent color**. Using that color will result in transparency everywhere the color is used.

The rest of the color wells pane shows a range of colors beginning with blues and greens and ending with reds. Scroll down using the down arrow at the side of the pane.

Press **Theme** to invoke thematic formatting. Press **More** to open the standard Windows color-picking dialog.

**Example**

This example shows changes to area formats, line formats and point formats. Area border formatting will not be changed in this example.

We begin with a map of California containing four layers:

- **CA areas** contains areas showing the land regions of California
- **CA hydro** contains lines showing various hydrological (water) features.
- **CA roads** contains lines showing main roads.
- **US towns** contains points showing the center points of populated places with populations above 20000.
In this example map, all of the layers contain one type of object (areas, lines or points) only. In the illustration above, the CA areas layer is the active layer so the format toolbar shows the formats for that layer (all default settings). Even though the CA areas layer contains areas only, the lines and points format controls are enabled so we can set values that will be used for any lines or points that might be created in this layer. The illustration is zoomed into the southern part of San Francisco Bay, into the heartland of Silicon Valley.

To change the color of the areas in the CA areas layer, we click into the background color well for areas and change the color. Let’s change it to a khaki green color. All areas in the layer will instantly change background color. Note that the default area pattern draws the edges of areas with a pixel of foreground color, which remains the default dark gray.

Let’s make the water features blue. These are located in the CA hydro layer so we click the CA hydro tab to make this layer the active layer. As we click the CA hydro tab, the format toolbar will switch to show the settings for this layer. We haven’t changed anything in this layer so it still shows the default settings. For example, note
that the area background color shows the default gray color since in this layer (unlike the CA areas layer used in the previous illustration) we have changed the area background color.

Solid lines are drawn in foreground color, so we click into the foreground color well for lines and change the color to a bright blue. Instantly, all lines in this layer will change to blue color. Note that this change affects lines only in this layer. Road lines, for example, are not changed when we change the formatting of the CA hydro layer.

To change the format of road lines, we click the CA roads tab. The format bar changes to show the formats for this layer, which are still the default settings.
Let's make the road lines a dark green. We do this by clicking on the foreground color well for lines and changing the color to dark green.

If we want the road lines to be less visually apparent, we can change them to a dashed line style by clicking into the style well for lines and choosing a dashed pattern. The dashed pattern we chose uses foreground color for the dark bits and background color for the light bits. If we choose the same color as was used for the areas in CA areas for the background color for our lines, they will appear to be dashed segments.
A better way of achieving this same effect is choosing transparent color for the background color; that is, to use no color (for complete transparency) for the background color of lines. Click on the transparent color well at the upper right of the main palette to chose transparent color.

If we chose transparent color for the background color, the alternate segments of the dashed line style would be transparent. This would avoid the unpleasant effect seen above where the road lines cross San Francisco Bay but still have the light green background color in alternate dashes. Had we used transparent color the white color of the bay's background would have been visible through alternate dashes and thus the dashed line effect we seek would be preserved no matter what color background.

We now click the **US towns** layer tab to set it active. This layer still uses default formatting as the format toolbar shows.
We can make the points in this layer instantly more visible by changing the background color for points (the fill color) to bright yellow.

Clicking into the style box for points and choosing a square changes the points to square boxes. Increasing the size parameter to 10 makes the boxes larger.
Changing line or area format settings for the **US towns** layer will have no visual effect, since there are no objects in this layer except points. However, if we would like to set formatting to be used for any area or line objects that might be created or moved into this layer we can do so. In the illustration above, we have changed the area colors to a black foreground color and a brick-red background fill color.

If we now use the *Shapes* toolbar to draw an area in the **US towns** layer it will be drawn using the new format colors specified for areas in this layer. In the illustration above, we have drawn a circular area centered on the Gordon Biersch brewery restaurant in Palo Alto. This is a somewhat contrived example, since it is poor organization to mix different conceptual things (center points of towns as well as areas showing different types of zones of interest) in the same layer.
Finally, if we click back on the CA hydro layer, note that none of the formatting changes made to other layers has applied to this layer. It still retains default formatting for areas and points, with the only change being the use of bright blue color as the foreground color for lines. Changes made with the format toolbar apply only to the active layer.

**Points and Lines in the Same Layer**

Drawings are often imported from GIS formats intended for use in maps where the roads might be used for transportation network analysis. In such cases the map of roads is drawn as a network with point objects located at the ends of each line. This is done because mathematically a network is defined by points (nodes) and not the lines (links) between them.

When imported into Manifold, such road drawings will appear in default formatting. Because default formatting uses a size of 3 for points, the roads will have lots of "bubbles" throughout. Changing this is easy.

Simply click on the size well for points and change the size to 1. A size of one draws each point symbol as a single printer's point in size, so the points will blend into the default size of lines.
The above is a quick means of dealing with the visual appearance of the drawing, but it still leaves the points in the same layer as the lines. If we change line colors or size, we will have to remember to change those parameters for the points as well if we want the points to continue to appear blended in with the lines. A better idea is to select all the points in this layer and to move them to their own layer. We can then turn that layer off and on at will whenever we want to see the network node points. Should we want to do transportation network analysis, we can select the lines and points to be used as a network. Manifold has no problem working with nodes and links that are in separate layers.

**Thematic Formatting**

Thematic formatting is the use of a controlling data field to automatically vary the color, style or size of objects. For example, we might vary the size of points showing cities based on a population field for each point. Cities with greater populations would be shown as larger points.

See the Thematic Formatting topic for more information.

See the Color topic for fast "four-color" coloring of drawings.

**Themes and Drawings**

-Thematic formatting is the use of a controlling data field to automatically vary the color, style or size of objects. For example, we might vary the size of points showing cities based on a population field for each point. Cities with greater populations would be shown as larger points.

See the Thematic Formatting topic for more information.

See the Color topic for fast "four-color" coloring of drawings.

**Notes**

- The most common formatting error when formatting layers in maps is to lose track of which layer contains which objects. The best way to avoid this is to name layers in a sensible way ("Roads," "Streams" and so on) so that it's obvious which objects are in which layers. If we lose track anyway, we can always see which objects are in a particular layer by double clicking the layer tab to turn it OFF and ON. It will be immediately obvious which objects are in that layer as they turn OFF and ON.

- If one wishes to uses hundreds of formats in a map to show the same drawing in hundreds of different ways, doing so is perfectly possible. To do so, we create as many themes for the subject drawing as desired.

- To have a different visual appearance for objects in the same layer, use Thematic formatting. This assures there is some guiding pattern to the different colors or other format attributes.

- The hydrography lines in the California map example do not line up perfectly with the edges of areas because they were taken from two different data sets. The hydrography lines are from the 1:2M-scale USGS DLG map series while the CA areas layer was created using NOAA 1:100K-scale shorelines data.

- See www.gordonbiersch.com for more on where to find real beer when visiting your venture capitalists in Silicon Valley.

**Setting Background Color**

Drawings have an overall white background color by default. Background color for all components is set by default in the Tools - Options dialog. Each individual component can have its background color set by opening the component in a window and choosing View - Properties.

Transparent Color

Areas, lines and points in drawings are colored using two colors: a foreground color and a background color as described in Formatting Drawings. In addition to use of ordinary colors, a transparent color may be selected as a foreground or background color. The transparent color appears as the upper right choice in the pull-down color palette for color wells in the formatting toolbar. A choice of transparent color is a choice of 100% transparency (zero opacity) for those parts of objects rendered in transparent color.

To choose transparent color, click into the foreground or background color well desired in the format toolbar and then click on the transparent color well at the end of the main palette.

For example, suppose that in a map with two drawing layers we have a circular area in the upper drawing.

If the area is formatted as seen above, the white color used for background color is opaque. The white color prevents objects in the lower drawing from being seen through the "white space" parts of the crosshatch style pattern used for the area.

If we change the background color to transparent color then the transparent color icon appears in the background color well and the background portions of the area style pattern are made transparent. This allows the lower drawing to be seen through those lower portions.
Transparent color may also be used with line and point styles.

**Transparent Foreground Color**

Choosing a transparent color for foreground color for areas, lines or points will turn off display of areas, lines or points respectively. This is a short-cut way of turning off a class of objects (areas, lines or points) in certain effects. This allows a thematic format to be arranged so that foreground color is transparent with certain values, thus turning off for display any objects with transparent foreground color. For example, if a thematic format is defined that uses the *Selection (I)* intrinsic field to show foreground color as transparent if an object is not selected and black if an object is selected, then only selected objects will appear.
**Area Formatting**

Areas may be formatted to set foreground color, background color, style and size for both the interior of the area as well as the area border, a total of eight formatting characteristics that we may specify to control the appearance of areas. Any of these eight formatting characteristics may be automatically controlled via thematic formatting using a data field.

The wells in the leftmost partition of the format toolbar control the formatting of areas and area borders. The formatting controls for area borders are similar to those for the formatting of lines.

**Examples**

It is easiest to understand area formatting by creating an area and then changing formatting settings in the format toolbar.

The illustration above shows an area together with part of the undocked format toolbar. Default colors are used for the area.

We can click into the area border foreground color well and change it to blue. That will cause the area border to appear in blue color and be more obvious.

The default area border size is very thin, only 1/20th of a printer's point. The border will appear thicker, about 1 printer's point, in most computer displays because computer monitors do not usually have the resolution to display less than about one point. However, when printed out in a high resolution printer the area borders may appear to be very thin if the size of the area border is not increased.
We can make the area border thicker by clicking into the area border Size well and changing the size to 5. Note that the area border is not a line object surrounding an area object. It is all the same area object, just with an option to draw the edge of the area in a different manner.

We can change the Style used for the area border to an alternating foreground color and background color dashed line.

We can change the area border background color to yellow to show how the background color is used with the foreground color in this particular area style.

Some area border styles are asymmetric, in that they appear oriented towards the interior of the area or towards the exterior of the area.
We can choose one of the asymmetric area border styles to see the effect.

In this case, the style results in an area border that appears oriented towards the interior of the area.

For a different effect we can choose an asymmetric area border style with the opposite orientation.

This results in an area border style that appears to be oriented toward the exterior of the area.
Let's go back to a plain alternating color area border style. We will click into the area style and choose a dashed horizontal line pattern to get the effect shown above.

Changing the area foreground color to red shows how this style uses foreground color for the horizontal lines.

Changing the area background color to light blue shows the use of area background color.
If desired, we can use these eight formatting controls (foreground color, background color, style and size for areas and area borders) to create strikingly ugly and confusing graphics.

It is best to use simple and understandable formatting for drawings. The area border formatting controls should be used with restraint.

**Technical Note**

Although asymmetric area border styles may appear to be oriented towards the interior or towards the exterior of areas, in actual fact they are oriented to the left or the right of the path of sequential coordinates that define the shape of the area. In the above case the area shown happens to be drawn using a sequence of coordinates proceeding in a clockwise manner so the asymmetric border styles ended up having the orientations shown. The very same area could have been drawn using a sequence of coordinates proceeding in a counter-clockwise manner and in that case the area border styles shown would have had opposite orientations. When the same asymmetric border style is used for all areas in a drawing it is important to have those areas drawn in the same clockwise or counter-clockwise manner for the resulting orientation to be the same in all areas.

Area Styles and Size

When using Windows 2000, XP, or 2003 area styles are resizable. Changes in the size parameter will alter the spacing of the lines used in these patterns. The size parameter is in number of printer's points, the same unit of measure used for font sizes. One printer's point is 1/72 inch.

If sizes are set very small (2, for example), the resultant styles will be drawn with lines so close that they appear to be solid areas. To avoid coating printed pieces with solid dark ink, area size of 1 will default to solid background color.

The following sequence of examples reformats a province in Mexico using size parameters of 1, 2, 4, 8, 16, and 32 with the crosshatch area style. The province being changed is in a map layer above the other provinces so it can be formatted differently. In all cases the foreground color is black and the background color is white. The other provinces in the map have been formatted in a solid style using black as the foreground color. Boundary lines are in green and the map background is blue. Note: A size of 8 is the default.
To change the size used in an area, click on the size box for areas in the Format toolbar.

**Transparent Foreground Color in Areas**

Choosing a transparent color for foreground color for areas will turn off display of areas. This is a short-cut way of turning off areas in certain effects. This allows a thematic format to be arranged so that area foreground color is transparent with certain values, thus turning off for display any areas with transparent foreground color. For example, if a thematic format is defined that uses the `Selection (I)` intrinsic field to show foreground color as transparent if an area is not selected and black if an area is selected, then only selected areas will appear.

**Notes**

Area styles are not resizable in '98 or Millennium. Area styles are fixed at size 5 in those systems since all they support is an 8 x 8 pixel bitmap matrix.

Fractional area sizes, such as 1/20th of a point, are available in the size selection pull-down menu. Such very small sizes might be useful when printing to high-resolution printers, such as 2880 DPI printers, where such tiny patterns might not blend together into solid color.

The `/list` command line option provides a handy way of getting a list of all available formatting styles and their names for use by programmers. See the Command Line Options topic.
Areas and Boundary Lines

Areas are "solid" objects consisting of a defined region. The default area style as well as the area styles most frequently used to format drawings will use contrasting color for the pixels at the very edge of the area. This makes it possible to see different areas when the same color scheme is used for all areas.

In the illustrations above, a "seamless" area style (all solid background color) was used for the illustration on the left. The default style was used for the image on the right. It's clear how coloring the pixels on the very edge of an area with a contrasting color will show the "seams" between area objects that fit together perfectly.

The risk from this visual convenience is that area styles using contrasting color for the edges of areas might make areas seem to be "two part" objects that consist of an interior area object plus a differently colored boundary line. Because area borders, that is the boundary line of an area, may be separately formatted from the main "body" of the area it is especially easy for new users to make the mistake of thinking of an area border as though it is somehow a separate object.

This will especially be the case when transparent area styles are used (as above) or when the background ("fill") colors of areas are thematically formatted with different colors while the foreground color (used at the edge of the area) is the same:

If an area style is used that does not use contrasting foreground color for the edges of areas, we can see that the above illustration is made of area objects only without any lines in use:
In general, when areas in the same layer are thematically formatted so their colors are different it is easy to tell them apart. When they use the same color, it is difficult to tell them apart if a contrasting foreground color for their very edges is not used.

There are times when we do not wish areas to be drawn with an apparent boundary line. Using styles that show areas with an apparent boundary can be confusing when doing topological work involving the creation of areas from enclosing boundary lines or the creation of boundary lines from areas. In such work, it is often helpful to use formatting styles that cannot be misinterpreted as showing objects that do not exist.

Another example of when we might not want to use styles showing the boundary is when using thematically formatted areas like the states above a background layer in a complex map. In such cases we will often not use styles showing apparent boundary lines to prevent the map from becoming too “busy.”

At other times we will wish to emphasize the boundaries between areas to a degree even greater than is possible using area styles that color the edges of areas. To do so, we can create boundary lines using real line objects that follow the exact shape of the edges of the areas. We can then format those boundary lines as thick or thin as we would like them to be.

**Using Boundary Lines**

Manifold makes it easy to create lines that follow the edges of existing areas or to create areas that “fill” closed lines.

If we start with a group of areas, we can instantly create boundary lines for each area using objects using Transform - Boundaries command.

The new lines shown in red are new lines in addition to the "apparent" lines at the area edges, as may be seen in the middle illustration where the boundary lines have been offset slightly:
If we have separate lines that run along the boundaries of areas we can format these lines (say, by changing their color and size) to achieve a wide range of representational effects than is possible just with area styles:

We could also achieve the above visual effect by simply changing the formatting of area borders to use black foreground color and a thicker border line. In the above case we achieved the visual effect by creating new objects (using the transform tool bar operator) that are area boundary lines and then formatting them. If we simply changed the formatting of the area borders no new objects would be created although the visual effect would be the same.

**Notes**

A quick way to see if lines are in the drawing is to set the selection mode to lines only and then make a selection with the mouse. If lines are present, they will be selected and shown in red selection color. It's also a good idea to keep boundary lines in a different layer.

The antialiasing appearance of area boundaries is controlled by the Antialias Lines choice in the Tools - Options - User Interface options.
Transparent Area Styles
Maps often contain areas in drawing layers where we would like to be able to see objects in layers "below" the area. There are two ways this may be accomplished:

- Use Layer Opacity in the map layer to apply a given percentage opacity to the entire layer.
- Use a "transparent" area style to provide open space of transparent color within the area format style that allows objects below to be visible.

Both methods have advantages and disadvantages.

The advantage of layer opacity (as seen above) is that it may be applied within a map at any time to allow items underneath an area to be seen. More or less layer opacity can be applied to achieve exactly the right effect desired. At any time we can remove it since layer opacity is a property of the map, not of an individual drawing.

The disadvantage of using layer opacity is that it changes the appearance of objects. By making them transparent it can mute bright colors. Because layer opacity must be set in a map layer we could use a drawing in a different map without remembering to set layer opacity and not realize that objects beneath the layer are hidden. See the Layer Opacity topic for a full discussion of this capability.

Another way of allowing areas in drawings to reveal what is below them is to use "transparent" area styles. These are area styles that consist of hatch patterns where a large part of the pattern is either foreground or background style color and the color has been set to transparent color to allow regions beneath the area to show through.

The example above shows an area drawn with formatting that allows objects below it to be visible. To accomplish this, pick an area style that has large extents of contrasting background or foreground color and then use transparent color for one of the colors. For example, in the illustration above we chose the area style using fine dots of foreground color on a large extent of background color. We then set the foreground color to white and the background color to transparent color.
Drawings

Click on the transparent color well at the upper right of the main palette to choose transparent color.

Use of transparent color is what gives an area style a transparent effect. Any objects that are below the area will be visible through regions of transparent color. In the case of the map illustration above, all objects in layers below the area will be visible through the transparent color parts of the area. When we use the term "transparent area" we are not referring to any special sort of area or style. We are simply referring to any ordinary area that's been formatted using transparent color for foreground or background color so objects below it may be visible.

The above illustration shows the area in the topmost layer. One may also use transparent areas in drawings anywhere within the layer stack.

For example, this illustration shows the same area where the layer tab for the layer containing the area has been dragged to the right so that it is below the drawing layers containing the green line and some of the various dots, but above the layers containing the other lines. Note how the area overlaps the green dot on its right most border, but is overlapped by the green, blue, and purple dots within the area.

More than one area can use transparent color with various styles to appear transparent. The illustration above shows a second area that partially overlaps the first area. The new area was created in a drawing layer above the white dotted area, so the foreground parts of the new area will be drawn over the white dotted area.

The examples employ area styles where the background color makes up most of the pattern and so transparent color has been used for background color. Manifold has other area styles where the foreground color is the predominant part. For such area styles, one can use transparent color for foreground color.

In addition to areas, we can always use transparent color with point and line styles (usually the background color) to achieve partial transparency of points and lines.

This topic has discussed transparent areas as used in separate areas. However, one often encounters overlapping areas drawn within the same drawing layer, which can result in ambiguous visual effects. See the next topic, Overlapping Objects for a discussion of issues that may arise and for notes on why use of transparent area styles can help resolve ambiguities in such cases.
Tech Tip

When an area's foreground color is set to transparent color the entire area will not appear. This convention works with points and lines as well and is a useful way of turning off some objects in a drawing. For example, if a thematic format is defined that uses the Selection (I) intrinsic field to show foreground color as transparent if an object is not selected and black if an object is selected, then only selected objects will appear.
Overlapping Objects
Maps will often contain objects that overlap. Lines representing streams might run over lines that represent roads, and both sets of lines may be drawn over areas. In Manifold, the best way to control what objects are drawn over other objects is to keep them in separate layers (that is, separate drawings) and to arrange the layers in the order desired within a map.

When objects are all in the same layer they are drawn in the following order from uppermost to lowest:

- Points
- Lines
- Areas

This results in a natural display for most geographic maps. Within the same type of objects (such as overlapping areas in the same layer, for example) the order in which each individual object is drawn on screen depends in unpredictable fashion on their occurrence of data within the drawing. For this reason, it is not a good idea to have overlapping objects such as areas in the same layer or drawing. The correct method of specifying display order is to place objects into different layers and to then order those layers as desired within a map.

There are numerous methods within Manifold of selecting different sorts of objects so that they may be placed into different layers. For example, Objects that are co-mingled in the same layer often have different data attributes that may be used to separate them. We can use SQL or column sorting in Table View to select all lines and points with values in a "Roads" data attribute and then send them off to a new drawing.

There are rarely ambiguities involved when lines and points are organized in layers. It's easy to take care of obvious issues such as making sure that points are located in drawing layers above areas that would otherwise hide the points. Layers that contain overlapping areas within the same drawing are more complex to manage because of visual ambiguities that might arise if we organize them and format them carelessly.

Overlapping Areas
Although the correct way of ordering which objects are drawn over others is to use layers, one might encounter maps that have yet to be organized into orderly layers. This happens when importing maps from foreign formats or when drawing maps casually. At times one might launch into a project with casual expectations and then after some work realize that a drawing has become complex and needs to be better ordered. Areas are especially likely to overlap in unpleasant ways when importing and combining drawings from many different sources.

When overlapping areas occur in the same layer, it is possible to encounter confusing effects. The same rich repertoire of formatting effects that enables Manifold to provide almost any desired display can also mislead a user if applied carelessly. This discussion explores some effects one should keep in mind when working with areas that might overlap.

First, a reminder of the effects of "transparent" area styles:

Our first example shows an area that's been formatted with a simple crosshatched area style. If this is the only area in the map, there's no issue. However, if the area is drawn on a white background, it is not clear from looking at the area if the "holes" in the crosshatch mesh are filled with white background color, or with None background color. Both cases will have the same appearance when white is also used for the background color for the entire map.
By changing the map’s background color to light brown we can see the difference between the two cases. The example above uses a white background color within the crosshatch area style, while the example below uses a None background color for the crosshatch area style.

Note that using a white background color with the crosshatch area style "fills in" the "holes" in the crosshatch mesh with solid white color. Anything below the area will not be visible through the solid white color. Using None leaves the holes in the mesh transparent, so that anything below will be visible through the mesh.

If two areas overlap in the map one may encounter various effects depending on how the areas have been formatted. The example above shows two areas in different drawing layers within the same map where one area is formatted in a solid color and the other area has been formatted with a crosshatch style using None as the area background color. Because we used a transparent area style for the crosshatched area it is clear that the areas overlap, but only because the transparent area appears in a layer above the blue area.

It is wise to format potentially overlapping areas so that users of the map can instantly see any overlaps without needing to check layer ordering or otherwise resolve ambiguities. For example, the above illustration might be unambiguous if we know that the blue area is above the hatched area. Suppose we’re not sure if a transparent area style were used? It could well be that the situation above is an example of two areas overlapping or simply of a triangular blue area fitting perfectly without overlap into a crosshatched area shaped like this:
The reverse situation is also ambiguous:

Again, in this case if we were unaware that the area was formatted using a crosshatch style background color of white we could not tell whether it is simply drawn as overlapping a blue triangle area, or if it fits perfectly into an irregular blue area shaped as follows:

To be sure, we would have to check the layer ordering and the formatting used for areas.

For these reasons, we suggest using the following guidelines when formatting areas:

- Do not use the same background or foreground color within area styles as is used for the map background, or as occurs as a widespread color in lower layers. This allows areas to stand out even if “open” area styles like the crosshatch style are used.

- If overlaps might be an issue, use None as the predominant foreground or background color in “open” area styles like the crosshatch style. This assures that ambiguities in possible overlapping / non-overlapping situations will be easily resolved because overlapped areas will be visible through the None parts of the area style regardless of layer ordering. At times, however, one might wish to use a solid background color even within open styles to distinguish areas from the background. The need to do so should be balanced against the need to unambiguously portray overlapping areas.

- Avoid careless mixing of solid and open mesh area styles in the same map. Although one may always produce an example such as that below that is for the most part unambiguous, in complex real-life maps the situation is not always so clear. Using None in open styles will resolve ambiguities when the open styled area is drawn over a solid style, but if the solid style happens to be drawn over the open mesh style an ambiguity remains.

**Overlapping Area Effects when both Areas use Open Styles**

It is tempting to simply advise the user to always use an open area style (such as cross hatch) together with None background color for all areas in the a map whenever there is a possibility that areas in the same map may overlap each other. In general, this is not a bad idea, but it does have one nuance of which the reader should be aware.
When two overlapping areas are formatted in the same color and cross hatch style as shown above, the crosshatch pattern is continued uniformly throughout both areas. The "border" line typical of open mesh area styles will be drawn for both objects and so will provide clarity that there are two areas involved.

The effect when the "lower" area in the same drawing is selected shows the highlighted border. Note that even though the portion of the crosshatch pattern associated with the "upper" area is not displayed in red selection color the situation is still clear.

Perhaps the best refinement when overlapping areas occur in the same map would be to format areas in each drawing layer using a slightly contrasting color and slightly different open pattern area style as shown above.

**A "Real Life" Example**

Manifold Technical Support received the following question from a Manifold user:

"Suppose you have Area Z. Completely contained in Area Z is Area Y. There are points inside Y. There are points inside Z that are not inside Y. When the query to show all points within Z is given, all points, both inside Z and Y are selected. I don't know if that is intended."

The resolution was a matter of visual ambiguity caused by overlapping areas.
Suppose the illustration above shows the situation as described by the customer showing the points that are inside area \( Y \). Based on the visual appearance only, there is some ambiguity as to whether those points are also inside area \( Z \) as well.

If we move area \( Y \) out of the way, we might discover that area \( Z \) may or may not have a square shaped hole in it. The illustrations above show the two possibilities.

If \( Z \) does not have a hole, then the dots in the original illustration were clearly **Within \( Z \)** at the same time that they were also **Within \( Y \)**.

Using transparent area styles can clear up any ambiguity right away. The example above shows that there is no hole in area \( Z \) and so the points really are within \( Z \) as well as being within \( Y \). Another way of resolving the ambiguity is to quickly click OFF and ON the layer containing area \( Y \) to see what's going on with area \( Z \).

**Resolving Visual Ambiguities with Layer Opacity**

Individual layers in maps can be set to a given percentage opacity. See the Layer Opacity topic for examples and details.
When layer opacity is used in a map it is often easy to quickly resolve visual ambiguities between overlapping objects in different layers, especially if the default white background is clicked off and the checkerboard background pattern is revealed. The screen shot above, from the Layer Opacity topic, shows two overlapping squares that are in different layers where each layer has 50% opacity. The overlapping squares are easily distinguished as different objects.

However, if both of the overlapping square areas were in the same drawing layer opacity would not help us. The two squares would first be rendered as they would be in any case in the drawing (in a visually ambiguous way) and then layer opacity within the map would be applied. The result still would be visually ambiguous, it would just be fainter.

Consider a round area drawn within a drawing so that it overlaps other areas.

If the drawing is shown in a map with 50% layer opacity the effect is applied to however the drawing is rendered in the ordinary course of events.

If the round area were drawing in a different drawing and placed in its own layer above the other objects, then if both layers were given 50% layer opacity we would get a combined layer opacity effect that allows us to see through the round area.

The conclusion is that layer opacity within maps is fine for resolving visual ambiguity when the objects involved are in different layers but that it cannot resolve visual ambiguities between overlapping areas in the same drawing.
Lines and Line Styles

Settings in the format toolbar control the appearance of lines. The format toolbar settings apply to all lines in a given drawing. The **size** parameter sets the thickness of the line in printer's points, the same unit of measure used for font sizes. One printer's point is 1/72 inch.

![Map with layers](image)

By default, lines are shown in a solid line of size 1 with black foreground color. The illustration shows a map with a layer containing lines positioned above a layer containing the background areas.

![Solid line style](image)

We can change the line style by clicking on the **Style** button for lines and choosing a different style.

![Dotted line style](image)

A dotted style shows alternating foreground and background color. Because the background color used is the same color as that used for the areas, the line appears as a dotted line of foreground color.

![Dotted line with white background](image)

We can change the background color to white to show the alternating color effect of this line style.
When size is increased in dotted line styles, only the thickness of the background color is increased. This provides a vivid effect.

If we use the Layers pane to turn on some other layers in the sample map, we can see how the vivid style helps these lines stand out from other lines. The format toolbar illustration shows the formatting for the blue lines in one of the other layers, a “hydrography” layer showing water features such as streams and lakes.

In this illustration we have increased the size of the dotted lines to 5 to give them a thicker appearance. We have also “toned down” the brightness of the lines by changing the opacity of the layer hosting them to 50%. See Layer Opacity for information on changing the transparency/opacity of layers. Making the layer partially opaque allows some of the blue lines behind the dotted line layer to show through. Clever use of opacity will often allow complex maps to be more legible.
In the illustration above we have changed the style back to a solid line, we've changed the size to 3 and we've changed the foreground color to yellow. Solid styles that are "all foreground" will increase the thickness of the foreground color as well.

**Directed Line Styles**

Some line styles are asymmetric in that their appearance depends on the direction of the line. All lines in Manifold have a "direction" that is implied by the order in which they are drawn from the first coordinate that defines the line to the last.

A triangle line style is one such style. When looking along the direction of the line from the beginning to the end the triangles point to the left in this style. This can be seen by drawing a line.

We can use this style with the Insert Line tool to draw a new line by clicking at the left and then clicking at the right in the direction shown by the red arrow.

The result is a line drawn in triangles with the triangles pointing to the left along the direction of the line.
Suppose we draw a second line in the opposite direction as indicated by the red arrow.

In this case, the triangles will point in the opposite direction.

We can see that the orientation of the lines depends upon their direction, as shown by the red arrows. To switch the direction of a line (and thus the orientation of any asymmetric line style) select the line and use the *Reverse Lines* transform toolbar operator.

**Lines with Arrowheads**

Manifold includes directed line styles that have arrowheads. The arrowheads are placed at the end of a line.

In the example above four lines are drawn using directed line styles with arrowheads. The lines are drawn in a map above a layer containing points.

Line styles can be combined with other line styles in a map. The illustration above shows a line that was copied from one drawing and pasted into another drawing. Both drawings were shown together in a map. The upper drawing formats the line using a series of arrowheads for the line with the same yellow color for foreground and background. The lower drawing formats the line as a single thick black line.

**Antialiasing**

Antialiasing is a computer technology used to make lines appear smoother and less jagged.
Without antialiasing lines are drawn using pixels where each pixel is either turned on in the color used by the line or it is turned off. The result is a jagged line appearance for some lines.

Seen in detail, the jagged appearance arises from the stair-step nature of lines drawn at some angles for which transitions from one pixel to the next must be abrupt.

Antialiasing as seen above provides a smoother appearance to lines.

Antialiasing works by interpolating pixel colors between the color specified for the line and whatever color is visible surrounding the line. In the case of a black line seen against a background of white color antialiasing will use gray scale colors between white and black in addition to the pure black of the line. When seen from afar the use of interpolated colors fools the eye into seeing a smoother line.

Manifold can draw lines either with or without antialiasing as specified in the Tools - Options - User Interface options. The default setting uses antialiasing to provide lines with a smoother appearance.

Although antialiasing usually provides a better visual effect it does have some drawbacks. Lines will appear slightly thicker with antialiasing and some line styles or lines drawn at certain angles may appear to be unacceptably fuzzy compared to other lines. We may also want to turn antialiasing off before converting a drawing to an image if the touch selection will later be used with the image to select all lines. Touch selection can be used to select pixels that represent a line in an image if the line is not antialiased because all of the pixels in the line will be the same color. Touch selection cannot be used conveniently to select all the pixels that represent a line in the case of antialiased lines because the pixels will be many different colors.

**Transparent Foreground Color in Lines**
Choosing a transparent color for foreground color for lines will turn off display of lines. This is a short-cut way of turning off lines in certain effects. This allows a thematic format to be arranged so that line foreground color is transparent with certain values, thus turning off for display any lines with transparent foreground color. For example, if a thematic format is defined that uses the Selection (I) intrinsic field to show foreground color as transparent if a line is not selected and black if a line is selected, then only selected lines will appear.

**Note**

The /slist command line option provides a handy way of getting a list of all available formatting styles and their names for use by programmers. See the Command Line Options topic.

Creating Bordered Lines

Thematic Formatting
**Point Styles and Sizes**

Settings in the format toolbar control the appearance of points. The format toolbar settings apply to all points in a given drawing. The **size** parameter gives the size of the point symbol in printer's points, the same unit of measure used for font sizes. One printer's point is 1/72 inch.

Point objects are shown by default as small gray circles. The settings in the format toolbar are a size of 3, a round style, a foreground color of black and a background color of light gray. The background color is the "fill" color in most styles.

To change the size we can click on the size well.

In the resulting pull-down menu we can choose the size desired. In this case, we'll choose **12**.

All points in the drawing will immediately appear as size **12** circles.

To change the style we click on the style well.

We can scroll down through the menu of styles and choose a style that shows a dollar sign.
All points in the drawing will now appear as dollar sign icons in size 12.

To change the color, we click on the background color well.

We can choose green from the palette of available colors. The More button calls up a classic Windows color-picking dialog allowing us to choose any color.

Changing the background color to green changes the "fill" color used in this particular point style. Styles appear in the style menus with dark gray indicating where foreground color will be used and light gray showing where background color will be used.

The format toolbar summarizes the settings we now have in use

Displaying Different Points

We have two methods to display different point styles, sizes and colors in the same window:

- Use a map with different layers. Each layer in a map is a different drawing, so each layer can have different formatting for points. Map layers provide a means of controlling overlaps since upper layers are drawn over lower layers. If we have one layer with many small points and another layer with a few large points, if we want the small points to never be overdrawn by the large points we can move their layer up above the layer containing the large points.

- Use thematic formatting. Thematic formats can change the appearance of points based on the contents of a data field in the drawing’s table. Thematic formats can vary the appearance of points within the same drawing. The same drawing can host a different thematic format for point style rotation, size, style, foreground color and background color.

Points Appearing in Line Drawings
Many drawings that may be downloaded from government Internet sites will have a point object positioned at the ends of all lines. For example, virtually all USGS maps that show roads or watercourses will have point objects positioned at the ends of the lines. This is done so such lines may be used within network studies. However, when such drawings are imported into Manifold the default point size of 3 will show lots of points throughout the drawing.

If we intend to use such drawings within network analytics, we should preserve the point objects. If we want to use the drawing for purely illustrative or measurement work we can remove the points.

To remove the points, we begin by setting selection modes to Select Points only.

We can then use Edit - Select by Type to select all the points in the drawing. A keyboard shortcut is to use CTRL-T to select by type.

The selected points will be highlighted in red selection color. We can then press Delete to delete them.

The result is a drawing consisting of lines only without any points.

**Single Pixel Points**

Points of size 1 appear as slightly larger than one pixel. Because a single pixel is easy to overlook, Manifold sets the default size of points to 3 so that points appear in drawings in an obvious manner. The presumption is that if a drawing contains points they are intended to be seen. Because single pixel points are so small they will blend into any lines they terminate. We can make unwanted points seem to disappear from line drawings by changing their size to 1/4.
That's fine for a quick fix in some cases, but as soon as the formatting of the lines changes the points may become visible again. Consider the following set of illustrations as an example.

If we begin with a typical drawing of roads downloaded from USGS we will see points of size 3 at the ends of all lines.

We can change the size of the points to $\frac{1}{4}$ so they blend in with the lines. That's fine, but it is not a permanent solution if we intend to change the formatting of lines.

If we change the color of the lines, we will have to also change the color of the points from the default black foreground color so they do not appear as seen above.

Selecting the points and deleting them removes them from a drawing.

**Custom Point Styles**

Manifold can load point styles from four sources: point styles that are compiled into the product, point styles that are loaded from graphics files, point styles that are loaded from True Type fonts installed in Windows and point styles created using custom scalable styles that are provided by the user. Point styles are loaded from graphics files or from True Type fonts based upon directions specified within `.xml` files found in the `Config` folder.

Point styles created from True Type fonts may be used just like any point style, except that they are always created using one color, foreground color, only. Many of the point styles that appear in formatting menus are taken from the Microsoft *Wingdings* font and can be formatted in foreground color only. Point styles created from graphics files cannot have their colors altered, but they can use any color (as specified in the graphics file) for their pixels.

See the Customization and Custom Point Styles and the Custom Scalable Styles for Points, Lines, Areas and Labels topics for additional information, including instructions for adding your own point styles.

**Transparent Foreground Color in Points**
Choosing a transparent color for foreground color for points will turn off display of points. This is a short-cut way of turning off points in certain effects. This allows a thematic format to be arranged so that point foreground color is transparent with certain values, thus turning off for display any points with transparent foreground color. For example, if a thematic format is defined that uses the Selection ($I$) intrinsic field to show foreground color as transparent if a point is not selected and black if a point is selected, then only selected points will appear.

**Note**

The `/slist` command line option provides a handy way of getting a list of all available formatting styles and their names for use by programmers. See the Command Line Options topic.

- Rotating Point Styles
- Thematic Formatting
Thematic Formatting

Thematic formatting is the process of automatically coloring objects in drawings based on the value of data fields in tables associated with the drawing. This capability is called "thematic mapping" in some GIS systems. Manifold refers to the process as thematic formatting since it is simply changing the formatting of objects in a drawing or a map based on the value of a data field.

Manifold can use thematic formatting to automatically change:

- Foreground color
- Background color
- Style
- Size
- Rotation (for point styles and labels)

All four of the above formatting characteristics may be simultaneously changed via thematic formatting at the same time for areas, area borders, lines or points. In one drawing, for example, the foreground color of areas may be changed using one field while the style of areas may be changed using a different field. In the same drawing the style and size of points may be changed using other fields.

Uses for Thematic Formatting

Change Foreground or Background Color: Color adjacent areas in maps with different colors so they more obviously stand apart. This effect uses the Color dialog for drawings.

Change Size: Make points larger or smaller automatically to show larger or smaller populations, profit, number of customers or other data.

Change Color: Color countries, provinces or other regions to show differences in population or other data fields.
**Change Point Style:** Change point styles to show different characteristics at different locations. See Custom Point Styles for information on adding point styles created from images like those seen above.

**Change Area Style:** Change area styles to set areas apart or show trends with different patterns.

**Change Size:** Make lines thicker or thinner to show differences in data such as traffic volume associated with each line.

All of the above illustrations are the same map and the same data with different thematic formats.

Thematic formatting chooses a data field associated with the drawing and then assigns all the objects being formatted into the desired number of intervals based on that field. Objects can be assigned to intervals using several different methods. We can then specify how each interval should be formatted.

**To Create a Thematic Format**

1. Choose the drawing to be formatted by clicking it open or by clicking on its layer in a map.
2. In the Format toolbar, click on the display characteristic to be formatted: for areas, lines or points choose the foreground color, background color, style or size.
3. In the pull-down choice dialog that appears, choose Theme.
4. In the thematic formatting dialog, choose the controlling Field to be used.
5. Choose the Method to be used to construct intervals. Equal Count, for example, will assign approximately the same number of objects to each interval.
6. Choose the number of Breaks between intervals. This specifies the number of intervals as well.
7. Change the Align to value if even numbers of tens, hundreds, thousands, etc., values are desired for intervals. Change the Range if the default entire range needs to be extended or contracted.
8. Press the Tally button to create the given number of intervals. If interval numbers different than those created by the Method are desired, double-click into the interval numbers to change them.
9. Either use a preset color palette or click into the interval color boxes to change colors to whatever range is desired. To use a palette, select it in the Palette box and press Apply to apply the preset to
the intervals. Check the **Preview** box to try out different combinations and see how they look in the drawing without committing the changes.

10. When satisfied, press **OK**.

When a formatting characteristic, such as foreground or background color, style, size or rotation has been thematically formatted the corresponding color or sample well in the format toolbar will change appearance to show that characteristic is now specified by a thematic format.

Color samples, like the two different examples shown, will attempt to show the range of colors used in the thematic format. Obviously, there is not enough room in a small toolbar sample to show many colors, so not all colors in a complex format will appear. The idea is to provide enough colors to refresh our memory of the thematic format specified.

Characteristics such as style or size will be represented by the thematic format icon. When we see this icon in a format toolbar we know that the corresponding formatting characteristic is specified by a thematic format.

**Thematic Format Dialog**

The thematic formatting dialog is used to apply colors, styles and sizes automatically based upon the contents of a controlling field. Not all controls will be enabled for all types of formatting. For example, when changing styles or sizes the **Interpolate**, **Lighten**, **Darken** and **Grayscale** controls will not be enabled.

In the **Values** pane the numbers at left are the numeric breaks between intervals. The color wells at right show the coloration that will be applied to each interval. The small numbers immediately to the left of the boxes show how many objects fall into that interval. In the example above we thematically format provinces in Mexico by their populations using the **Spectrum** palette. The **Natural Breaks** method has assigned 7 provinces to the interval containing provinces with populations less than 580000 and only 3 provinces occur in the interval from 580000 to 1051000. There are 11 provinces in the next interval and so on.
The (default) color well shows the color that will be used by default for objects that are newly created that do not fit into any of the existing thematic categories. This is most important in cases where a thematic format has been created based upon individual values and then, after the format has been created, a new value is introduced when a new object is created.

**Thematic Format Dialog Controls**

**Field**
The data field that controls the thematic format. All data fields available with this drawing will be available in this list box. Also available will be intrinsic fields that are automatically computed by the system.

**Method**
The method used to classify records into different intervals.

**Palette**
Preset color combinations that may be applied to intervals. Press **Apply** to apply the palette to the selected intervals. Palettes are scalable and will be interpolated to apply the color range to a greater or lesser number of intervals.

- **Apply** - Apply the chosen palette to the **Values** pane. This allows scrolling through the palettes without changing colors until we press **Apply**. Pressing **Apply** only changes the color scheme in use for values. It does not change the thematic formatting of the drawing until the **OK** button is pressed. To see a preview of how the applied colors will look, use the **Preview** check box.

- **Reverse** - Reverse the formats used in the values box from high to low.

- **Interpolate** - Change the colors or sizes used in the values boxes by interpolating between the top and the bottom boxes. A quick way of creating smooth gradients of colors or sizes.

- **Lighten** - Lighten all colors. Each click on the Lbutton lightens the colors a bit more.

- **Darken** - Darken all colors. Each click on the button darkens the colors a bit more.

- **Grayscale** - Convert all colors to grayscale.

- **Move Up** - Enabled when the **Unique Values** method is used and an interval (value) has been selected. Move this value up in the range of intervals shown.

- **Move Down** - Enabled when the **Unique Values** method is used and an interval (value) has been selected. Move this value down in the range of intervals shown.

- **Load from File** - Load a previously saved theme from an XML file. Works with all field types except lookup fields. See the Custom Palettes and Themes topic for information on how the XML file is structured.

- **Save to File** - Save this theme to an XML file. Works with all field types except lookup fields. See the Custom Palettes and Themes topic for information on how the XML file is structured.

**Values**
A display of intervals created using the specified **Method**. The **Values** pane is updated with each press of the **Tally** button. If a **Palette** is used, the color wells will be updated with each press of the **Apply** button. The values may also be changed by double-clicking into any value to edit the number. The (default) color well allows editing the default value that will be applied to any objects outside the thematic format specified, such as, for example, if a new object is added with a value outside the
range of a range of **Unique Values** that have been specified.

**(interval numbers in the Values pane)** Double-click on an interval number to set it manually. For a different arrangement of intervals, choose the desired **Method** and the desired number of **Breaks** and press **Tally**.

**(color wells in the Values pane)** Double-click on a color, style or size sample to change it. Choosing a **Palette** and pressing **Apply** will apply the palette colors to the **Values** pane's color wells. Press **Interpolate** to create a smooth gradient of color from the topmost well to the lowest. Press **Reverse** to reverse the order of colors.

Continuous Shading Interpolate colors shown in the wells so that values between the numbers shown for the intervals will result in color shades that are taken from a continuous gradient of color.

**Align to** Select the number of digits to align **Values** to even values of tens, hundreds, thousands, etc.

**Range** Shows the lowest and highest values that occur in the controlling field. Change the values to specify the range over which intervals will be tallied. Values outside the range will be assigned to uppermost and lower intervals that bracket the intervals over which the method specified is tallied.

**Reset** Reset the **Range** to the lowest and highest values that occur in the controlling field.

**Breaks** The number of breakpoints between intervals.

**Tally** Re-compute intervals by specified method using given number of breakpoints.

**Preview** Temporarily shows the effect of the format when **Apply** is pressed.

**Methods**

- **Equal Count** Assign interval values so that each interval contains the same number of objects.
- **Equal Intervals** Assign interval values so that each interval contains the same range of values.
- **Exponential Intervals** Assign interval values so that each interval contains an exponentially increasing number of values.
- **Natural Breaks** Find clusters or groupings of objects by the given field and assign break values so that each cluster is in a different interval.
- **Standard Intervals** Choose break values so that each interval represents one standard deviation.
- **Unique Values** Used with text and enumerated fields. Assign a break value for each unique value that occurs in the field.

**Thematic Formatting Capabilities**

Thematic formatting uses data fields to independently control:

- Foreground color
- Background color
The above characteristics may be thematically formatted independently for areas, lines and points. In effect, it is as if we can set twelve different thematic formats for each drawing (four different types of formatting characteristics times three types of objects results in twelve different thematic formats available per drawing). If desired, we can use one data field to vary the size of points, another data field to vary the color of the points and yet a third field to vary the style of point used.

For example, we can increase or decrease the size of points representing cities based on the value of their population fields. The greater the population, the larger the point.

The illustration above shows cities in Texas where each city has a population field in the associated table. In the default format all points are the same size.

If we click on the **Size** button for points in the format toolbar and then choose **Theme** we can alter the size by the population field. Manifold will draw thematically formatted points by drawing the largest points first and then the next largest and so on to the smallest so that the smaller points are not covered by the larger points.

If we click on the **Background Color** button for points in the format toolbar and choose **Theme** we can also alter the background color of the points by their population. This results in a map where both the size of the point and the color of the point are changed depending on the population.
If desired, we can change **Style** with a thematic format. This is handy when preparing maps for black and white printers. **Style** can also be used to automatically vary point and line styles as well as area styles.

All of the different characteristics at once can be thematically formatted. The above illustration shows foreground color, background color and style thematically formatted. To assure that maps do not confuse the viewer it is usually wise to use the same data field in the same manner for all thematic formats applied to the same class of objects. That is, if thematically formatting the background color in areas based on a state's population, refrain from simultaneously thematically formatting the foreground color using the number of houses in the state.

**The Controlling Field**

Thematic formatting works with drawings that have a table associated with them. The thematic format is controlled by the value of a specified field in the table. This field is most often a numeric field, but it can be a text or other type field as well. Intrinsic fields will appear in the list box as available choices for controlling fields. Intrinsic fields are automatically computed by Manifold for each object in the drawing.

Intervals are created and objects are assigned to them using the given method. For example, the intervals can be created with breakpoint numbers so that each interval ends up with an equal number of objects. This is a useful method to use if we wish to avoid a situation where there are six intervals / color settings but all the objects end up in only one interval so our map is colored with only one color.

If the controlling field is a text field the only choice available for methods is **Unique Values**

**Breaks and Intervals**

Thematic formatting divides the objects into **intervals** that are set by the number of **breaks**. Each break is a value that specifies between the border between two intervals. The minimum value and the maximum values are always taken from the lowest and highest value in the data set. The break point values specify how the range from minimum to maximum is to be split up into intervals.

The following examples use a map of the United States that's linked to a table that has a series of fields giving educational achievement for each state. We will use a field that gives the percentage of the population that has advanced degrees (that is, some graduate degree beyond college).
If we specify three breaks as shown above we end up specifying four intervals. The first interval is the range from the minimum value in the table (the red box) to the first break point (at about 7.63%). The red color will be used to color the first interval. The blue color will be used to color the second interval starting at the blue break point of 7.63% and so on.

**Methods: Automatically Choose Break Values**

Once we choose the number of breaks we want we can either have Manifold choose the values for each break point or we can set the value for each break manually. Manifold has several different methods it can use to automatically choose values for each break.

The numbers for the three breaks shown above were computed by Manifold using the **Equal Intervals** method. This method chooses numbers for the breaks such that the total range from minimum to maximum value for the controlling field is split into intervals of equal size. In this example, because we have four intervals each equal interval represents one quartile of the distribution of values in the range from minimum to maximum.

The red box shows the interval from the minimum found in the data set (in this case, about 4.45% of the population) to the first break at about 7.63%. The minimum, red color is used to color states from the minimum to the first break. From 7.63% onward the blue color specified at the 7.63% break is used to color the interval. The green color specified for the second break takes over at 10.82% and is used to color objects until we get to the third break, after which yellow will be used.

Note that the **Equal Intervals** method makes the intervals the same size: that is, the range from 7.63 to 10.82 is the same size as from 10.82 to 14.01. In this example, because there are four intervals each equal interval represents one quartile. The number of objects in each interval can be quite different. In the above map, there are very many states with educational attainment in the lowest interval. There is only one “state,” the District of Columbia in the last interval. Yellow does not appear in the above map because the District of Columbia is too small to be visible at the zoom level shown.

**Applying Palettes**

The **Palette** box contains color schemes that may be applied to color wells in the Values pane.
The default theme uses default color for all intervals.

To apply a palette, choose it in the **Palette** box and press **Apply**. In the example above we have chosen the **Savannah** palette and will now press the **Apply** button.

Colors will be applied to the interval color wells as seen above. Palettes will usually have a wide range of colors available. Only some colors from the palette will be used if the number of intervals is small.

To change the order in which colors are used we can press the **Reverse** button.
The Reverse button reorders the colors so that the uppermost color is now the lowest and vice versa. Note how the blue color well is now at the bottom of the range.

We can also use the Interpolate button to rapidly create a gradient of colors from white to blue.

Interpolate is a handy way of creating gradients. It creates a smooth range of color from the top box to the bottom box. A rapid way of creating custom gradients is to double-click into the top box and choose a color and then choosing a color for the bottom box and pressing Interpolate. The Interpolate button works for colors and size gradients but does not work for styles.

Rounding Intervals with Align to

We often would like to have intervals that begin and end at even number values. This can be accomplished with the Align to setting.

To align intervals to even thousands, for example, we choose 3 digits in the Align to box and then press Tally.
The interval numbers will be changed to even thousands and the objects in each interval will be re-computed using the method assigned, as adjusted for the aligned values of the intervals.

Very important: Re-tallying intervals, even by just aligning them to even numbers, requires a re-application of the color intervals. For example, the illustration above was created by reapplying Interpolate after changing the Align to value. The usual workflow is to create the intervals desired (including any Range, Breaks and Align to options) and then apply colors.

Lighten and Darken

Some of the standard palettes provided may result in garish colors depending on the setting. For example, the Spectrum palette provides a continuous range of rainbow colors that may be too bright in some drawings.

Use the Lighten button to automatically lighten colors.

Use the Darken button to darken colors.

Using Range

An important use of Range is to assure that two drawings that appear together in a map have the same formatting over the same range of values. By default, Manifold takes the lowest and the highest values that occur in a drawing and uses those values to compute methods. Using Range can override these values.

Suppose for example we have a drawing of counties in California with a percent achievement scale on a standardized test where each county has a value on a scale from 0% to 100%. Suppose we also have a drawing for Oregon with results from the same test.

If the California drawing has test results that range from 5% to 85% and we thematically format it using Equal Intervals into 4 breaks the default formatting calculation will use the range 5 to 85. Using this range will create 4 intervals of 5 to 25, 25 to 45, 45 to 65 and 65 to 85.

If the Oregon drawing has test results that range from 10% to 90% and we thematically format it using Equal Intervals into 4 breaks the default formatting calculation will use the range 10 to 90. Using this range will create 4 intervals of 10 to 30, 30 to 50, 50 to 70 and 70 to 90.
If we use the same colors for both California and Oregon, counties with a test result of 27% will have different colors in the California and Oregon drawings, providing an inconsistent visual presentation if the two drawings are shown together in a map. We can avoid this inconsistency by telling Manifold to use a **Range** of 0 to 100 when thematically formatting the California and Oregon drawings.

If we use a **Range** of 0 to 100 and **Equal Intervals** with 4 breaks then each break will be the same in both drawings. Each drawing will have 4 intervals of 0 to 25, 25 to 50, 50 to 75 and 75 to 100 and all counties in both drawings will be colored using the same scheme.

Another use for **Range** is to exclude unusually high or low values from the main thematic coloring. For example if we have a lot of data that is evenly dispersed through the range 30 to 80 and but a handful of scattered values from 0 to 30 and from 80 to 100, we might tell Manifold to use an **Equal Count** method using a **Range** of 30 to 80. Intervals will be assigned so the bulk of data is divided into even intervals between 30 and 80 with the scattered values in the lowest and the highest intervals. The lowest and highest intervals can then be clicked by hand and changed to less prominent colors.

**Continuous Shading**

If we check the **Continuous shading** box, the color for each state will be drawn from its field value as interpolated between the colors specified at the breaks.

![Continuous Shading Image](image)

Without checking the **Continuous shading** box, all states use one of the colors specified for the intervals. Without the **Continuous shading** box checked it looks like the entire country is not highly educated with California, Colorado and New Mexico in the West and a handful of states in the Northeast providing some slightly elevated educational achievement. A very few states in the East have educated populations shown in green color.
When the **Continuous shading** box is checked, each state gets a color that is interpolated between the colors specified for each break. The **Continuous shading** box allows us to specify a relatively small number of breaks and colors yet still see some visual differences within the intervals. Using continuous shadings is the reason we have a color box available to set the color value for the "maximum" value. This box is used only when the **Continuous shading** box is checked since without continuous shadings each interval is colored with the color box of the break point that starts the interval.

With the **Continuous shading** box checked we see that the situation is more complex that it initially appeared. Most states are still in the low-achievement range with Arkansas leading the way in low educational achievement. The blue states are now seen to divide into two classes of states: lower-end states like California that are more like the low-achieving mass of states, and a few higher-end states like Colorado, Virginia, New York and Massachusetts. States in the latter group have more in common with highly educated states like Connecticut than they have with California. That they were grouped by color with California is an accident of choosing three break points to divide the entire range into four equal intervals.
A better way to reveal groupings is to use the **Natural Breaks** method. This method allows Manifold to find clusters of similar values within the field and to choose break points so that each cluster is in an interval. The above example shows **Natural Breaks** working with 5 breaks to create six intervals.

The natural breaks thematic map shows the highly irregular distribution of populations with higher education in the US. Most states fall into one of four groupings having less than 7% of the population having higher degrees. For the most part, states are clustered into different levels of mediocrity around the 5.7% level. A handful of states fall into a cluster above 8.27% and are shown in green.

The Manifold **Natural Breaks** algorithm works remarkably well. People who are familiar with these states would say that California, Washington, Illinois and New Hampshire are definitely in the same bucket when classing states by percentage of highly educated people. **Note**: the educational attainment thematic maps shown in this topic are based on Census Bureau percentages of advanced degrees in 1990.

**Interval Styles in Legends**

**Legends** will automatically adapt to the status of the **Continuous shading** box.

```
Mexico Drawing
Areas: [POBL_1990]
_<-1837981
-1837981...240047
240047..2318075
2318075..4396103
<4396103...6474131
>6474131
```

Legends for thematic formats not using continuous shading will show the range of values to which each color applies.
If the **Continuous shading** box is checked the legend will show the discrete values and colors between which a continuous range of colors is interpolated.

Automatic legends will use the same number of digits beyond the decimal point that are specified for that column in table column formatting.

**Example: Use Thematic Formatting to Show Territories**

Suppose we have a **Territory** field in our table of US States. This is a text field and contains the name of the sales territory that includes that state. Sales territories have names like "Northeast" and "West Coast".

**Step 1: Click open Thematic Format Dialog.**

Click open the drawing to be formatted, or click on the drawing's layer tab in a map to make it the active layer. Click on the format toolbar's **Background Color** well for areas. Choose **Theme** to launch the thematic formatting dialog.

**Step 2: Choose the Controlling Field and Method**

In the thematic formatting dialog, choose **Territory** as the controlling field and **Unique Values** as the method. The breaks and intervals part of the dialog will automatically change to the list of unique values found for the territory field. There are only six different strings (that is, six different territories) found in this particular example.

**Step 3: Choose Colors to be Used**

Double-click into each color well and choose a color or use one of Manifold's preset color arrangements. Click **OK**.
The resultant thematic format colors the background colors of each state area by the value found in the Territory field.

**Example: Use Thematic Formatting to Show Population**

We open a drawing of Mexico showing provinces.

The drawing's table has a field called **Population** that we would like to use to color the provinces by their populations.

<table>
<thead>
<tr>
<th>ID</th>
<th>SQMI</th>
<th>Population</th>
<th>Vl</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>26535.63</td>
<td>2003187</td>
<td>38</td>
</tr>
<tr>
<td>2</td>
<td>32089.18</td>
<td>1276323</td>
<td>23</td>
</tr>
<tr>
<td>3</td>
<td>52374.05</td>
<td>1349378</td>
<td>26</td>
</tr>
<tr>
<td>4</td>
<td>76106.63</td>
<td>1823606</td>
<td>38</td>
</tr>
<tr>
<td>5</td>
<td>23603.84</td>
<td>2264045</td>
<td>43</td>
</tr>
</tbody>
</table>

The "body" color of the provinces is set by their background color. Click on the format toolbar's **Background Color** well for areas. Choose **Theme** to launch the thematic formatting dialog.
Choose **Population** as the controlling **Field**. Choose **Equal Count** as the **Method**. This will assign approximately the same number of provinces to each population interval. Choose the **Red to Yellows** palette and press **Apply**.

Those are nice colors, but we note that the lower population intervals are colored red and higher population provinces will be colored yellow. We would like to reverse this so that provinces with higher populations will be colored red. To do so we press the **Reverse** button.
From experience we know that the very bright colors used in the Reds to Yellows palette will result in a garish map. To lighten the colors we press the Lighten button twice.

That results in a more muted palette that will still show variations in the provinces well.

The final product is a drawing of Mexico that shows provinces colored by the contents of their Population field. Provinces with higher populations are colored red. Those with lower populations are colored yellow. Right away
it is obvious that much of the population of Mexico is clustered in a small band of provinces in the middle of the country. Regions such as southern Baja California and the provinces to the East are less populated.

**Fixed Interval Palettes**

Palettes in Manifold occur in two forms:

- Relative palettes, where colors from the palette will be "stretched" and interpolated as necessary for use in the number of breaks specified in the **Format** dialog. The examples above all use relative palettes.
- Fixed palettes, where colors are associated with specified intervals. When a fixed palette is used in thematic formatting, applying the palette will automatically create as many intervals as are required by the numbers specified for the palette.

Fixed palettes are most frequently used to color surfaces that show terrain elevations. They allow a standard color scheme to be applied for specific elevations that is the same from surface to surface. Manifold includes a few fixed palettes for use with surfaces. Altitudes are predictable since the general elevation of the Earth is known and covers a fairly narrow range. Standardized palettes may therefore be created for altitudes and incorporated into Manifold.

Fixed palettes are less frequently used with thematic formatting in drawings since normally the range of values that may be displayed in thematic rendering covers a very wide range. It is usually faster to create fixed intervals by specifying the **Breaks** option, tallying the desired number of intervals and then applying a relative palette. We can then "clean up" the breaks to desired interval numbers.

However, for some applications such as land classification a specific, fixed palette may be desired for use in thematic formatting. Use the customization features noted below to create fixed palettes that have ranges of values that correspond to colors desired.

**Saving and Loading Themes**

Press the **Save** button to save a theme to an XML format file. Themes for color, size or style may be saved.

Press the **Load** button to load a theme from an XML format file. When attempting to load a theme file for a different type of theme (for example, trying to load a theme file that saved a thematic format for different point styles when working in a thematic format dialog to set color) the system will load the formatting breaks from the saved theme and will reset formatting to default.

Loading a saved theme file will also reset the **Method** to a method that makes sense for the type of field (column) being used as follows:

- When loading a file containing value-based formatting such as **Unique Values** the system sets the formatting method to **Unique Values** since this method is supported by columns of any type.
- When loading a file containing interval-based formatting such as **Equal Intervals** the system checks if the current column supports interval-based formatting (that is, if the current column is not a **Date**, **Text** or **Boolean** type field) and if the current formatting method is value-based. If so, it sets the formatting method to **Equal Intervals**.

**Customization**

Palettes used in thematic formats may be customized, and new palettes may be added to Manifold. See the Customization topic.

**The Color Dialog**

The **Color** dialog makes it easy to automatically apply a thematic format to a drawing that colors each adjacent area using a different color.
When applied to a drawing that contains adjacent areas, the color dialog will add an integer field called **Color** to the table. (If a field exists that is already named **Color** the system will create the new field using a name like **Color2**). The drawing is then examined using Manifold’s internal graph theoretic algorithms to assign a small number to each area in the **Color** field so that no two adjacent areas have the same value in their **Color** field.

The **Color** field is then used in a thematic format to specify both foreground and background color. The colors used are made slightly darker in the foreground color so that the borders of area styles will be distinct.

It’s easy to change the color scheme after applying the color dialog to automatically color areas. Simply click on the color well to be changed for areas and choose theme and then apply one of the preset color schemes. The color applied by the color dialog is simply a thematic format using the **Color** field with a **unique values** method.

Note that the word **theme** is used both for the application of a palette of colors to a drawing or a theme and is also used as the name of the **theme** component. We apologize for this minor lexicographic inconsistency, but it seems clear which is which in actual usage.

**ColorBrewer Palettes**

Users with experience in thematic formatting know that it can be sometimes difficult to choose colors for thematic formatting that do not result in a miserably garish display. Manifold includes **ColorBrewer** palettes, beginning with a **CB** in the name of the palette, which are arrangements of colors that have been cleverly picked by Cynthia Brewer to work well together. Using one of the **CB** palettes almost always results in a pleasant and legible effect. See the Miscellaneous topic and [http://www.colorbrewer.org](http://www.colorbrewer.org) for more info on the ColorBrewer project.

The **CB** palettes are each designed with a fixed number of colors, the number of colors being indicated by the number at the end of the palette name. For example, **CB Pastel 4** is a palette of four colors. The number of colors should be the same as the number of breaks used in the thematic format. So, for example, if we use the default 5 breaks when formatting a map by, say, population using the **Natural Breaks** method we should use **CB Pastel 5** as the **CB** palette so that there are five colors in use.

**Thematic Formatting Example**

Thematic Formatting and Labels
Rotating Labels
Themes
**Thematic Formatting Example**

An example of Thematic Formatting is automatically changing the size, color or style of points based on the contents of a data field for each point.

Suppose we have a drawing with various city points. The illustration above shows our drawing of points as a layer in a map with a background map of the United States. Suppose the city points drawing's table has a **Population** field that gives the population for each city. We would like to change the size of points based on the contents of the **Population** field for each point.

![Map illustration](image)

We begin by clicking on the point size button in the format toolbar and then choosing **Theme** from the menu. This launches the thematic formatting dialog.

<table>
<thead>
<tr>
<th>Field: Population</th>
<th>Method: Equal Count</th>
</tr>
</thead>
</table>

In the thematic formatting dialog, we choose **Population** as the controlling field. For this example, we use the **Equal Count** method so that there are an equal number of points in each of the intervals defined by the thematic format. We've also used alignment to 4 digits and pressed **Tally** so that the interval breaks occur at even 10000 values.

![Thematic Format Table](image)

By default, each interval has a size of 3 for the point sizes. The other numbers show how many of our cities fall within each population bracket. We can change the point size for each interval by double clicking into each size number and changing it.
In this illustration, we’ve changed half of the values. We’ve chosen a progression of sizes that we think will be a reasonable increase in size for each interval. For example, the cities with populations from 20000 to 30000 will have a size of 4. If this turns out not to provide the desired visual effect we can open this dialog again and adjust the values.

We’ve now changed all the values. The interval from zero to the first number has a size of 1 and the interval from the last number up has a size of 10.

When we press OK the points will be redrawn with size values corresponding to the contents of their Population field. Points with larger Population will be drawn as larger size as specified in the thematic format.

Changing Color

We can also change color using a thematic format. In fact, we can change color with a thematic format even as we change size. To change color, we click on the background color well and choose Theme to launch the thematic format dialog.
In the thematic format dialog we once again choose Population as the controlling field and Equal Count as the method to use. Once again, we use an alignment to 4 digits and press Tally to get intervals of even 10,000. When creating thematic formats for colors, Manifold provides a choice of Palettes as well. Each palette provides a handy color range. We choose the Blues to Greens palette.

We press Apply to apply this palette to the intervals used.

The palette applies a range of graduated colors from blue to green to the intervals in our thematic format. We then press OK.

The points will now be drawn with color that varies by the value of their Population field. Note that the color change is in addition to the change in size for each point. This provides greater emphasis on the more populated cities.

Changing Style

If desired, we can even vary point style with a thematic format. To do so, we click on the point style button in the format toolbar and choose Theme. This launches the thematic formatting dialog for varying point style. Once again, we will use Population as the controlling field and Equal Count as the method for assigning intervals. We will also choose an alignment to 4 digits and press Tally to get intervals of even 10,000.

This time, when we double-click into each interval’s attribute we will change the style instead of changing a size value or color. The dialog opens with all circles. We can double click on the circle for each interval and change the circle to the desired style. In this case, we have specified a series of styles from a simple cross to a circle to a square and so on to an inverted triangle.

We press OK to apply the thematic format.
The points will now be drawn with a style symbol that varies in accordance with the Population field. Note that the style variation is in addition to the color and size variation specified in the other thematic formats we applied.

**Tips**

When applying more than one thematic format, it is almost always best to use the same method and the same number of intervals for all thematic formats. It's too much to ask of viewers to expect them to keep in mind that size varies in accordance with five intervals but color varies only by three intervals.

It is not easy to visualize three different variables at once even when they are each coded by size, color or style. Use multiple thematic formats with great restraint. Note how in the above examples the image with circles of varying size but all of the same color does a good job of conveying the relative populations of the towns. There is some value added in adjusting color and style in some circumstances; however, the more frequent case is that overuse of thematic formats to display many different attributes at once will lead to a confusing presentation.

A fast way to assign a range of values is to use the **Interpolate** button. Click on the topmost interval and assign the value (such as color or size) for that interval. Next, click on the bottom interval and assign the value for that interval. Finally, click the **Interpolate** button to fill in the intervals in between with interpolated colors or values.

When interpolating styles, the intermediate intervals will be filled in with the symbols that occur, in order, in the styles menu from the first interval's symbol to the last interval's symbol.

**Thematic Formatting and Labels**
Rotating Point Styles

Point styles in Manifold may be rotated using the **Point Rotation Angle** button in the format toolbar for labels. This topic assumes the reader is familiar with formatting in general and with the techniques set forth in the Formatting Drawings and Point Styles and Sizes topics.

To rotate all of the point styles in a given drawing, open the drawing, press the **Point Rotation Angle** button and choose a rotation value.

For example, the point style shown above (a point style in the shape of a letter "A") has been rotated through 0, 30, 60, 90 and 120 degrees.

**Example**

Suppose we have a drawing of points that include a **Direction** field for each point. The points are measurements of flow direction in a stream.

By default, the points appear as small round circles.

We can change the point style to an arrow.
To rotate the points, we can press the **Point Rotation Angle** button.

In the pull-down menu we can choose **90** to set the point rotation angle to **90** degrees.

The result is that all points in the drawing will have their point style rotated to **90** degrees.

If desired, we can also rotate each point based upon the value of a field using thematic formatting. To do so, press the **Point Rotation Angle** button and then choose **Theme**. In the thematic formatting dialog that follows, choose a thematic format that sets the rotation angle by a given field, such as a **Direction** field. The fastest way to do this is to use the **Continuous shading** option in the thematic format dialog.
Using the values of a Direction field to control rotation:

1. Open the drawing, click the Point Rotation Angle button and choose Theme.
2. In the Format dialog, choose Direction as the field and any interval-based method, such as Equal Count as the method.
3. Choose 2 as the number of breaks.
4. Check the Continuous shading box.
5. Press the Tally button to establish two intervals.
6. Double click into the two Values cells and change the upper one to 0 and the lower one to 360.
7. Double click into the rotation values and change the upper one to 0 and the lower one to 360. Press OK.

The above procedure creates two intervals, of 0 and 360 degrees and then continuously formats all values in between. In effect, this assigns a continuous range of rotations from 0 to 360 degrees to any Directions values between 0 and 360.

See the Rotating Labels topic for examples using thematic formatting to set rotation angle.
In that case, each point will be rotated by the given field as seen above.

Point Styles and Sizes
Themes

Themes are project components that store formatting choices for drawings. Opening a theme shows the drawing with the formatting specified by the theme. A drawing can have many themes, each of which may show that drawing through a different set of formatting choices. Adding a new theme to a project requires virtually no storage space.

Themes may be used as though they were a drawing, for example, appearing as a layer in a map. Selections and editing commands may be done in a theme. Because a theme window is simply a drawing viewed through a particular format, any selections, edits or other changes except formatting made in any theme of a drawing will affect the drawing and all other themes of that drawing as well.

Themes are most often used with thematic formatting to show values of different data fields in a drawing. For example, the same drawing may be shown in different themes to show the values of populations, per capita income or other demographic attributes. Themes make it easy to show the same drawing in different ways without having to either reformat the drawing or make copies of the drawing for use with different formats.

To create a theme for a drawing:

1. In the project pane choose Create - Theme from the project pane toolbar or right click into the project pane and choose Create - Theme from the context menu.
2. In the Create Theme dialog choose a name and an optional description for the theme.
3. Choose the Parent drawing for the theme. This is the drawing that will appear in the theme with the specified formatting.
4. Check the Inherit formatting box if the theme is to automatically inherit any formatting changes made to the parent drawing. Uncheck this box if the theme is to have no connection to the formatting of the parent drawing.
5. Press OK.

Every theme is created based upon some parent drawing. The parent drawing appears in the theme. Any selection made in the theme will be a selection from the objects (points, lines or areas) in the parent drawing. Any editing changes in the theme, such as adding or removing objects, will be implemented in the parent drawing.

Themes may also be created based upon other themes. In that case, enter the name of the parent theme in the Parent box. If a theme is created based upon a parent theme, whatever is the ultimate parent drawing will also be the parent drawing for the newly-created theme.

Example

Suppose our project contains a drawing of Mexico provinces, created from the Mexico_eg drawing on the Manifold CD.
We can open the drawing and see that it uses default formatting.

We can create a theme by choosing **Create - Theme** in the project pane toolbar. We enter the name **Population** and choose the Mexico drawing as the parent. We uncheck the **Inherit formatting** option so that the theme takes no formatting attributes from the parent drawing.

A new theme appears in the project under its parent drawing.
If we open the theme we see it has default gray formatting.

We can click into the area background format well in the format toolbar and apply a thematic format that colors the theme based upon the population in each province, with darker greens indicating greater population. The POBL_1990 field in the example Mexico drawing gives the 1990 population for each province.
The theme will immediately show the new formatting applied.

Next, we can create another theme called **Size**.

The parent for this theme will also be our Mexico drawing. Once we uncheck the **Inherit formatting** box.

A new theme appears in the project underneath its parent drawing.
We can apply a thematic format to the **Size** theme that colors provinces based upon their size in square miles, with larger provinces having a lighter color.

We will create one more theme, called **Buses**.

As with the other themes, this theme appears in the project pane underneath its parent drawing.

We will thematically format this theme based upon the number of buses in each province.
The darker the color, the more buses in the province.

If desired, we can open all three themes as well as their parent drawing. Each theme appears like a drawing in a drawing window and each theme has all of the characteristics that a drawing has. Each theme is derived from the parent drawing. Although there may appear to be four different “drawings,” there is in fact only a single drawing and only one copy of all the objects in that drawing. The themes are just different ways of displaying that same drawing by using different formatting. We can have as many themes as we like and still there will be no increase in the amount of disk space required for the project.

**Selections and other operations**

We can make selections in a theme window, edit objects and otherwise do anything we could do in a drawing window.
For example, if we have all three themes open and their parent drawing as well, a selection made in any of the windows will immediately appear in all of the other windows.

If we make any edits in any of the windows, such as deleting objects or changing their position or size or form, the edits will take effect in all of the windows. The reason is that a parent drawing and any theme based upon that parent all show the same objects. The themes simply show those objects with different formatting.

Any selections saved in the Selections pane will also be the same for all themes of the same parent drawing.

Themes inherit any views in the Views pane from their parent drawing. Adding a view to any theme will add it to the parent drawing and to all other themes of that parent.

Likewise, themes inherit any Viewbots from their parent drawing. Adding a Viewbot to any theme will add it to the parent drawing and to all other themes of that parent.

**Themes and Toolbars**
Themes can be used in the Query and Transform toolbars. Object sets defined on themes will always use the name of the theme's parent drawing. For example, if there are selected objects in a theme named T whose parent is a drawing named D the selection choice will appear in the query or transform toolbar boxes as Selection in D.

This is done so that it is immediately clear that modifying a theme will modify the parent drawing (and thus all other themes bound to that drawing).

Inherited Formatting

In the example above we've considered a simple use of themes, where each theme is formatted completely independently of the parent drawing. Themes may also be created so that some or all of the formatting of the theme is automatically derived from the formatting of the theme's parent. Such formatting is called inherited formatting.

When a theme is created with inherited formatting, any changes made to the formatting of the parent will be applied automatically to that theme as well for those formatting characteristics that are inherited. If we like, at any time we can disinherit any particular formatting characteristic so that it is no longer inherited from the parent and can be set independently of the parent. Likewise, it is easy at any time to change a local formatting characteristic in a theme to be automatically inherited from the parent.

Inherited formatting allows us to pick and choose what formatting characteristics are automatically displayed in themes based upon changes to their parents. A theme can even use another theme as a parent, which makes it possible to create subtle and sophisticated relationships between different themes to specify what formatting characteristics will be automatically changed and what characteristics are unique to a specific theme.

Because the project pane always shows the hierarchical relationships of parent drawings to themes and then to themes that have other themes as parents, we can always use the project pane as our guide to the relationships we have created.

To create a theme with inherited formatting:

1. In the project pane choose Create - Theme from the project pane toolbar or right click into the project pane and choose Create - Theme from the context menu.
2. In the Create Theme dialog choose a name and an optional description for the theme.
3. Choose the Parent drawing for the theme. This is the drawing that will appear in the theme with the specified formatting.
4. Check the Inherit formatting box if the theme is to automatically inherit any formatting changes made to the parent drawing. Press OK. This creates the theme with all formatting characteristics being inherited from the parent.
5. Open the theme. To disinherit any formatting characteristic, click the formatting well for that characteristic and set some local format. As soon as we set a local format in the theme the inheritance for that format is disconnected.
6. If we change our minds and would like any characteristic to be inherited again, simply click on the formatting well for that characteristic and choose Parent in the pull-down color well dialog.

Example

Let's begin by creating a theme from the Mexico sample drawing (now simply called "Mexico").
However, this time we will check the Inherit formatting box.

As before a new theme appears in the project pane.

If we open the theme we see it has default formatting.

The format toolbar for this theme now shows four corner brackets displayed for each formatting characteristic. Corner brackets indicate that a particular formatting characteristic is inherited from a parent. Because this theme was created with Inherit formatting checked, all of the formatting characteristics are inherited from its parent, the Mexico drawing.
We next click open the *Mexico* drawing and thematically format the background color as seen above.

If we click open the *Theme 1* theme, as expected it has the same formatting as its parent *Mexico* drawing. The formatting changes made to the area background in the *Mexico* drawing have been inherited automatically by the *Theme 1* theme.

At any time we change an inherited formatting characteristic into a non-inherited formatting characteristic simply by applying a format to that characteristic.

For example, if we would like to change the area background color for *Theme 1* into a non-inherited, local format we can simply click on the area background well in the format toolbar.
We choose a new color for the area background…

…and the format toolbar will show the area background without corner brackets to indicate it is a local format and not inherited from a parent.

**Theme 1** will now show area background color as specified within the theme and not as inherited from its parent **Mexico** drawing. If any change is made to area background color in the **Mexico** drawing it will not be propagated to the **Theme 1** theme. However, any other changes made in formatting to the **Mexico** drawing, such as changes in area foreground color, area style, line colors, etc. will be automatically propagated into the **Theme 1** theme.

We will now create a theme based upon another theme.
In the project pane we choose Create - Theme and then in the Create Theme dialog we create a new theme called Theme 2 that use Theme 1 as the parent. Note that we’ve checked the Inherit formatting box.

Our new theme is created in the project pane below Theme 2. The theme's position in the project pane hierarchy shows that Theme 1 is its parent.

When we open the theme we see that Theme 2 appears the same as Theme 1, which is what we would expect since Theme 1 was the parent and we created the new theme with inherited formatting. The toolbar for Theme 2 shows that all formatting characteristics are inherited from a parent. Note that even though Theme 1 is the parent of Theme 2, because Mexico is the ultimate parent of Theme 1 all of the objects that are seen either in Theme 1 or Theme 2 come from the Mexico drawing.

Let's now make some formatting changes in both Mexico and in Theme 1 and see how they are propagated through the two themes we have created.
In the Mexico drawing we change the foreground color for areas to blue so that the area borders are rendered in blue (a strikingly ugly combination, given the thematic formatting of the background color for areas).

The foreground color for areas will immediately change in the Theme 1 theme, because this formatting characteristic is inherited from the Mexico drawing.

In the Theme 1 theme, let us now change the background color for areas to a light green.
If we open **Theme 2** we see that **Theme 2** has inherited the light green area background color from **Theme 1**. It has also inherited the blue area foreground color from **Theme 1** which in turn inherited the color from **Mexico**.

Suppose we change a formatting characteristic so that it is not inherited but then at some future point we would like to change it back to inherited formatting? That’s easy to change.

Let’s go back to **Theme 1**, seen above. Note that the area background color well in the format toolbar has no brackets, so it is not inherited from **Mexico**.

To change it back we click on the area background color well…
…and choose Parent within the color choice dialog.

This changes the area background color into an inherited formatting characteristic and automatically Theme 1 will be displayed using the thematic format used by the Mexico drawing for area background color. Theme 2 (not illustrated) will also have the same appearance because Theme 2 inherits all formatting characteristics from Theme 1.

Notes

Although there may seem to be no downside to using themes, there is one minor user interface issue of which users should be aware. In earlier editions of Manifold System, when themes were not yet available, a user could tell from the visual appearance of a drawing layer exactly which drawing was being manipulated because every window that showed a particular drawing always showed that drawing in the same format, the drawings’ format.

Because themes make it possible to show the same drawing using many different visual appearances we should take care to use formatting in sensible ways to avoid visual confusion.

For example, suppose we have two drawings that show European countries: Drawing A is formatted with mostly green colors and drawing B is formatted using mostly blue colors. It would be unwise to create a theme A1 for drawing A that is formatted with blue colors so it looks like drawing B, and it would be unwise to create a theme B1 for drawing B that is formatted with green colors so that it looks like drawing A. We don't want users to make edits within A1 thinking they are editing the B drawing because of the visual similarity between the two.

It's true that at any moment a user could look at the title bar of a theme window or the name of a layer in a map window and compare them with the names of drawings and themes in the project pane. Nonetheless it makes sense to keep in mind the possibility of visual confusion when working with large, complex projects that might include dozens or hundreds of components.
A good approach is to adopt naming conventions that clearly state the parentage of themes. For example, we might call a drawing "US States" and name its themes "US States - Income," "US States - Birthrate," "US States - Population" and so on based upon how the themes are formatted.

**Tech Tip**

When pasting a theme as a labels component to create a bound labels component, the parent of the labels component will be the parent drawing of the theme.

**See Also**

* Formatting Drawings

**Editing Drawings**

**Editing Drawings**

There are two classes of tasks when editing drawings: creating new objects or modifying existing objects.

We can create **new** objects by:

- Importing them from a non-Manifold source.
- Pasting them into this drawing from a different component.
- Creating them as the result of a command or a script.
- Drawing them "free hand" using interactive editing capabilities as shown in Adding Shapes or in Adding Points, Lines and Areas or in the Dialog Mode and Visual Tools topics.
- Creating them automatically from images using tracing (vectorizing) capabilities.
- Using commands such as Dissolve.
- Using the Transform toolbar to create one or more objects.

We can change the size, shape and position of **existing** objects by:

- Using the Transform toolbar to change many objects at once throughout the drawing.
- Using Cut, Copy and Paste to move objects between drawings and drawing layers in maps.
- Changing the objects as the result of an editing command such as the Dissolve command.
- Editing objects such as by changing their shapes using simple interactive commands or by using the Edit Toolbar during interactive editing. If not already displayed, the edit toolbar will appear when an object is selected for editing with a **CTRL-ALT** clicking the object.
- Altering objects "free hand" using interactive editing capabilities such as using the Context Menu commands.
- Editing the coordinates that define objects using the Object Coordinates dialog.
- Editing the position of the object by editing intrinsic fields in a table.
- Changing the position of points or repositioning other objects by editing their intrinsic fields in a table.
- Moving objects in drawings using the alignment toolbar to align them as desired.
- Using Topology Factory (if the Business Tools extension is installed) to detect and correct a variety of topological errors, such as undershoots or dangles.
- Using Topology Overlay to edit objects and their data attributes in a target drawing using the areas in a source drawing.

In addition to editing the **geometry** of objects (that is, changing their location or shape) we can also edit the data fields, if any, associated with those objects by:

- Editing the table associated with the drawing.
- Using Spatial Overlay to transfer data between objects in different drawings.
- Using Transfer Heights (if available) to transfer data from a surface to the objects.
- Using the Color or Districts tools to change fields used to format or organize objects.
Most operations will automatically apply only to the selection, if one is present. If no selection is present they will apply to the entire drawing.

**Transfer Rules**

Many editing / transformation operations in drawings (see Transform Toolbar - Drawings and Drawings - Dissolve, for example) will create new objects from existing objects. When new objects are created from existing ones the system must know how to transfer data attribute fields from the existing objects into the new objects. The Transfer Rules dialog in tables sets forth the rules to be used for each particular column.
Using Cut, Copy and Paste in Drawings

Use the standard Windows Clipboard **Cut**, **Copy** and **Paste** commands in Manifold to delete objects and to move them between drawings and drawing layers in maps. There are three paths to using clipboard commands:

- **Use commands from the Edit menu.** In this case **Cut** and **Copy** will apply to all selected objects in the active drawing window.
- **Use standard Windows keyboard shortcuts:** **CTRL X** to **Cut**, **CTRL C** to **Copy**, and **CTRL V** to **Paste**. Keyboard clipboard commands will apply to all selected objects in the active drawing.
- **Right click** onto an object in a drawing and choose **Cut** or **Copy** from the drawings context menu, or **right click** anywhere in the drawing and choose **Paste** or **Paste Append**.

Windows Clipboard commands will work between two different Manifold sessions if you have two Manifold programs launched at the same time on your computer. We can copy objects from one Manifold session, switch to the other Manifold session using the Windows taskbar and then paste objects into a drawing in the new session. This is a handy way of copying or moving objects between different projects.

When copying and pasting, objects remember their geographic location. They always appear at the same geographic location no matter how the target drawing or map is panned or zoomed.

**Clipboard Commands in Maps**

When used in maps, Clipboard commands operate on the active layer only. This provides a handy way of rapidly moving objects between drawings that appear as layer in maps. Click on the source layer tab to activate it, **Cut** desired objects, click on the destination layer tab to activate it and then **Paste**.

**ALT Key in Maps**

Selection and Clipboard operations in maps work only on the active layer. To extend the action of these operations to all visible layers, press the **ALT** key. For example, drawing a selection box in a map will only select objects in the active layer. Holding the **ALT** key while drawing a selection box will select objects from all visible layers. Pressing **Delete** deletes selected objects in the active layer only. Pressing **ALT-Delete** deletes selected objects in all visible layers. Think of **ALT** as a mnemonic for "All."

**Cutting**

Suppose we have one drawing that contains a triangular area. This drawing is formatted so that areas appear in blue.

We have another drawing that contains a square and a circular area. This drawing is formatted so that areas appear in yellow.
If we place the two drawings together in a map with the yellow drawing in a layer above the blue drawing we can see the relative positions occupied by the objects in the two drawings.

Let's select the yellow square. If we use **Edit - Cut** (or the standard Windows keyboard shortcut, **CTRL x**) it disappears.

**Pasting**

In Windows, how a **Paste** command works depends on whether or not something is selected. If nothing is selected, the objects in the Clipboard are pasted as new items in addition to any objects in the target drawing. If some objects in the target drawing are selected at the time of **Paste**, the clipboard is pasted *in replacement* of those items. The selected items are deleted and then the new items are inserted.

We can see this by continuing the above example by pasting the clipboard into the blue drawing layer. The screen shots below show two different cases: on the left we have not selected anything before the **Paste** and on the right we have selected the triangle.

Suppose we have just **Cut** the yellow square. We are about to **Paste** it. On the left, nothing is selected. In the example on the right, the blue triangle has been selected.

Now we **Paste** the clipboard into the blue layer. On the left we see that the square appears in the blue layer (in blue formatting, of course) in addition to whatever is in that layer. In the example on the right where the triangle had been selected, we see that the **Paste** command replaces the selected triangle with the new, blue square. Note that if there had been many objects selected in the blue layer in addition to the triangle, *all* of them would have been deleted before the new, blue square was pasted.

As a conceptual analogy, this is exactly how Windows cut and paste works in standard Windows applications such as Microsoft Word. If we highlight a phrase in Word and then **Cut** it we copy the phrase to the clipboard. If we paste this phrase back into the document what happens depends on whether any text is subsequently highlighted. If no text is highlighted, the phrase that was cut will be pasted back into the document in addition to all existing text. If, on the other hand, we highlight some text and then do a **Paste**, the pasted phrase will replace whatever text was highlighted.

**Paste Append** is like **Paste** except that it will not delete and replace any previously selected objects.

**A Geographic Example**
Suppose we have two drawings showing features in the San Francisco Bay region. The drawing on the left shows features from the hydrography layer of a USGS map. The drawing on the right shows Congressional districts for the 106th Congress as areas. We have selected one of the districts and have used Edit - Copy to copy it to the clipboard.

If we now click on the bay_hydro drawing to switch focus to that drawing and choose Edit - Paste the area object in the clipboard will be pasted into that drawing. We have used the Format toolbar to specify use of yellow color for areas in bay_hydro, the same light yellow color used for areas in the districts map. Pasted objects will take on whatever color is defined for objects of that type in the destination drawing.

Suppose now we select the area object just pasted into the bay_hydro drawing. We open a third drawing, called California, which shows California counties as areas. We select San Mateo county in the California drawing and use Edit - Copy to copy it to the clipboard.
If we now click on bay_hydro again and Paste, the previously selected district object will be deleted and replaced by the San Mateo county object being pasted in from the clipboard.

Notes:

- The illustration above shows the pasted object in light green. When it was first pasted into bay_hydro it appeared in the light yellow color defined for areas in that drawing. We used the Format toolbar to change the color to light green. We did this to visually emphasize the replacement of the district object by the county object.

- When objects are pasted into a destination layer they are selected. This is just like pasting text into Microsoft Word: the pasted text is highlighted after it appears in the document.

A Troubleshooting Example

If we Copy selected objects like those at the left and Paste them into a different drawing and get the result at the right, the problem is that the drawing on the right uses Orthographic projection while the drawing at left uses Geographic Latitude Longitude projection. If a drawing is created when the project pane has the focus, by default it is created using the Orthographic projection. When the objects were pasted into the Orthographic drawing they appeared as they would be shown in that projection.

Situations like the above arise when we selected the objects in the lat-lon drawing, chose Edit - Copy and then clicked on the project pane and chose File - Create - Drawing. At the moment we clicked on the project pane we moved the focus to the project pane and so the new drawing was created in Orthographic projection. What we should have done was choose File - Create - Drawing while the lat-lon drawing was still the active window. In that case, the new drawing would have been created by default to match the drawing that was open and had the focus.

Note that the pasted North and South America objects are correctly seen in default Orthographic projection, which is, after all, a view from space centered on the intersection of the Equator and the Prime Meridian just off the coast of Africa. From that position North and South America appear greatly foreshortened as they are on the edge of the visible part of the Earth. The default Orthographic projection uses a "transparent globe" so that Alaska in the drawing at right is seen through the Earth. See the Projections topics for more information.
We can retrieve the situation by re-projecting the drawing on the right into Geographic Latitude Longitude projection.

Adding Points, Lines and Areas

There are many ways of adding points, lines and areas to drawings in Manifold. This topic explains how to draw these objects free hand using the Tools toolbar for drawings.

To draw new objects begin by clicking on the map layer tab in which the areas are to be created to make it the active layer. New objects are created in the active layer. It is a good idea to create new objects in a new, blank layer so that they may be easily moved up and down in the layer stack. New objects will be created using whatever formatting is specified for that drawing or map layer.

To add points to a drawing:

1. Click the Insert Point button
2. Click anywhere you wish a point to be created. Points will be created in the active layer/drawing.
3. When finished inserting new points, click out the Insert Point button.
4. If desired, use the Formatting Toolbar to change the formatting of the points.

Very handy: When adding points to a drawing we will often use Instant Data to also add values to a data field.

To add lines to a drawing:

1. Click the Insert Line button
2. Click anywhere you wish the line to begin. Lines will be created in the active layer/drawing.
3. Continue clicking to grow the line with each click to that next position.
4. Right click to finish the line. The line will end at the last left-click position.
5. Click anywhere to begin a new line, and repeat steps 4 and 5 to make another line.
6. When finished inserting new lines, click out the Insert Line button.
7. If desired, use the Formatting Toolbar to change the formatting of the lines.

To add areas to a drawing:

1. Click the Insert Area button
2. Click anywhere you wish the area to begin. Areas will be created in the active layer/drawing.
3. Continue clicking to grow the area with each click to that next position. The area will always grow so that the preview outline of the area is a closed figure.
4. Right click to finish the area. The area will end at the last left-click position.
5. Click anywhere to begin a new area, and repeat steps 4 and 5 to make another area.
6. When finished inserting new areas, click out the Insert Area button.
7. If desired, use the Formatting Toolbar to change the formatting of the areas.

Example: Add an Area

Click on the beginning position of the area and then click at the first position where it is to change shape. Keep clicking about the periphery of the area. As we move the mouse the boundary preview figure will "rubber band" to the current mouse position from the starting point. The rubber band is a preview of what the area will look like if the last left click is made at the current mouse position.
At the end of the desired figure, we would click once to mark the last position and then right click the mouse to create the area.

The area will be drawn within the figure.

Creating Complex Areas

We may wish to create areas that contain "holes" or which consist of several non-contiguous pieces ("islands"). Such areas are called branched or complex areas. To create such areas in Manifold, use a CTRL-click between several sequences of boundary line clicks. Suppose in the example above we wished to create a pentagonal area that contained a pentagonal hole:
At the end of clicking our way around the outer periphery, instead of right clicking we would CTRL-click. We would then click once at a new starting point and click to the first position to change direction. Just as before, as we click our way around the periphery of the "hole" the boundary preview line will "rubber band" from the starting position to the current mouse position.

At the last position we would click once to mark the last position and then right click to end the figure.
Manifold knows that after the CTRL click we have drawn a figure within a figure, so it knows this is to be a hole and creates the complex area accordingly. Had we drawn the second figure outside the first figure, it would have been drawn as an “island.” In fact, we can draw complex overlapping figures by CTRL clicking between them to create new areas of great topological complexity. Note: to keep things reasonably obvious it is usually best to create complex areas with holes or islands but not with complex internal overlaps.

CTRL click also works during the creation of lines. In such cases, a group of what appear to be separate lines will all be created as a single line object. This capability should only be used by experts (and sparingly, at that) since it quite easily leads to confusion.

**Insert Line Sequence**

Curved lines in Manifold are really *polylines*: what appears to be a curve is really one line object that is a sequence of straight portions between coordinates drawn in a “connect the coordinates” fashion.

At times we wish to create a sequence of straight line segments where each straight segment is a separate line object. **Insert Line Sequence** does this. It works just like **Insert Line**, except that it creates a new line object between each click.

Creating a line using **Insert Line** with a few clicks and a right click will result in a single line object.

Using **Insert Line Sequence** with the same clicks and a right click will result in three line objects (the middle of which has been moved to a new layer and colored orange to show it is a different object from the other two straight segments).

**Creating Straight Lines between Points**

Either **Insert Line** or **Insert Line Sequence** may be used to rapidly create a series of straight lines between points.

Suppose we need to create a series of straight lines between the points above. Begin by setting **Snap to Points** so that the mouse cursor will snap to the nearest point.
Make each line by clicking on the first point, clicking on the second point and then right clicking. The resultant "Click, click, right-click" pattern is very fast.

**Status Bar Reports**

When moving the mouse in creating a vector shape the status bar reports the length and angular bearing of the current segment as well as the location of the mouse cursor. Pressing **CTRL** will convert the report to use of alternate units (English or Metric) and will also enable use of ellipsoidal trigonometric calculations for the report.

For example, when creating a line as seen above...

![Status Bar Report Example](image)

...the status bar will report the mouse cursor location followed by **L:** length and **A:** angular bearing. The mouse cursor is located 75.1393 meters from the beginning of the segment at an angle of 43.88 degrees. The mouse cursor is also located at the latitude and longitude indicated.

**Notes**

Using Snap is a great way to guarantee positional accuracy when creating objects free hand.

By default, the **Tools - Options** parameter **Automatically Set Insert Mode** is checked ON. Automatically Set Insert Mode will automatically switch shape modes whenever an insert shape tool button is pressed to that the shape mode that is typically used with that tool. For example, when Automatically Set Insert Mode is ON, pressing **Insert Line** will automatically push in the **Create Lines** mode button and push out the **Create Areas** and **Create Points** buttons. This default choice may be overridden by choosing whatever combination of shape modes is desired after choosing the tool.

In another example, when Automatically Set Insert Mode is checked ON the **Insert Areas** and **Insert Box**, **Circle**, and **Ellipse** commands will create areas only. To create lines and points as well simply push IN the **Create Lines** or **Create Points** buttons after choosing these commands.

• See the Autocomplete with ALT for an important shortcut in the **Insert Area** and **Insert Line** commands when creating areas or lines that fit exactly into existing areas or lines.

• See the Adding Shapes topic to learn to use **shape mode** buttons to automatically create objects as any combination of areas, lines and points.

• See the Dialog Mode and Visual Tools topic for a parameter or value oriented way of creating objects.
Adding Shapes

The commands in the Tools toolbar are used to insert new points, lines and areas into a drawing. Objects may be created free hand or pre-built shapes may be inserted.

- To create areas, lines or points, simply choose the appropriate Insert command and draw the desired shape using left mouse clicks. A right mouse click indicates you are finished and the shape is to be created.
- To create a pre-built shape, choose the shape command desired and then click and drag open a mouse box showing the placement and size of the desired shape.

Shape mode buttons allow automatic creation of the shapes using areas, lines, points or any combination of the three.

See the Adding Points, Lines and Areas topic for additional details and examples. See the Instant Data topic to learn how to quickly add data attributes when creating an object.

- **Insert Area**
  Draw areas within the mouse cursor region defined by a series of clicks followed by a right click.

- **Insert Freeform Area**
  Draw areas within the mouse cursor region defined by clicking and dragging, followed by a right click.

- **Insert Freeform Line**
  Draw lines as defined by clicking and dragging, followed by a right click.

- **Insert Line**
  Draw lines as defined by a series of clicks followed by a right click.

- **Insert Line Sequence**
  Draw lines as a sequence of separate lines.

- **Insert Point**
  Draw points - click to create a point.

- **Insert Box**
  Draw a rectangular box shape with a click and a drag.

- **Insert Box on Center**
  Draw a rectangular box shape centered on initial mouse click.

- **Insert Circle**
  Draw a circle with a click and a drag.

- **Insert Circle on Center**
  Draw a circle centered on initial mouse click.

- **Insert Ellipse**
  Draw an ellipse with a click and a drag.

- **Insert Ellipse on Center**
  Draw an ellipse centered on initial mouse click.

- **Insert Geographic Circle**
  Draw a shape centered on the initial mouse click that forms a circle on the Earth. That is, each location on the shape will be the same distance from the center point. May appear to be a non-circular shape depending on the projection of the drawing.

- **Create Areas**
  Create areas when drawing shapes.

- **Create Lines**
  Create lines when drawing shapes.

- **Create Points**
  Create points when drawing shapes.
Shape Modes

The **shape mode** buttons specify what types of objects should be created when a shape is drawn. Push in the mode button for the type of object desired. For example, if both the **Area** and the **Point** buttons are pushed in, then any circles or other shapes drawn will be created using both area objects as well as points at the coordinates defining the shape. This is an extremely useful effect for simultaneously creating area and line objects for complex shapes.

The following examples create the same star shape using **Insert Area** but with different combinations of shape mode buttons:

- **Areas**
- **Lines**
- **Points**
- **Lines and Points**
- **Areas and Lines**
- **Areas and Points**
- **Areas, Lines and Points**
Automatic Shape Modes

By default, the Tools - Options parameter Automatically Set Insert Mode is checked ON. Automatically Set Insert Mode will automatically switch shape modes whenever an insert shape tool button is pressed to that the shape mode that is typically used with that tool. For example, when Automatically Set Insert Mode is ON, pressing Insert Line will automatically push in the Create Lines mode button and push out the Create Areas and Create Points buttons. This default choice may be overridden by choosing whatever combination of shape modes is desired after choosing the tool.

In another example, when Automatically Set Insert Mode the Insert Areas and Insert Box, Circle, and Ellipse commands will create areas only. To create lines and points as well simply push in the Create Lines or Create Points buttons after choosing these commands.

Shapes, Geographic Circles and Coordinate Systems

With the exception of the Insert Geographic Circle command, all shapes are drawn using the local coordinate system of the drawing. That means that when we insert a circle using the Insert Circle tool a circle is drawn on the XY plane of whatever coordinate system is in use. The result is exactly the same as if we drew a circle on a paper map showing the same region with the same projection.

In many cases, if we are viewing a reasonably small region and the projection in use preserves lengths and other geographic characteristics (and projections are normally chosen so as to preserve such characteristics), drawing a circle in that region will be very close to the shape of a true circle drawn on the Earth's surface at that region. However, because it is not possible to represent the three dimensional, ellipsoidal shape of the Earth in a two dimensional plane (such as a paper map or a computer monitor) without distortion if we draw a circle on a projected map showing a large region of the Earth the figure we draw will not form an actual circle on the surface of the Earth.

To draw a circle that is guaranteed to be a circle no matter what projection is in use we should use the Insert Geographic Circle command. This command allows us to draw a circle of given Earth radius centered on a specified location. The actual shape created in the projected view may be considerably different than a circle depending upon the distortion introduced by the projection, but the object will be a true circle on the Earth's surface.

Example

Consider a map of the Earth drawn in Sinusoidal projection.

Regions far from the center of the map are significantly distorted. In the above illustration we've added a point on the Southwest coast of Australia.

Using Snap to Point we use the Insert Geographic Circle tool to create a circle centered on that point.
The **Geographic Circle** dialog will open already loaded with the coordinates of the central point in the local coordinate system. We choose a radius of 1000 miles and set the number of divisions to 64 to create a nice, smooth object. Press **OK**.

The result is that a very non-circular object appears in the drawing. However, the object has been calculated so that if we looked at it from directly overhead, that is, with none of the distortion introduced by the Sinusoidal projection, it would be a circle.

We can see that is the case by re-projecting the map into Orthographic projection centered on the point that was the center for the geographic circle.

(We can find the latitude / longitude of the point by snapping the cursor to the point and reading the lat/lon value on the status bar. For a cleaner map image in the illustration above, we’ve also re-projected the drawings used and clipped coordinates.)

The Orthographic projection shows us what we would see on the Earth's surface if we were hovering in space over the central point. Clearly, the object created is indeed a circle on the Earth.
To see how the Insert Geographic Circle command differs from the Insert Circle command, we can use the Insert Circle command to create a freehand circle above and to the right of the geographic circle.

Note that in the projected view, the circle we have created appears to be a circle. However, it is just as if we had drawn a circle in that location on a paper map that used the Orthographic projection. The region of the Earth that is covered by a circular figure drawn on such a projection map is not a geographic circle.

If we re-project the map view to use an Orthographic projection centered upon the approximate center of the new "circle" we drew, we can see that the object we drew does not cover a circular region of the Earth.

Tech Tip

To avoid confusion, it is best to use Insert Geographic Circle with projected drawings and maps. If used with latitude / longitude coordinate systems the results can be confusing because degrees are different sized in different parts of the Earth.

See Also

- See the Snap To topic for information on using Snap to snap the cursor to exact locations.
• See the Autocomplete with ALT for an important shortcut in the **Insert Area** and **Insert Line** commands when creating areas or lines that fit exactly into existing areas or lines.
• See the Dialog Mode and Visual Tools topic for a parameter or value oriented way of creating objects.
Instant Data

**Instant Data** make repetitive data entry a snap in drawing windows or in drawing layers in map windows. This is a mode command. It is either checked or not checked in the **Edit** menu. When checked, all subsequent object creation commands, like **Insert Point**, will call up the **Object Fields** dialog, ready for action.

When an object is created, the **Object Fields** dialog in **Instant Data** mode allows us to enter values rapidly into desired fields. The dialog will be pre-loaded with most recently used data and the cursor will already be in editing mode within the most recently edited field. This makes it easy to rapidly enter repetitive values when adding lots of points or other objects to a drawing. For example, if we are using the GPS Console to automatically fetch location data when adding information on, say, fire hydrants or other assets in a town, **Instant Data** makes it easy to rapidly add other annotations.

![Object Fields dialog](image)

**To use Instant Data**

1. Open a drawing window or click on a drawing layer in a map to make it active.
2. Click **Instant Data** in the **Edit** menu to check it ON.
3. Choose a tool to insert the objects you want, for example, **Insert Point**.
4. Click the location where you wish to insert a point. The **Object Fields** dialog will open.
5. Double-click into the value box for which you want to edit data and enter the data.
6. Double-click into any other value box for which you want to edit data and enter the data.
7. When finished adding data for all fields, press **Enter** or press **OK**.
8. Continue adding objects. Each time the **Instant Data** dialog will appear preloaded with the cursor ready to edit within the last value added. Change the values as desired. If for some objects you wish to add a value in a different field, double click into the value for that field and edit it.
9. When finished using **Instant Data**, click it off in the **Edit** menu.

Use **Instant Data** when you must create many objects and wish to add a value for each. For example, suppose we need to add many points to a map and we wish to enter a name for each in a field called **Name**. Check **Edit - Instant Data** and then we can use **Insert Point** to click where we want each point. Enter the name, hit **Enter** and click on the next point. **Instant Data** thus allows a very rapid repetitive data-entry rhythm: click a point - enter a value, click a point - enter a value, and so on.

**Important:** Please note that because **Instant Data** is used to load values into a database field for newly-created objects the **Object Fields** dialog only appears when there are fields defined in the drawing’s table. If we create a new, blank drawing the **Object Fields** dialog will not be available until we add some fields to the drawing’s table.

**Instant Data** remembers the last value used for each drawing. If we turn on **Instant Data** and then add points to different drawing (say, by clicking into different drawing windows or by changing the active layer in a map), the **Object Fields** dialog will be loaded with the last field used and last value used for each drawing.
Using Instant Data when Several Objects are Created

Manifold commands can be used to create many objects at once. For example, if the Insert Areas tool is used with Create Areas, Create Lines, and Create Points modes on the area with a line object at the boundary and point objects at the coordinates that define the area.

When several objects at once are created, the instant data dialog tries to identify the “main” object for which a data field value is to be assigned, using the order of precedence: areas, lines and finally points. For example, when creating an area with a boundary line and points at the defining coordinates the area will be taken as the "main" object and the instant data dialog will set a data field value for the area.

If no object can be obviously identified as the "main" object the instant data dialog will not launch even if Edit - Instant Data is checked. For example, we can use the Insert Box tool with Insert Points mode set ON to create four points at the corners of a box. There is nothing to distinguish any of the four points as being more "main" than any of the other points, so the instant data dialog will not launch in this case.

Example

Suppose we are creating a map that shows the location of fire hydrants in our town. We have a drawing that overlays a high-resolution aerial photograph in a map. Using Insert Point we will click on each location that has a hydrant to create a point at that location. Our drawing's table has fields called Asset and ID Number we can use to identify each point. We would like each point to be created with Hydrant in the Asset field and a varying identification number in the ID Number field.

This is easy. We set Instant Data on and then click to insert the first point.

Since this is the first point to be created in the drawing, the Object Fields dialog launches with no values, but with the cursor ready to enter a value for the Asset field. We enter “Hydrant” and then double-click into the Value field next to the ID Number field.
We now enter the desired value for the **ID Number** field and then press **Enter**. We've just created a point with the desired values.

We can now click into the drawing once more to create another point at the next hydrant location using **Insert Point**.

Once again the **Object Fields** dialog launches, but this time the fields are pre-loaded with default values (the last used) and the cursor is already positioned in editing mode within the **Value** box for the **ID Number** field. We can rapidly change the ID number for this hydrant and press **Enter** to create this next point.

Obviously, if there are many more fields than just one or two that must be filled in with default values when manually adding objects to drawings, **Instant Data** can save a lot of time.

**Note:** When finished using **Instant Data**, remember to take a moment to uncheck **Edit - Instant Data**

**See Also**

See the Add Points with Instant Data example topic for an example of adding points, using **Instant Data** and moving points by editing intrinsic fields.
Editing Objects

Objects in drawings (areas, lines or points) may be edited in several ways:

- Use of Interactive Editing to interactively move or reshape objects by interactive dragging of coordinate locations as discussed below.
- Use of the Edit Toolbar during interactive editing. The edit toolbar provides powerful commands that should be mastered for rapid interactive editing. If not already displayed, the edit toolbar will appear when an object is selected for editing with a CTRL-ALT clicking the object.
- Use the Object Coordinates dialog to manually edit the coordinate values that define the object.
- Edit the coordinates of objects (usually points) by changing their values using intrinsic fields in a table.
- Changing objects using the Transform toolbar or commands such as the Dissolve command.
- See the Dialog Mode and Visual Tools topic for information on using dialog mode when creating new objects.

Objects are Defined by their Coordinates

Objects in drawings are defined by the coordinates necessary to draw them. Coordinates are simply the numbers for each X and Y position that defines the object.

Consider a drawing that contains an area, a line and three points.

The objects are defined by the coordinate numbers that are used to draw them in a "connect the dots" fashion. The area, for example, is nothing more than a list of five coordinates:

3 7
2 9
3 10
5 9
5 8
Through various clever means Manifold knows how to interpret the above list of coordinates as an area and how to draw the area knowing correctly what is the inside and what is the outside of the area.

We can see the coordinate numbers that make up an object at any time using the Object Coordinates dialog. To use this dialog, right click onto the object in a drawing window and choose Coordinates from the context menu. This launches the Object Coordinates dialog that lists all of the coordinates that define that object.

Although it is not the user-friendliest way of editing objects, if desired we can change the shape of an object by editing the coordinate numbers that define it. To edit an object by changing the coordinates manually, double click into any coordinate value to change it. See the Object Coordinates topic for additional information on this dialog.

Points are easier to edit via coordinates than lines or areas because points are defined by a single coordinate pair. It is conceptually simpler (as well as less keyboarding) to change the location of a point by changing the latitude and longitude of the point than it is to edit a long series of coordinates for a line or an area. We can move points by changing the latitude and longitude of their location as shown in their intrinsic fields in a table. We can move lines and areas by changing their latitude and longitude intrinsic field values in a table; however, doing so moves the entire line or area by moving its centroid and does not reshape the object. See Editing Intrinsic Fields in Tables.

**Interactive Editing**

**Smart Mouse** touch selection is used to select objects for editing. An object selected with smart mouse selection will appear with edit handles at each coordinate position that can be used to move or reshape the object. An object chosen for editing is also called the **primary selected object**.

To select an object as the primary selected object for editing, exit all command modes so that the mouse cursor is in the default arrow form and then CTRL-ALT click on the object to be edited. Edit handles will appear on the selected object at the location of each coordinate that defines the object. We can then move these handles about to change the shape of the object. This is a lot easier than editing coordinate numbers manually via the Object Coordinates dialog.

If we change our minds and we don’t want an object to be the primary selected object for editing, we can deselect it by CTRL clicking on it. A CTRL click on an object will toggle the selection status of that object (selects it or deselects it) without changing the selection status of any other object.

**Keyboard Modifiers with Smart Mouse Touch Selection**

Because a selection may already exist in the drawing when we wish to select an object for editing, smart mouse selection uses keyboard modifiers to allow a richer set of commands.

- **Click** Equivalent to Select Touch in Replace mode. Click on an object to select it. All other objects are deselected.
  
  Clicking into an empty part of the drawing deselects all objects (with confirmation dialog).

- **CTRL-ALT-Click** Select an object for editing. Click on an object to select it as the primary selected object.

- **CTRL** Invert the selection state of the object without changing the selection state of any other object. Equivalent to Invert mode.

- **SHIFT** Select the object if it is not yet selected. Does not change the selection state of other objects. Equivalent to Add mode.

**Editing Commands**

The primary selected object may be moved or changed in shape by clicking and dragging its editing handles:

- **CTRL-click and drag** CTRL-click an editing handle and drag to move the entire object.
SHIFT   Hold the SHIFT key down while clicking an editing handle and dragging to move the entire current selection, which includes the primary selected object as well as all other selected objects in the active drawing or drawing layer.

ALT-SHIFT The ALT key extends the action of the SHIFT click and drag to all visible layers. Moves all selected objects in all visible layers.

Click and drag Click an editing handle and drag to move just that handle and so reshape the object.

CTRL-SHIFT Holding down the SHIFT key while using CTRL-click to move an ending handle will move only that particular branch in multi-branched objects.

Right-click Right-click an editing handle to call up a context menu of additional editing choices. These will allow deletion of coordinates, for example, via the Coordinate sub-menu.

Right-click a segment between editing handles to call up a context menu allowing choices such as adding a new editing handle in that segment.

Editing works by first clicking on the object to make it the primary selected object. Edit handles will appear at the coordinates that define the object. One may then move the entire object or move the edit handles to change its shape. Edit handles may be deleted or added via the commands in the right click context menu. In the case of branched objects (which include islands or holes in area objects), one may delete branches or move them about.

Note that ALT-SHIFT editing will apply to all objects in visible layers, whether or not those objects are visible at that moment due to Zoom range or Layer Opacity settings. It is possible to have a layer be enabled for display (that is, the layer tab was not clicked off) but the objects within that layer not be visible because the layer's Opacity was set to zero percent. Likewise, a layer's objects might not be visible because of a Zoom range setting. In both cases, the ALT-SHIFT editing will still apply to any such invisible objects.

Editing Example

We begin all smart mouse selection and editing by clicking out any mouse command mode. This restores the mouse to the default arrow cursor.

To edit an object we CTRL-ALT-click on it. In this example we CTRL-ALT-click on a triangular area.

The triangular area becomes selected and shows edit handles at the coordinate positions that define the area. This is a simple area that is defined by only three coordinates. A more complex area would show an edit handle at each coordinate that defines it. Larger areas in geographic drawings are often so complex and will have so many edit handles appear that they will blend together in what might appear, at first glance, to be a very wide border.
To move the object, we **CTRL**-click and keep pressing on any edit handle. Note that the entire outline of the area changes color to show the entire object can be moved.

Without releasing the mouse button, we drag the object to whatever new place is desired. A preview outline shows where the drawing will go.

When we release the mouse button at the new position the object moves to that location.

We can edit the shape of the object by clicking and dragging the edit handles. If we click on the edit handle as shown above the area borders adjacent to the edit handle change color to show that these borders will be altered by moving the edit handle.

Dragging the mouse button shows a preview of how the shape will be altered when this edit handle is moved.

Releasing the mouse button causes the area to change shape to the new position of the edit handle.
To deselect the object, we can either **CTRL**-click on the object to toggle the selection state off, or we can simply click anywhere in "empty" space in the drawing to deselect all objects.

The result is a reshaped object in a new location.

**Selecting Boundary Lines**

Beginners at GIS often confuse the idea of an area object with the idea of a region enclosed by a line object. Please read the Drawings topic to clear up this confusion if you have not already done so.

When using smart mouse selection and editing we must click on the object that is to be edited. Suppose we have a line that forms a closed figure. If we wanted to select that line for editing we must click on the line itself and not simply click within the enclosed region as if it were an area object.

Clicking within the enclosed region has no effect except deselecting all items (if we confirm the desired deselection in the dialog that pops up).

To select the line, we must click on the line itself.
This results in the selection of the line object for editing.

Errors of this nature may be avoided by working with the **Background** off in the layers pane so it is more clear that there are no objects inside lines that happen to form enclosed regions.

**Selecting for Editing**

We may wish to edit an object within a selection without changing the selection. We can choose objects for editing using smart mouse selection with a **CTRL-ALT** click without changing the selection state of other objects. Suppose, for example, we have made a selection in a drawing showing Denmark.

**CTRL-ALT** click on an object to select it for editing as the primary selected object. Here we **CTRL-ALT** click on the island of Langeland to select it for editing.

When it is selected for editing, edit handles will appear at all coordinates that define the object. Note that the selection state of all other objects has not been changed.

**CTRL-ALT** click on a different object to select it for editing. Here we **CTRL-ALT** click on Falster island.
CTRL-ALT clicking on Falster selected it for editing while leaving Langeland selected along with the other objects.

**Context Menu Editing Commands**

Right clicking on an object selected for editing calls a context menu that contains advanced editing commands. When right clicking on an editing handle, the context menu will also include editing commands for that coordinate.

**General** (Right clicking onto object)

- **Duplicate**
  Duplicate the object. It is wise to immediately move the new object while it is selected. This avoids creating coincident objects that might later cause confusion.

- **Orthogonalize**
  Move coordinates to orthogonal grid positions. Used to trim insignificant digits.

- **Segmentize**
  Add redundant coordinates to increase the number of coordinates used to define the object. See the Segmentization topic for discussion.

- **Simplify**
  Remove coordinates that define the object to simplify the shape of the object.

- **Center**
  Pan the view to center this object in the window.

- **Zoom**
  Zoom to fit this object.

**Coordinates**

Launches the Object Coordinates dialog to allow direct editing of the coordinates that comprise the object. Right clicking onto an edit handle and choosing **Coordinates** will launch the Object Coordinates dialog with that particular edit handle coordinate highlighted.

**Fields**

Launches the Object Fields dialog that shows any table fields associated with this object.

**Coordinate** (Right clicking onto an edit handle)

- **Delete**
  Delete this coordinate. It is not possible to delete the last coordinate necessary to define a point (one coordinate) a line (two coordinates) or an area (three coordinates).

- **Delete / Split Branch**
  Delete this coordinate splitting the branch it is in into two branches. Only available when editing a line object. It is not possible to split the branch by deleting its first or last coordinate, the coordinate after the first coordinate or the coordinate preceding the last coordinate.

- **Duplicate**
  Duplicate this coordinate. It is wise to immediately move the new coordinate/edit handle to avoid confusion that might be caused by coincident (redundant) coordinates.

**Coordinate** (Right clicking onto a segment between edit handles)

- **Add**
  Add a new edit handle (coordinate) at the location on the
segment that was right clicked. Such a click will not likely be exactly on the line segment, as a click reasonably near a selected object will be interpreted as involving that line even if the click was not exactly on the line segment.

**Add on Segment**  Add a new coordinate to the object exactly on the line segment nearest to the click.

**Add Mid-Segment**  Add a new coordinate to the object exactly in the middle of the line segment nearest to the click.

---

**Branch**  (Right clicking onto a branch or edit handle)

**Delete**  Delete this branch. It is not possible to delete the last branch of an object.

**Duplicate**  Duplicate this branch. It is wise to immediately move the new branch to avoid creating coincident branches that might later cause confusion.

**Split**  Enabled only when right clicking onto a coordinate of a line object. Splits the line into two branches at this edit handle. This is an expert-level command that is not the same as splitting the line into two line objects at this position.

---

**Segment**  (Right clicking onto a segment between edit handles)

**Delete**  Delete this segment. It is not possible to delete one of the last two segments of a line branch or one of the last three segments of an area branch.

**Delete / Split Branch**  Delete this segment splitting the branch it is in into two branches. Only available when editing a line object. It is not possible to split the branch by deleting its first or last segment.

---

The above context menu commands should be used in combination with the Edit Toolbar interactive commands.

**Changing the Shape of Objects**

We can change the shape of objects by moving existing editing handles, by deleting editing handles or by adding new editing handles, which may then be moved to new positions.

Suppose we would like to change the shape of a selected area. We would like to add an editing handle, so we right click at the location in the segment where we would like to add the handle.
We choose **Coordinate - Add** from the context menu to add a new coordinate and editing handle to the clicked segment at the place clicked.

We can now click and drag to move this new editing handle.

For example we can drag it out to the right. A preview line shows the new shape of the area as we drag.

When we release the mouse button at the end of the drag the area changes shape to fit the new location of the edit handle.

To delete a coordinate and associated edit handle we right click on the handle and choose **Coordinate - Delete**.
This deletes the coordinate at that position. The area will immediately change shape to the shape defined by the remaining coordinates.

**Editing Branched Objects**

This is an advanced topic. A **branched** object is one that includes islands or holes as one object. What appear to be separate objects are really the same object but implemented using a complex internal definition comprised of several sequences of defining coordinates all concatenated into one object. Each sequence of coordinates is called a branch.

The usual case is a state or some other geographic region that includes islands. Instead of each island being a separate object, they are all formed into a single area object.

When selecting objects for editing it is easy to see if what appear to be separate objects are in fact a single, branched object. CTRL-ALT clicking on an object in smart mouse selection will cause all the branches to appear with edit handles if they are all different branches of the same object.

In this example, we've CTRL-ALT clicked on one of the three islands and all have appeared with edit handles. This is a certain indication they are all just branches of a single area object.

Right clicking on one of the branches and choosing **Branch - Delete** from the context menu will delete the branch.
The other two branches will be left unchanged.

The example above shows use an area where multiple branches are used to create islands. Multiple branches are also used to create "holes" within areas. Clicking and dragging an edit handle will move the entire object, including all branches. This default behavior assures that all holes in areas that use branches to define internal voids will be correctly moved.

We can use a CTRL-SHIFT click on an editing handle and drag to move individual branches, whether they are used to represent islands or holes.

Suppose we have a rectangular area with an internal, triangular hole. The hole is a separate branch from the outer border of the area.

We can CTRL-ALT click on the area to make it the primary selected item so that edit handles appear. We can then CTRL-SHIFT click and drag on an edit handle of the internal hole to move just that branch.

While dragging, a preview will show us how the branch is being moved.

When we release the mouse the branch will move to the new position. In this case, we have moved the position of the hole in the area.

Note that we could use the same CTRL-SHIFT-click and drag on an edit handle to move the relative positions of the "islands" in the previous example.

Moving Objects by Changing Intrinsic Fields

Manifold tables can show intrinsic fields that are computed from the object, such as the position of the center of the object. See the Editing Intrinsic Fields in Tables topic for a discussion of how we can move objects by editing their locations as they appear in intrinsic fields in a table.
Keyboard Zoom Commands during Selection and Editing

When making selections or editing objects (such as inserting areas using the Autocomplete feature) we will often want to zoom in or out in the middle of a selection or editing command. Use the + and - keys on the keyboard to do so. Usually the + and - keys in the numeric keypad are used.

+  "Plus" key: Zoom in at the current tool position.
-  "Minus" key: Zoom out at the current tool position.

The current tool position is the position of the mouse at the time the + or - key is pressed. When editing, using these keys allows us to easily zoom into a desired location, make a few precise clicks and then zoom back out and proceed at the usual scale.

Notes

See the Selection in Drawings topic for additional information on smart mouse selection.

This topic discusses interactive editing of objects using the mouse. However, as a reminder for the reader we should note the following when using non-interactive editing methods such as transform operators or menu commands.

Many editing / transformation operations in drawings (see the Transform Toolbar - Drawings and Drawings - Dissolve topics, for example) will create new objects from existing objects. When new objects are created from existing ones the system must know how to transfer data attribute fields from the existing objects into the new objects. The Transfer Rules dialog in tables sets forth the rules to be used for each particular column.

**Editing with Snap**

The Snap To cursor modes are very important when editing objects. Before proceeding, please review the Snap To and Editing Objects topics.

Beginners should practice editing using the interactive commands described in Editing Objects until they have perfect fluency without any Snap modes set. Snap modes can be confusing to beginners because the action of the command takes place at the snap cursor and not at the mouse. It therefore is imperative that the new user learns basic editing motions before beginning use of Snap.

When editing with Snap we will often wish to use a mix of mouse commands so that sometimes Snap is on and sometimes Snap is off. At times we will want to toggle Snap on and off in the middle of a mouse motion.

To temporarily turn off Snap we use the space bar. Pressing the space bar will turn Snap off even in the middle of a mouse motion. Press the space bar again to turn Snap back on. To edit effectively with Snap we must therefore practice so that use of the space bar becomes second nature. Beginners may be confused until they have enough experience to use the space bar correctly without having to think about it. This is a simple neuromuscular skill that is best learned through repetition.

**Note:** The snap toolbar is turned off by default. To turn it on, open a component that uses the snap toolbar (such as a drawing), choose Tools - Customize and check the box for the snap toolbar.

**Example: Reshaping an Area to match Another Area**

We first consider an example using Snap that does not use the space bar. Suppose we have two rectangular areas near each other in a drawing:

![Example 1](image1)

We would like to reshape the area on the left so that along its right edge it perfectly matches the area on the right:

![Example 2](image2)

We can accomplish this with simple interactive editing, and by setting Snap to Areas. This snap mode moves the cursor only between coordinates that define areas.
Using smart mouse editing we **CTRL-ALT** click on the rectangle on the left to select it as the primary selected object. (See Smart Mouse Selection for notes on "smart mouse" moves.) Edit handles will appear at all coordinates that define the area. Note that as we bring the mouse near one of the coordinates that define either area the snap cursor will jump to that coordinate.

We’ll move the lower corner first. To move it, we click the edit handle and drag down and to the right. It’s easy to click exactly on the edit handle because the **Snap to Areas** mode jumps the cursor directly onto edit handles.

As we continue to drag down near the corner of the second area, the secondary snap cursor (the box) jumps to that coordinate.

When we release the mouse button, the area will be reshaped to adjust to the new position of the edit handle.
We repeat the process with the upper edit handle by clicking on it and dragging to the right.

As the mouse nears the other area the secondary snap cursor will jump to the coordinate of the corner.

When we release the mouse button the area adjusts to the new position of the edit handle.

If we deselect the area we can see we have achieved our objective.

**Note:** Clicking and dragging an edit handle moves just that handle to reshape the object. CTRL-clicking and dragging an edit handle will move the entire object.

**Example: Moving Points with Snap**

In the example above we did not use the space bar to toggle Snap off temporarily. We did not need to do so because we were editing areas and it was convenient that Snap to Areas jumped the cursor between coordinates (and thus edit handles) in either of the areas involved. In many situations we will need to temporarily turn Snap off during an editing command.
Suppose we have a drawing with some points near an area. Perhaps the area represents a coastline. We would like to move the middle point onto the coastline using **Snap** to assure that it is located precisely on the coastline.

If we CTRL-ALT click on the area object to select it for editing using smart mouse selection, we can see edit handles appear at the coordinates that define the area. We can then **CTRL** click the area to turn off selection for editing.

If we set **Snap to Areas** the snap cursor will jump between these coordinates.

With **Snap to Areas** set, no matter where we move the mouse the snap cursor will move only between coordinates in the area.

To temporarily turn **Snap** off, we press the space bar. For example, to select the middle point for editing using smart mouse selection we can press the space bar and then click the point. The space bar temporarily turns off **Snap** so the mouse can click on the point.
To move the point, after pressing the space bar we can click onto the point and drag it towards the desired location. The magenta snap cursor in the illustration shows the snap to position before we pressed the space bar. The secondary box cursor shows the destination of the edit move.

With snap temporarily turned off, the secondary box cursor moves with the mouse.

At any time we can press the space bar again to turn snap back on. If we do so, the box cursor will jump between only allowed Snap to Areas coordinates. If desired, while dragging we can press the space bar several times to turn snap off and on again and so cause the box cursor to jump back and forth between the mouse cursor and allowed Snap locations. As long as we do not release the mouse button we can go back and forth as many times as we like.

To move the point to the location denoted by the original snap cursor, after pressing the space bar a second time to turn snap back on we can drag near that location. The box cursor will Snap to that location.
When we release the mouse button to end the dragging motion the point moves to the new location.

If we deselect it we can see it is now in a new place.

**Snap Tolerance**

The **Snap Tolerance** parameter may be optionally specified in the Tool Properties pane to control how close the mouse must be to a snap item before a snap mode takes effect.

When a snap mode is on, the **Snap Tolerance** setting gives the distance in screen pixels or in physical units within which the cursor must be to a given snap item (such as a line when snapping to lines) before the cursor snaps to that item.

When the cursor is outside the snap tolerance range, snaps are not effective. Setting a small snap tolerance is therefore a good way of retaining the benefits of snap modes without having the snap cursor jump about in a disconcerting way if the mouse is nowhere near a snappable item.

**Layer Snap Restrictions**

Using Layer Restrictions a map layer can be made non-snappable. When a layer is so restricted, any snap modes will ignore items in that layer.

**Edit - Snap To**
Autocomplete with ALT

When editing maps we often would like to create a new area that fits exactly into an existing area. Manifold provides an autocomplete capability within the Insert Area and Insert Line tool to make this easy. When Snap to mode and an Insert Area or Insert Line command is operational, pressing the ALT key will cause Manifold to autocomplete the area or line between the last clicked coordinate and the current snapped cursor position.

To create an area using autocomplete to follow an existing area:

1. Engage Snap to Areas.
2. Choose the Insert Area command.
3. Click on the location where the area is to begin.
4. Holding the ALT key down, click on the location where the area is to end.
5. Right-click to create the area.

Autocompletion using the ALT key requires a small amount of manual dexterity that comes with practise. Practise creating areas in this way until the motion is automatic.

Example

We would like to create a new area in the bay shown above. The new area must match exactly the area surrounding it with no overlaps and no gaps.

We begin by engaging Snap to Areas. The cursor will now move only between the nearest coordinates that define an area.

Choose the Insert Area command. To create an area with this command we left-click onto the coordinates we want to define the area and then we right-click to create the area.

We move the cursor near to the starting coordinate of the new area. The Snap mode jumps the cursor directly to the nearest coordinate of the existing area. We click to mark that coordinate as the starting coordinate for our area.
If desired, we could move the mouse over all of the coordinates in the existing area and click on each. The **Snap** mode will assure that any coordinates we click will be coordinates in the existing area. However, it is very tedious to click on all of the coordinates that define the edge of a complex area without missing a few. Missing any coordinates will result in overlaps or gaps.

If **Snap to Areas** is on, pressing the **ALT** key during the **Insert Area** command instructs Manifold to **autocomplete** the area between the last-clicked point and the current **Snap to** cursor position. All of the coordinates in between will be chosen for the new area. Autocompletion is indicated by a contrasting tracking/marquee line following the edge of the existing area.

As long as we hold the **ALT** key down, the autocompleted edge will be shown in black between the initial point and the current mouse position.

At any time we can lift or hold down the **ALT** key. Lifting it drops the **Insert Area** command back into its default mode, where a straight line edge would be created between the previously clicked coordinate and the current mouse coordinate. Pressing the **ALT** key turns autocompletion back on.
To create the area, while holding the **ALT** key down we move the mouse cursor to the desired ending position of the area and then we click (while still holding the **ALT** key down). We can now release the **ALT** key and right-click to create the area.

The result is an area that is created between the initially clicked point, through all of the coordinates in the edge of the other area and the final clicked point. The new area is shown in blue above.

**Shortest Edge and Longest Edge**

The **ALT** key generates an autocompletion boundary following the shortest path from the initially clicked point to the current mouse position. Pressing the **SHIFT-ALT** key combination generates an autocompletion path following the longest path.

- **ALT** Autocomplete boundary using the shortest edge path.
- **SHIFT-ALT** Autocomplete boundary using the longest edge path. Same as **ALT** when following lines with autocomplete.

Using **ALT** autocompletes the area boundary using the shortest edge. Using **SHIFT-ALT** autocompletes using the longest edge.
With **ALT** the resulting area is a small bay. With **SHIFT-ALT** the resulting area is a large object that encompasses (is a union of) the original object plus the bay.

**Autocompletion across multiple objects**

The autocompleted boundary must be all in the same object. One cannot click to start a new area in one object and then try to autocomplete it in a different object. To create areas using more than one other area as the defining boundary, we must use autocompletion in two steps.

To create an area using the two existing areas in the illustration above we begin by clicking on the starting coordinate in the first area (**Snap to Areas** is enabled and the **Insert Areas** command is in action).

Holding down the **ALT** key we move the mouse over the last coordinate in the first area and we **ALT**-click to mark that coordinate.
Next, we move the mouse cursor slightly downward onto the first coordinate that we would like to use from the second area and we click to mark that location. Note that we simply click on this location and we do not ALT-click.

We can now press ALT and the autocompletion will follow the boundary of the second area from the position of the last click, which is indicated with a red arrow in the illustration above. (Manifold does not draw red arrows as seen above. The red arrow was added to the screen shot.) We can then ALT-click to mark the final coordinate followed by a right-click to create the area.

When using autocompletion across multiple areas it is tempting to work at a high zoom level and to use autoscroll to follow the edge of the areas. When areas are complex, working at a high enough zoom level to be sure to mark the "last" and "next" coordinates of adjacent areas at boundaries between two areas results in a lot of slow autoscrolling.

There are more efficient ways of managing zoom. One alternative is to use the + and - keyboard keys to zoom in and out even in the middle of the Insert Areas command. Pressing + on the keyboard will cause a zoom in. Using the + and - keys we can zoom in where greater precision is required and then zoom out where less precision is required. Using the + and - keys while simultaneously operating the mouse within an Insert Areas command takes some manual dexterity and practise.

A second approach is to work at a zoom level that is convenient for the overall scene and to make a best effort to mark the last and next coordinates at the boundaries between areas. We can then zoom far into the scene at each boundary between areas and add/delete coordinates to the newly created area and move them as desired (using Snap to Areas) to adjust the fine detail of the new area in that location so there are no overlaps or gaps. See the Editing Objects and Editing with Snap topics.

**Autocompletion with Lines**

We can create lines using autocompletion as well as areas. We can also use lines to guide the autocompletion as well as areas.

For example, suppose we have a line that defines a boundary. We would like to create an area using this line as a guide.

We turn on Snap to Lines and Insert Areas. We click on the starting point of the area.
Holding the **ALT** key down to autocomplete along the line we **ALT**-click on the ending point of the area.

We can then right-click to create the area.

We can also create lines using areas as a guide.

To do so we turn on **Snap to Areas**.

We will create the line with **Insert Line**.

Suppose we want to create a line at the boundary of two areas. We click on the beginning coordinate.
Next, we **ALT**-click at the ending coordinate. The **ALT** key will cause an autocompletion along the edge of the area we are following.

Right-click to create the line. It is shown in the illustration above with a line size of 2 to show the new line better. Note that when creating a line on the common edge of two adjacent areas it doesn’t really matter which area is the "upper" area, since both have the same coordinates in common at their adjacent edge.

### Keyboard Zoom Commands during Selection and Editing

When making selections or editing objects (such as inserting areas using the **Autocomplete** feature) we will often want to zoom in or out in the middle of a selection or editing command. Use the + and - keys on the keyboard to do so. Usually the + and - keys in the numeric keypad are used.

+ "Plus" key: Zoom in at the current tool position.
- "Minus" key: Zoom out at the current tool position.

The current tool position is the position of the mouse at the time the + or - key is pressed. When editing, using these keys allows us to easily zoom into a desired location, make a few precise clicks and then zoom back out and proceed at the usual scale.

### Limitations

Autocompletion has several limitations:

- The autocompleted boundary must be all in the same object. One cannot click to start a new area in one object and then try to autocomplete it in a different object. See the notes above when autocompleting across multiple objects.
- Autocompletion works only within the same branch of a multi-branched object.
- When a starting coordinate occurs at a spot where several objects in the same drawing have a defining coordinate, the autocompletion path follows only the topmost object. If desired, we can move an object to a new drawing to force it to be the "topmost".
Notes

The "A" in ALT is a mnemonic for Autocomplete.

The colors used for both the primary marquee (the selection "box") and the autocompletion trackline are set in Tools - Options by the Marquee color. The autocompletion trackline is the RGB color inverse of the Marquee color. When setting Marquee color it is important to choose colors that result in reasonable contrast when the primary marquee and the trackline are seen against the colors used in the drawing.

See the Snap to topic for information on Snap modes.
Shared Edit

The Edit - Shared Edit setting controls the operation of mouse-based editing commands. When Shared Edit is on, any click and drag of the mouse will affect all objects that have a defining coordinate at the mouse click location. When Shared Edit is off, only that object that has been selected for editing will be affected. When Shared Edit is on, read-only layers, non-editable layers and invisible layers are ignored.

Shared Edit may be turned on and off using CTRL-E as a keyboard shortcut ("E" being a mnemonic for "Edit"), or by clicking the Shared Edit choice in the Edit menu.

When Shared Edit is on, a box will appear around the Shared Edit icon in the Edit menu.

When Shared Edit is off, there will be no box around the Shared Edit icon in the Edit menu.

Example

The easiest way to show the effect of Shared Edit is to turn it on and try a simple example.

Consider a drawing that has four lines. Three of the lines have been drawn using the Snap to Lines snap mode so that their ends are exactly at the end of the fourth line. At the ends of the four lines five points have been placed, also using Snap to Lines snap mode, so that the points are exactly at the ends of the lines.

This is a fairly typical example of lines and points that might occur in a drawing of, say, a system of roads or a network, where the ends of lines are exactly coincident and where points might be placed exactly at the ends of lines. Suppose we would like to edit this drawing to move, say, the position of one of the points and we would like to simultaneously change the position of any incident lines.

That would be tedious to do without Shared Edit capability, but with Shared Edit mode turned on it is very easy to do.
Suppose we would like to move the central point and to move all incident lines with it. We begin by `CTRL-ALT` clicking on the point to select it for editing. An edit handle appears.

We can now click on the point and drag it to a new location.

With **Shared Edit** mode turned on, when the point moves, the coincident coordinates of all incident objects move with it. The four lines with ends exactly under the point will have their ends also moved. What is happening is that the coordinates defining the end of each line are also changed when the point's coordinates are changed by moving the point.

This works regardless of which object has been selected, and it even works if the different objects are in different layers and we are editing them in a map.
Suppose, for example, we *CTRL-ALT* click on the uppermost line to select it for editing. Edit handles appear at the two coordinates that define the line.

We can now click and drag the edit handle on the bottom coordinate to move it.

With *Shared Edit* mode on, when we move the edit handle for the line we change the line, but the point at that location also moves and so do the ends of the other three lines.
Let's consider what would have happened if we did not have Shared Edit mode on. Suppose we CTRL-ALT click the upper line to select it for editing.

Once again, we could click and drag the bottom edit handle to move it.

However, if Shared Edit mode is turned off then moving the bottom edit handle will move only the coordinate for that one object and will not move the point and the ends of the other three lines that were coincident with it.

**Editing Areas with Shared Edit**

Shared Edit mode is very useful for editing areas where areas are adjacent. It's often the case with geographic maps that areas will be drawn adjacent to each other. If we want to edit the boundary of an area to move it slightly we will also need to correspondingly move the boundary of any adjacent areas to avoid creating gaps or overlaps.

Geographic regions such as provinces or states are often represented as areas in geographic maps. The "border" between two states in an error-free geographic map is a place where the boundaries of two different areas coincide. Let us digress for a moment to make this concept clear:
The illustration above shows a map that has two layers, each containing an area object. The areas have been drawn so they are exactly adjacent to each other along a common border. What appears to be a single line, a "border," is in fact simply the place where the coordinates of two different area objects happen to coincide.

We can see this by clicking the layers on/off for display that contain the two areas.

One layer contains an area colored in gray. This area is defined with seven coordinates, five of which define the right edge of the area.

The other layer contains an area colored with a blue pattern. This area is also defined with seven coordinates. The left edge of the blue patterned area is also defined with five coordinate locations.

What gives the appearance of a common "border" is that the five coordinates defining the right edge of the gray area are exactly coincident with the coordinates defining the left edge of the blue area.

This is the usual case in most geographic maps. Unless there is a boundary dispute between two states, normally where the territory of one state ends is where the other state begins, so there should not be any gaps or overlaps at the place where two areas meet.

To move the common boundary line, we want to move the coordinates of both the gray area and the blue area simultaneously. To do this, we turn Shared Edit mode on and we will use regular editing commands to change the shape of one area with the other area's shape being changed automatically.
For example, we can select the area on the right for editing by **CTRL-ALT** clicking it so edit handles appear at each of the area's coordinates and then we can drag edit handles about to change the shape of the area.

To move the central part of the border we can click and drag the leftmost edit handle to the right.

With **Shared Edit** turned on, the result is that the corresponding coordinate for the gray area is also moved to the right. This changes the shape of the gray area as well so that no gaps or overlaps appear. Note that this works even though the two areas are in different layers in the map window in which we are working.

Had we done this same edit with **Shared Edit** turned off, only the coordinate for the area selected for editing would have been moved. The coordinate for the gray area would not have been moved and thus a gap would appear between the two areas.
Dissolve

**Dissolve** is so named because it “dissolves away” or removes the borders between areas that have identical values in data attribute fields. Given a set of areas, it can automatically create new areas that are spatial combinations of areas having the same data attributes. **Dissolve** can also work with lines, to join lines together. It is available for drawings or drawing layers in maps.

Suppose we have a drawing of the US where each state has a region field.

<table>
<thead>
<tr>
<th>Name</th>
<th>Region</th>
</tr>
</thead>
<tbody>
<tr>
<td>Alabama</td>
<td>East</td>
</tr>
<tr>
<td>Arizona</td>
<td>West</td>
</tr>
<tr>
<td>Arkansas</td>
<td>Central</td>
</tr>
<tr>
<td>California</td>
<td>West</td>
</tr>
<tr>
<td>Colorado</td>
<td>West</td>
</tr>
<tr>
<td>Connecticut</td>
<td>East</td>
</tr>
</tbody>
</table>

The value in the region field can be **East, West** or **Central**.

If we **Dissolve** all objects in the map using the **Region** field we combine all areas of like region value into one area. Thus, all the states with the value **West** in their **Region** field will be unioned into a single area.

**Dissolve Dialog Controls**

The **Drawing - Dissolve** dialog allows us to choose which areas are to be dissolved and what the guiding field should be.
**Dissolve**

Choose [All Objects] or the name of a saved selection.

**Using**
Choose the field to use to guide the dissolve process.

**Ignore Case**
Combine text strings treating any variation in case as the same string.

**Ignore leading and trailing whitespace**
Combine text strings without regard to whitespace characters before or after the string.

**Ignore internal whitespace**
Combine text strings without regard to whitespace characters occurring within the string.

Manifold uses the Transfer Rules specified for the table's fields to combine data attributes when dissolving objects into one object. Before using **Dissolve** it is essential to read and understand the Transfer Rules topic.

Different transfer rules will be used with different types of information. For example, suppose each state has an **Area** field that gives the area of the state in square kilometers (or more likely for the US, in square miles…). We would like the **Area** field for the combined area created by **Dissolve** to be the **Sum** of all the areas of the states that were unioned together. To accomplish this, we would right click onto the **Area** column head in the drawing's table, choose **Transfer Rules** in the context menu and then verify that **Sum** is the **N to 1** transfer rule for that column (which it is, by default).

**Dissolving Lines**

Suppose we have a drawing that shows streets as lines. Each street has a **Name** field that gives the name of the street.

It's often the case that each street will be represented with many line objects where the end of each line is exactly coincident with the next line. In the illustration above we can see such a situation by selecting (with select touch) every other line object that makes up a particular street.

If each of the line segments that makes up a given street has the same name, such as "Fisher Street" we can use **Dissolve** to automatically join all the line objects that make up a particular street into a single line object.
To do so, we run **Dissolve** with the settings above.

![Dissolve interface](image)

The result is that all of the line objects that form a given street will be dissolved into a single line object. We can see this by using touch selection to touch the line anywhere and see the entire line selected at once.

**Performance Tips**

- Don't use high-resolution data when lower resolution will do. For example, if you are mainly interested in showing provinces for thematic display purposes and are not really interested in very detailed shorelines a relatively low resolution data set will work fine. Resample the data with Normalize Topology (for drawings) using a lower Location Precision value to create a lower resolution equivalent that makes sense at the display level of interest. **Dissolve** can work much faster if the objects involved are defined with fewer coordinates.

- Re-project all drawings involved into the same projection. All projection parameters must be the same for this to help and not just the name of the projection in use.

- When importing drawings, don't import data fields that will never be used. Many data fields will slow the system down. If a drawing has been imported with superfluous data fields, edit tables using Design to eliminate the unnecessary fields. When working with commands such as Dissolve, check the Transfer Rules for the tables being used to make sure that no fields are being transferred that are not necessary to transfer.

See the comprehensive list of suggestions in the Performance Tips topic.
Districts

The **Drawing - Districts** command assigns areas in the drawing to different districts by writing a district code to a specified data field. Given a drawing that contains areas the command assigns each area to one of the given number of districts such that each district is reasonably compact and contiguous. The **Districts** command is normally used with drawings showing adjacent areas like a drawing of the countries of Europe, provinces in a given country, counties in a US state and so forth.

If you have acquired the optional Business Tools extension to Manifold System, use of the Districts (Visual) dialog is much preferred to the basic **Districts** dialog.

**Scope**
The set of areas to be assigned to districts. [All Objects] by default, but can be set to the selection or any saved selection.

**Save to**
The column to be used to save the district assignment code. [New Column] by default to create a new column called **District**, or a choice of any existing column.

**Balance**
Field to be used to balance districts. Districts will be created so each district (as much as possible) has the same total value of this field.

**Threshold**
Areas within this distance will be considered adjacent. The default value of 0 means that areas touching each other are considered "near" and that areas with no common points are "far" from each other.

**Districts**
The number of districts to which the areas should be assigned. Choosing 4, for example, will cause each area in the drawing to be assigned to one of four different districts.

**Modify formatting**
Reformat colors of areas so that areas in each district are colored similarly. Colors used are taken from the same palette used in the Color dialog.

Choosing 4 districts will cause the Districts command to create a new column called **District** and then place a value of 1, 2, 3 or 4 into that column for each area. All areas with the value 1 will be grouped together next to each other in one district as will the areas with values 2, 3 and 4 respectively. Redistricting can be accomplished by opening the drawing's table and changing the **District** code for any area that is to be reassigned to different district.

**Note:** A value of 0 is assigned to newly-created areas that do not yet participate in any district as well as to lines and points.

The thematic format created by default will use the **District** column with unique values to specify color. To change the color scheme used, use thematic formatting to change the colors used to format using the **District** column.

**Example**

We will create districts using the **mexico_eg** sample drawing (referred to here as "mexico" for brevity).
Seen in default formatting in a drawing window, the *mexico* drawing consists of areas for provinces, each of which has a variety of columns giving geographic and demographic information.

Choose **Drawing - Districts** and choose **SQKM** as the **Balance** field. This field gives the area of each province in square kilometers. Change the number of **Districts** to **4** and press **OK**.

The Districts command will create a new column called **Districts** and will assign each province in *mexico* to one of four different districts by placing the value 1, 2, 3 or 4 into that column for each province. Thematic formatting will then be applied using the **Districts** column as a guide for formatting. The objective of the Districts command is to assign each province into districts so that the sum of the total **SQKM** for each district is the same and so that all areas in each district are contiguous (within the threshold parameter distance). To achieve districts where each district has the same overall **SQKM** total can require some oddly shaped districts although the Districts command will try to keep districts as compact as possible.
We can see that in the case of an irregularly shaped country such as Mexico it is a challenge for the Districts solver to create compact districts that also balance the desired field. In particular, we can select one province that seems it could be swapped for a different province.

Opening the drawing's table we can see that the province of Zacatecas has an area of 73252 square kilometers. It has been assigned to district 2, the brown district. [We used Table - Columns to show only three columns in the table.]

We can click on another province in the green district that seems it could be swapped for Zacatecas.
We see in the table that the province of **Guerrero** has an area of **64281** square kilometers. It has been assigned to district **1**, the green district. Swapping this province for **Zacatecas** would reduce the total square kilometers in the brown district and increase the total square kilometers of the green district, but not by much. We might decide that it is a reasonable trade to keep the provinces more compact.

We can reassign the **Guerrero** province to district **2** by double clicking into the **Districts** cell for the **Guerrero** record and entering the value **2** as seen above. We can then change the **Districts** cell for the **Zacatecas** record to **1** (not illustrated).

We can then click on the drawing, click on the background color well in the formatting toolbar, click on **Thematic** and reapply the formatting to update the formatting of the provinces to using the new values just entered for **District** in the toolbar. The result as seen above is a more compact allocation of provinces into districts.

### Performance

Districting is easy to do if a drawing fulfills certain limiting conditions, such as a guarantee that areas never overlap and are always perfectly adjacent. Since "real world" drawings often have imperfections, the Manifold districting algorithm uses a **Threshold** factor for determining distance between areas. The algorithm also uses a variety of computational geometry and network algorithms to deal with common imperfections in data sets. As a result, computation with a large number of areas could be slow with a large number of areas and a slow machine. To assess the performance of a particular machine with a given data set, begin by applying Districts to small data sets such as the sample **mexico_eg** drawing and scale up gradually.
The Districts command can create up to one million districts although, of course, it is normally used with a far smaller number of districts, since many districts are not easily comprehended.

Orthogonalize

The Orthogonalize command moves coordinates to orthogonal grid positions at the specified X and Y grid steps. The command is used mainly to trim insignificant digits from coordinates. For example, suppose we are working with a projected data set expressed in meter-based coordinates and we know that our data set is only accurate within 10 meters. In such cases, there is only an illusion of accuracy when using coordinates such as 34592.490593845 meters. It may as well be 34590 meters. If every coordinate were moved to the nearest ten-meter coordinate position, we would achieve the effect of rounding all coordinates. Orthogonalize command performs exactly this function.

Scope  The set of objects to alter.
Steps  The X and Y dimensions of the grid cells.
Offsets  The X and Y offsets of a grid cell that may be used.

Offsets are combined with Steps to nudge the orthogonalization in desired X and/or Y directions. With X and Y Steps equal to 100 using zero Offsets will force the coordinates of objects to the nearest locations on a 100 x 100 grid of cells (for example, 0:0, 100:0, 0:100, ...).

With X and Y Steps equal to 100 using Offsets of 10 and 20 will force the coordinates of objects to the nearest locations on a 100 x 100 grid that is shifted in both horizontal and vertical directions by 10 and 20 units (for example, 10:20, 110:20, 10:120, ...).

Example

Suppose we start with a drawing of Durango province in Mexico using Orthographic projection.

After applying the Orthogonalize command with X and Y steps of 25000 meters the province takes on a distinctly stair-step appearance as coordinates are forced to the nearest 25000-meter grid position. The Orthogonalize command is not normally used in cases where the original coordinates appear in much finer resolution than the steps specified, so some regions have been collapsed into topologically redundant appendages. These can be fixed by running the Normalize Topology transform toolbar operator.
The Normalize topology operator cleans up the topology.
Segmentize
The Segmentize command adds redundant coordinates to objects. It is normally used to make ready for projection very large, simple objects that would otherwise suffer distortion. See the Segmentization topic for discussion of segmentization and projections. The Segmentize menu command applies additional coordinates so there is no straight segment of an object that has greater than the given Distance between coordinates.

**Scope**  The set of objects to alter.

**Distance**  Maximum distance between coordinates.

**Remove duplicate coordinates**  If checked (the default), removes duplicate coordinates. If unchecked, leaves duplicate coordinates intact.

**Example**

Suppose we have an area that is a simplified rendering of the province of Durango in Mexico, seen in Orthographic projection in a drawing. The province is approximately 440 kilometers wide. The simplified rendition was created by applying Simplify with a Distance setting of 25000 meters.

If we click on the area to select it as the primary selected object for editing, edit handles appear at each coordinate that define the area.
Zooming in to the Eastern side of the province we can see that the area consists of straight line segments between the coordinates that define the area.

If we apply Segmentize with a Distance setting of 10000 meters, Manifold will place redundant coordinates along the straight segments at a distance not exceeding 10,000 meters. Additional edit handles will appear for each coordinate.

**Transform Toolbar Segments Command**

The Segments command in the Transform Toolbar adds the specified number of segments, whereas the Segmentize command in the Drawing menu adds segments so that each segment is no greater than a given Distance parameter. For example, segmentizing a 100 meter line into 40 meter segments will create segments of 40, 40 and 20 meters.

**Tech Tips**

In some circumstances, Segmentize and Simplify are inverse functions. For example, if we applied Simplify again with a setting of 25000 after the Segmentize command shown above the redundant coordinates would be removed.

Many transforms automatically run a Normalize Topology transform before running to eliminate common errors that may affect correct operation. The Boundaries, Points and Node Points transform operators do not normalize target objects before running. This makes it possible, for example, to segmentize lines with a length threshold of 10 meters, and then use the Points transform to place point objects at the locations of resulting inflection points.

Segmentization
Segments
Simplify
**Simplify**

The **Simplify** command reduces the number of coordinates that define an object. Given a scope of action ([All Objects] or a selection) and a Distance, the **Simplify** command will reduce the number of coordinates such that the coordinates that define the object are approximately the given distance apart. The **Remove small branches** option will automatically remove branches in multi-branched objects (such as areas with islands or holes) that are smaller than the given distance.

In the example above, the province of Durango in Mexico has been simplified using **Simplify**. The drawing was first projected into Orthographic projection so that meter-based distances could be used.

The **Simplify** dialog was run with a Distance of 25000 meters.

**Comparison to Normalize Topology**

The **Simplify** command is similar to the Normalize Topology transform toolbar operator. However, the **Simplify** command is aimed at simplification on a per-object basis while the Normalize Topology operator considers relationships between objects when simplifying them. We can see the difference by running both commands on a drawing of Mexico.

We begin with a drawing of Mexico that's been projected into Orthographic projection.
Running **Simplify** with a distance setting of **25000** meters results in the simplification of areas. However, each area is simplified without considering any relationships with adjacent areas. This provides an optimal simplification when each area is considered by itself but also results in overlaps and gaps between areas.

If instead of using **Simplify** we used **Normalize Topology**, we would first use **View - Properties - Precision** to set the **Location Precision** to **25000** meters and then we would run **Normalize Topology**.

**Normalize Topology** takes a lot longer to run than **Simplify**, but the result in the end is free of overlaps and gaps. Each area has been adjusted both on the basis of capturing its own shape as well as to match its neighbors. However, it could be said that the resulting shape for each individual object (without regard to neighboring areas) is not as "optimal" a simplification as is done by **Simplify**.

When simplifying a single object it is probably best to use **Simplify** since the result is obtained much faster. When simplifying many objects for which adjacency must be maintained it is best to use **Normalize Topology**.

Spatial Overlay

Spatial overlays are a set of methods for transferring data between objects in drawings based on their spatial relationships to each other.

For example, suppose we have a drawing that shows states as areas and we also have a set of points showing the locations of cities. Suppose that each city record has a field called Population that gives the population in that city, but that we have no values for the population of each state. We could use spatial overlays to automatically add up the values of the populations for all cities in each state and place that combined value into the Population field for each state.

Spatial overlays transfer data from fields in a Source object set to a Target object set using some method. The specific rules used to transfer data are taken from the Transfer Rules specified for each column.

Spatial Overlay Dialog Controls

Source
Choose an object set to be the source of data. Choices will include the selection, all saved selections, and objects in drawing layers when launched from a map. The source set may contain only objects of one type (that is, all areas, all lines or all points).

Target
Choose an object set to receive the transferred data. Choices will include the selection, all saved selections, and objects in drawing layers when launched from a map. The target set may contain only objects of one type (that is, all areas, all lines or all points).

Method
Choose a transfer method. Only those operations that make sense for the objects in the source and target sets will be presented. If the source or target set do not contain all objects of one type the method box will not be enabled.

Spatial Overlay Methods

The following methods will appear in the Methods box as appropriate to the types of objects that have been selected in the Source and Target sets.

Areas to contained areas
Transfer fields from area A to areas that are completely inside A.

Areas to contained lines
Transfer fields from area A to lines that are completely inside A.

Areas to contained points
Transfer fields from area A to points inside A.

Areas to containing areas
Transfer fields from area A to areas that completely contain A.

Areas to intersecting areas
Transfer fields from area A to areas that have at least some location within A’s interior (that is not on a boundary).

Areas to intersecting lines
Transfer fields from area A to lines that have at least some location within A’s interior (that is not on a boundary). Excludes fully contained lines.

Areas to neighbor areas
Transfer fields from area A to areas that touch A only at A’s boundary (that is, have no common locations that are interior for A).

Areas to neighbor lines
Transfer fields from area A to lines that touch A only at A’s boundary.

Areas to boundary
Transfer fields from area A to points that lie on its

</tbody>
</table>

**Example**

Let's consider a simple example to see how spatial overlays work.
We've created a drawing with two areas and nine points. Select the points and save them as a saved selection called **Points** in the Selections pane. Select the two areas and save them as a selection called **Areas** in the Selections pane.

The table for this drawing shows that there is one integer field, **Population**. Each of the points has a value of **1** for the population field and is shown with red selection background color in the table. The two areas have values of **0** for the population.

Open the drawing’s table, right click onto the **Population** column and choose **Transfer Rules**.

In the Transfer Rules dialog choose **Copy** as the transfer rule for **1 to N** transfers and choose **Sum** as the transfer rule for **N to 1** transfers.

Click onto the drawing window and choose **Drawing - Spatial Overlay**.

In the Spatial Overlay dialog choose **Points** as the Source and **Areas** as the Target. The Method will be **Points to containing areas**. Press **OK**.
The result of the spatial overlay operation is that one area (the triangle) acquires a value of 2 and the other area (the circle) acquires a value of 4. These new values are the sums of the point values within the areas.

**Geographic Example**

Let's apply the above procedure in a geographic setting. We will sum up the populations of towns to get a total population for each county containing the towns.

We have a drawing called *Example* that shows counties in the San Francisco Bay area as areas together with points taken from a Census Bureau file of named places with populations.

</tr>
</tbody>
</table>

Opening the *Example Table* we see that there are ten areas each with a 0 value in the *pop1990* field. Numerous towns have populations for each town.

We begin by right clicking on the *pop1990* column header in the table and choosing *Transfer Rules.*
We set the transfer rules for this field to be \textbf{Sum} for \textbf{N to 1}. Since many points will be combined into each county this is a "many to 1" or \textbf{N to 1} transaction. We would like the population values to be summed to get the value for each county.

We don't want any values transferred for the \textbf{county} or \textbf{Name} fields. We right click onto the \textbf{county} column header, choose \textbf{Transfer Rules} and choose \textbf{None} for the \textbf{N to 1} transfer rule. We then right click onto the \textbf{Name} column header, choose \textbf{Transfer Rules} and once more choose \textbf{None} for the \textbf{N to 1} transfer rule.

If we were using spatial overlays between different drawing layers in a map we could skip this step; however, since we are transferring values between fields in the same drawing we will use saved selections. Select all points in the drawing and save this selection as a saved selection in the Selections pane called \textbf{Places}. Select all points in the drawing and save this selection as a saved selection called \textbf{Counties}.

With the focus on the \textbf{Examples} drawing window, choose \textbf{Drawing - Spatial Overlay}.

In the \textbf{Spatial Overlay} dialog choose \textbf{Places} for \textbf{Source} and \textbf{Counties} for \textbf{Target}. For the \textbf{Method} choose \textbf{Points to containing areas} and press \textbf{OK}. 
In the table we can see that the `pop1990` values are filled with the sum of the point values for each county. This is in accordance with the `N to 1` transfer rule we specified for this field. Note that there is no change in the `county` or `Name` fields for the county areas since we specified `None` as the transfer rules for these fields.

### Spatial Overlays in Maps

Spatial overlays may be used in maps when a map contains at least one non-empty drawing. To use spatial overlays between different drawings in a map, the following must be true:

- The same field name and type must be present in both drawings involved.
- Exactly the same set of transfer rules must be used in both drawings for each field involved.

If the above two conditions are not met for a particular field it will not be transferred at all.

Note that the "same type" requirement is meant literally: for example, fixed length ASCII text columns of different length are different types. Therefore, attempting to transfer data between a 20-character fixed length ANSI text column and a 40-character fixed length ANSI text column will not work due to the different lengths of the data allowed.

Note: A linked drawing or a shared drawing in Enterprise Edition that is not checked out itself but has a checked out table can nonetheless be the target of a spatial overlay.

### Troubleshooting

Difficulties with spatial overlays arise almost exclusively from failing to set Transfer Rules correctly for the desired action. For example, if the `Transfer column` checkbox in the `Transfer Rules` dialog has been unchecked a column will not transfer. If no columns are available for transfer the spatial overlay operation will report "No columns to transfer."

### See Also

Transfer Rules - Transfer rules specify how fields are aggregated or allotted when new objects are created using transform toolbar operators. Spatial overlays are a different concept than the idea of using transfer rules to aggregate or to allot values when creating objects with transforms. However, it is a related concept in that aggregations or allotments are used to transfer field values between objects.

Transfer Contour Line Height to Points - A simple example using Spatial Overlay.

Color Areas by Counts - A simple example using Spatial Overlay to color areas by the number of points they contain.

Shortest Path over Land - A complex example that uses Spatial Overlay.
Intersection Overlays - A small, but sophisticated, example that uses Transfer Rules, Split with, Clip with (Intersect) and Spatial Overlay commands with areas.
Topology Overlay

The Topology Overlay dialog creates a results drawing from two other drawings using Identity, Intersect, Union and Update overlay functions. These functions may also be performed by a sequence of transform toolbar operators. The Topology Overlay tool provides one-step functionality to make it easy to perform these common functions. Overlays simultaneously create new objects in the results drawing and also populate data columns as necessary. Overlay functions are also referred to simply as overlays.

All overlays require two drawings: a data drawing that may contain areas, lines and points and an overlay drawing that must contain areas. The areas in the overlay drawing guide the operation of the chosen overlay function to create a new, result drawing.

The result drawing will inherit all columns from both the overlay drawing and the data drawing. There is no mapping between the columns in the overlay drawing and the data drawing. Each resulting object inherits all attribute values from the overlay drawing and from objects in the data drawing from which it has been produced. A topology overlay will automatically copy over values from active columns, rank columns, and columns brought into a drawing's table via relations.

- **Identity** splits all areas, lines and points in the data drawing with areas in the overlay drawing and places each resulting part of the original object from the data drawing into the result drawing.
- **Intersect** intersects all areas in the data drawing with areas in the overlay drawing and places each resulting part of the original area from the data drawing that lies in at least one area in the overlay drawing into the result drawing.
- **Union** intersects all areas in the data drawing with areas in the overlay drawing and places each resulting part of the original area from the data drawing into the result drawing, then it intersects all areas in the overlay drawing with areas in the data drawing and places each part of the original overlay area that does not lie in any area in the data drawing into the result drawing.
- **Update** intersects all areas, lines and points in the data drawing with areas in the overlay drawing and first places each resulting part of the original object from the data drawing that does not lie in any overlay area into the result drawing, then second placing each overlay area into the result drawing.

The above overlays are similar to those in various legacy GIS systems, except that they are not subject to some of the limitations that these GIS systems have. In particular, Manifold allows the data drawing to contain areas, lines and points (and not just areas as is the case with some systems) and overlays these objects simultaneously without forcing the user to perform the overlay operation once for each object type as would be required by some other systems. Manifold also automatically resolves overlaps between areas and other topological anomalies both in the data drawing and the overlay drawing, without forcing the user to go through a separate topology cleaning step.

Performing a Topology Overlay

1. Open the drawing to be used as the overlay drawing or data drawing, or open a map containing the drawing and set the drawing's layer active.
3. In the Topology Overlay dialog, choose the Data drawing, the Overlay drawing and the Method. Press OK.

Topology Overlay Dialog Controls

When choosing object sets to use in the Overlay or the Data drawing, choices available will be all objects or any selection or saved selection in that drawing.

- **Data** Choose an object set in the data drawing upon which the overlay will operate.
- **Overlay** Choose an object set in the overlay drawing that will control the overlay. Only areas can be used to control the overlay.
- **Method** Choose an overlay method.
- **Force copy / copy transfer rules** When checked, ignores the transfer rules defined for each column and instead always applies a copy / copy transfer rule. Similar to how legacy GIS applications...
operate. Not checked by default.

**Topology Overlay Methods**

The following methods will appear in the **Method** box for topology overlays:

- **Identity** Split all areas, lines and points in the data drawing with areas in the overlay drawing and places each resulting part of the original object from the data drawing into the result drawing.

- **Intersect** Intersect all areas in the data drawing with areas in the overlay drawing and place each resulting part of the original area from the data drawing that lies in at least one area in the overlay drawing into the result drawing.

- **Union** Intersect all areas in the data drawing with areas in the overlay drawing and place each resulting part of the original area from the data drawing into the result drawing. Next, intersect all areas in the overlay drawing with areas in the data drawing and place each part of the original overlay area that does not lie in any data area into the result drawing.

- **Update** Intersect all areas, lines and points in the data drawing with areas in the overlay drawing and first place each resulting part of the original object from the data drawing that does not lie in any overlay area into the result drawing, then second place each overlay area into the result drawing.

**Examples**

Let's consider two drawings, **A** and **B** and the result of overlays between them.

![Image of a drawing with areas](image)

**Drawing A** consists of two areas.
Drawing B contains three areas.

If we show A and B together in a map we can see that the areas in A intersect the areas in B.

The following illustrations show the results of an "A operation B" where B is the Overlay drawing and A is the Data drawing. The results of each operation are shown as blue areas in a third results drawing shown in a layer above both the A and B drawings.

For example, we can use the Identity method with all objects in A as the Data drawing and all objects in B as the Overlay drawing.

Identity creates a result set of all the areas in A, but split up by their intersections with the areas in B. Instead of two areas in A, the result is eight areas in A. Each original A area has been split by its intersection with the three B areas to create three smaller areas plus a fourth area representing that part of the original A area not intersecting any B areas.
**Intersect** creates six areas in the result set, three areas from both of the original A areas where they intersect the B areas.

**Union** chops up all areas by their intersections between areas in A and B. It is, in effect, a dual “cookie cutter” operation performed using B areas to cut A areas and then using the results to cut B areas as well.

**Update** preserves all B areas and moves them into the result. It takes that part of any A area not lying within an intersection with a B area and moves it into the result as well. We can think of **Update** as being an “updating” of any changes in A areas using B areas (the **Overlay**) as being an overriding control. For example, suppose we have some town boundaries that have been changed but we want areas that represent unchanged water bodies (such as lakes or ponds) to be preserved in any intersection of water bodies and new town boundaries. In that case we could make our changes in town boundaries and then do an **Update** using the water areas as the **Overlay** and know that whatever changes were made in town boundaries the water areas would “cookie cut” through any boundary areas as necessary so that water areas would remain invariant.

Traditional Topology Tools - An optional add-in that may be downloaded from the manifold.net web site. This add-in provides operations using stored topology.
Traditional Topology Tools

The **Traditional Topology Tools** add-in may be downloaded from the [manifold.net](http://manifold.net) web site. If the add-in is not installed the capabilities in this topic will not be available. This add-in is often called **Topology Tools** for short. The add-in provides topology tools that employ stored topology using the methods of, and requiring constraints similar to, those of legacy GIS packages. In addition to being useful in some cases in expert hands, the tools also provide an interesting glimpse into the relative performance attainable in different cases using an "apples to apples" comparison between different topology computation approaches.

The add-in is published in 32-bit or 64-bit versions. Download and install the 32-bit version if you are running 32-bit Manifold System. Download and install the 64-bit version if you are running 64-bit Manifold System. Install the add-in by double-clicking on the .msi installation package.

**Using the add-in:**

1. Open a .map file that contains drawings. If any editing or changes have been made, save the project.
2. Choose **Tools - Add-Ins - Traditional Topology Tools** to launch the add-in.
3. Choose the operation desired and the drawings to be used as the initial drawing and overlay.
4. Press the **Perform Operation** button. The bottom pane in the dialog will record a running history of actions taken. Result drawings will be created in the project pane listing.

**Overview**

Unlike older GIS packages, Manifold does not build topological relationships into the data set: rather, topological relationships are computed on the fly as needed.

Years ago when computers were weak it made good sense to embed topological relationships into the data sets themselves. In modern times it is often better to compute topology on the fly. Doing so uses the intelligence of the machine to free the user from having to worry about low-level structural details. It allows us to mix points, lines and areas in the same drawing and to move objects about interactively with great freedom.

There are cases, however, when the use of stored topology will provide faster performance if we are willing to live within the constraints of this traditional method. For those users who have the expertise and the interest in using traditional methods, the Traditional Topology Tools add-in provides an optional toolset implementing those traditional methods. This add-in has been released on an informal basis. No technical support is available for this add-in.

The toolset is implemented as an add-in and not as a built-in part of Manifold because the usage of stored topology is very different from the topology on the fly approach used within Manifold. Using this add-in requires expert level understanding of the stored topology approach, which will probably have been acquired during work with a legacy system.

The add-in is not recommended for use by beginners. In particular, beginners in search of higher performance should not reach for this add-in: instead, they should study carefully the Performance Tips topic to learn how to assure maximum performance in Manifold operations. Although this add-in will increase performance in some cases, it will only do so when performing one of the four topology overlay operations available in the Topology Overlay dialog or in this add in. Using this add-in will not change the performance of any other Manifold operation. Even in those cases where this add-in may perform faster than the standard Topology Overlay dialog, it is unlikely any performance gain will be significant enough to be noticed unless the drawings involved are very large.

The add-in includes two basic types of functions:

- **Clean Topology** - Normalizes the topology of a given drawing and creates a "clean" version of the drawing as is often done within legacy GIS packages. The closest equivalent in regular Manifold usage is the Normalize Topology transform operator.

- **Overlays** - Four functions to perform **Identity, Intersect, Union** and **Update** overlays. The overlay functions will overlay a pair of drawings and create a result drawing. The closest equivalent in regular Manifold usage is the Topology Overlay dialog, which provides equivalent operations implemented using standard Manifold topology on the fly. See the Topology Overlay dialog for illustrations of these four operations.
Constraints

The functions operate like their counterparts in legacy GIS products. As a result, they have a number of limitations just like those in legacy products:

- Functions can only operate on entire drawings. They cannot operate using only a selection.
- Functions cannot alter existing drawings. The results must be stored in a new result drawing.
- Functions do not use transfer rules - they always copy data.
- Functions can only operate on objects of the same type. For example, they will ignore lines and points in a drawing that contains areas.
- Functions do not allow areas to overlap. If a drawing contains areas that overlap, every region that is covered by more than one area will be assigned to one of those overlapping areas for the purposes of the overlay function.

Controls

</tr>
<tr>
<td>Save topology data on disk</td>
<td>Cache stored topology on disk for maximum performance.</td>
</tr>
</tbody>
</table>

"Save topology data on disk" Option

For maximum performance, turn on the Save topology data on disk option, which tells the tool to cache topology structures on disk. With this option turned on, topology structures will be computed and saved in a separate file on disk for each drawing. Each drawing will have topology stored in a separate file named map.drawing-id.topology where map is the name of the .map file and id is the ID of the drawing within that .map file.

The size of topology data in the cache file will be approximately the same as the size of the producing drawing, excluding the size of the drawing's table. The system keeps track of changes made to the drawing and will not use outdated topology structures. If the .map file has not yet been saved, the option is disabled and the system can neither save topology data nor use already saved data.

One other limitation when caching topology data is that the coordinate systems and location precision parameters of overlaid drawings must be exactly the same. If either of these two characteristics are different, the tool will not be able to use cached topology data and will have to generate the topology of an overlaid drawings on the fly.

As a practical matter, therefore, operating the add-in without checking this option will result in performance not much different from standard topology on the fly. To take advantage of stored topology, check the Save topology data on disk option to turn on caching, do a Clean Topology operation on each drawing to be used to created stored topology, and then run the overlay operation desired. When drawings are selected in the Drawing and Overlay boxes, Manifold will report if the drawing has stored topology available in cache.

Example

Consider a project that contains two drawings, called A and B.
The illustration above shows both drawings together in a map. Drawing A contains rectangular areas formatted in blue. Drawing B contains circles formatted in yellow. The B drawing layer in the map uses partial opacity so that overlapping regions are clearly visible.

We launch the add-in and choose the **Intersect Overlay** operation, using A as the drawing and B as the overlay. The result is placed in a drawing called **A - Intersect - B**.

We can drag and drop the resulting drawing into the map to see how the objects it contains arise from the intersection of areas in the A and B drawings. Areas in the **A - Intersect - B** drawing have been formatted in magenta color.
If we click off the \textit{A} and \textit{B} layers we can see clearly the area objects in the new \textit{A - Intersect - B} drawing.

**Notes**

The Traditional Topology Tools add-in arises from experimental work done at \texttt{manifold.net} to quantify the performance differences between topology on the fly and stored topology. They have been released on an informal basis to allow users to experiment with and apply stored topology computation in cases where the user judges such computation to be advantageous.

Stored topology offers performance advantages when computing topology overlays for large data sets on weaker computer systems, but at the cost of significant limitations compared to topology on the fly. As computer systems get faster and Manifold topology on the fly computational algorithms get faster, it becomes possible to do topology on the fly even with larger data sets at a speed that equals or at times exceeds the use of stored topology. Already in most, but not all, cases topology on the fly is as fast or faster than using stored topology.

Stored topology is an effective approach for single-threaded operation but it is very poorly suited to multi-threaded, parallel or distributed operations using multiple processors. In contrast, topology on the fly is a very good approach for parallel or distributed code. Processors already feature dual cores or quad cores. As parallelization on the desktop increases, very rapidly the time will come when suitably parallelized topology on the fly algorithms will always exceed the speed of stored topology even when drawings containing very many objects are being overlaid.

This add-in has been released on an informal basis for users who wish to apply traditional methods for topology overlays. However, as computer systems continue to improve and desktop architectures become multi-core by default, it is expected that these tools will no longer be provided because they will be obsolete even as an informal, interim experiment. Therefore, any use of these tools should be conditioned on the understanding that they represent an experimental, interim toolset that may change without notice or at some time no longer be available.

Normalize Topology

Topology Overlay
The Transform toolbar makes changes throughout the entire drawing using the specified operators. Transform operators can create new objects, delete objects, change objects (for example, splitting them) and select objects using various algorithms such as the location of a shortest path. The transform toolbar is also used to make spatial selections using commands such as Select Touching or Select Contained within that work between sets of objects.

The Transform toolbar consists of three boxes, from left to right: a **target box**, the **operation box**, and a **source / argument box**.

**Target box**  Also known as the **scope box**. The objects that will be affected, altered or which will control the operation. Choices in the target box will be [All Objects], [Selection] or the names of any saved selections that have been saved in the Selections pane. The illustration above shows that the operator will be applied to all objects in the drawing.

**Operation box**  The function to be applied. The operation box is context sensitive and will show only those operations that make sense for drawings. The example shows we will add border buffer zones.

**Source / argument box**  The value to be used. Depending on the operator, this may be another object set or a value entered by the user. Many operators, such as Boundaries do not require a source or argument. The source / argument box will not be enabled for such operators. In the example above we use 10000 for the size of the border buffer zones, the size being specified in the native units of the drawing.

We use dark blue, black, and violet bold face fonts in this topic to distinguish the three boxes to make examples and explanation more clear. In real life Manifold uses the same black font color in all three Transform toolbar boxes.

**Using the Transform toolbar**

1. Click on the map layer or drawing that contains the target objects.
2. Make a selection if the operation is to be applied just to the selection and choose [Selection] in the target box. Alternately, choose the name of a previously saved selection.
3. Choose the desired operator in the operation box.
4. Choose or specify a value in the source / argument box, if this operation requires it.
5. Press **Apply**.
6. Some operators create new objects. Any new objects created will be created in the active drawing/layer and will now be the Selection. Move the Selection to a new layer/drawing if you wish to keep these objects organized separately from the original objects in the drawing (almost always a good idea).

**Target box**

The left-most box specifies the **target objects**. These are the objects that will be affected, altered or which will control the operation. The example above shows that there is no selection present, so the Transform toolbar will apply the Transform function to all of the objects in the drawing.
If we make a selection, we can switch the target box to [Selection] to apply the operation to only those objects that are part of the current selection. We could also choose the name of a saved selection.

**Operation box**

Choose a function from the long list of operators available in the operation box. The example shows **Boundaries**, which will create lines along the periphery of each area. The Transform Operators - Drawings topic lists operators available for use with drawings.

**Source / argument box**

Many operators do not require any sources or arguments. For these functions the source / argument box will be disabled.

Other functions will require specification of a source. This may an object set such as [All Objects], [Selection] or the names of saved selections, all of which can be chosen from the combo box.

Some functions require an argument value that is entered by the user. To enter a value, click into the source / argument box, enter the value using the keyboard and then press **Enter**.

**Examples**

[All Objects] **Boundaries** - Creates boundary lines on the periphery of all areas (if any) in the drawing.

[Selection] **Boundaries** - Creates boundary lines on the periphery of all areas (if any) that are in the current selection in the drawing.

[Selection] **Split with Roads** - Take all objects in the saved selection named Roads and split each selected object using these objects.

The selection pane is often very important when working with the transform toolbar. Saved selections can appear in either the target box or the source / argument box. See the Selection topic details on using the selection pane.

**Saved Selections in Maps**

When drawings appear together in a map, if any drawing layer has the focus the transform toolbar for the map will list all saved selections in all drawings. This is a great convenience, but it also leads to a slight complication in that all saved selections using the same name are treated alike. Saved selections in the same drawing are required to have different names, but saved selections in different drawings might use the same name.
The transform toolbar for the map will treat all drawing saved selections using the same name as one, combined saved selection. For example, if we have two drawing layers in a map, one called East and the other called West and they both have a saved selection called Cities, then using the transform toolbar to create a convex hull using the saved selection choice called Cities will use the objects from both the East and West drawings that appear in their respective Cities saved selection.

Therefore, it is a good idea to use unique names for saved selections in drawings that might appear together in the same map. For example, we could name the saved selection in one drawing East - Cities and that in the other drawing West - Cities.

**See Also**

Transform Operators - Drawings for a detailed list of operators available.
Transfer Rules for information on controlling how database table information is transferred to new objects that are created by transform operators. For example, when creating centroids the transfer rules within the drawing's table specify which fields should be transferred to the centroids.
Transform Operators - Drawings

The Transform toolbar for drawings includes a wide variety of operators. Some are specialized operators used to repair topology or to prepare drawings for use as networks in network or transportation analysis while other operators are more commonly used in GIS. The hyperlinks below will jump to the Help topic for the corresponding command.

**Attach to / Attach to Self**
These operators move the coordinates of one object to align to the coordinates of another object or objects. They are mainly used to adjust areas and lines to the shapes of adjacent areas or lines within the same object set or across different object sets.

**Border Buffers**
Create a buffer zone for each area object extending both outward and inward from the area's boundary the given distance.

**Boundaries**
Create lines in the shape of the periphery for each area in the target set. Will create duplicate boundary lines in places where the edges of areas coincide.

**Bounded Areas**
Create areas within regions enclosed by lines in the target set.

**Bounding Boxes**
Create an area in the form of a rectangular bounding box that encloses each object and is aligned vertically and horizontally with the map window.

**Buffers**
Create a buffer zone for each object extending outward by the given distance. For areas, this is an outer buffer zone.

**Centroids**
Create a point at the center of the minimum circle that encloses each object. (areas or lines)

**Centroids (Box)**
Create a point at the center of the minimum enclosing rectangle for each object. (areas or lines)

**Centroids (Inner)**
Create a point at the "center" of an area and adjust the position of the point so that it always falls within the area. (areas only)

**Centroids (Weight)**
Create a point at the approximate center of balance of each object. (areas only)

**Clip with (Intersect)**
Use the areas in the source / argument box set to "cookie cutter" objects in the target set and leave only those items inside the cookie cutter.

**Clip with (Subtract)**
Use the areas in the source / argument box set to "cookie cutter" objects in the target set and remove those items inside the cookie cutter.

**Clusters**
Given a Parameter value from 0 to 100, detects clusters and draws lines between all points in the cluster. Exists in standard and Zahn algorithm versions.

**Common Bounding Box**
Like Bounding Boxes, but creates one bounding box about all objects in the scope.

**Common Buffer**
Like Buffers, but creates one buffer zone about all objects in the scope.

**Common Centroid**
Like Centroids, but creates one centroid using the center of the minimum enclosing circle for all objects in the scope.

**Common Enclosing Circle**
Like Enclosing Circles, but creates one minimum enclosing circle for all objects in the scope.

**Common Enclosing Rectangle**
Like Enclosing Rectangles, but creates one minimum enclosing rectangle for all objects in the scope.
Constrained Triangulation  A constrained Delaunay triangulation consisting of both lines and areas that does not cross line segments within the source object set.

Constrained Triangulation Areas  A constrained Delaunay triangulation consisting of areas that does not cross line segments within the source object set.

Constrained Triangulation Lines  A constrained Delaunay triangulation consisting of lines that does not cross line segments within the source object set.

Convex Hull  Draw an area that just exactly encloses all objects using the extremal coordinates as bounding coordinates for the area's boundary.

Decompose  Split branched objects into simple (non-branched) objects. For example, a single, branched area object composed of three "islands" will be split into three separate area objects.

Decompose to Convex Parts  Splits area objects into smaller areas automatically. Each smaller area created will be a convex hull for the locations it encloses. This operator is often used to split area objects into smaller areas to allow computations or to create centroids that fall within areas.

Decompose to Triangles  Automatically splits area objects into triangles.

Distance Network  Build a network that connects every pair of points that are within a given distance of each other.

Enclosing Circles  Create an area in the form of the minimum enclosing circle for each object.

Enclosing Rectangles  Create an area in the form of the minimum enclosing rectangle for each object, allowing the rectangle to be rotated as compared to the map window.

Explode  Explode lines into multiple line objects where each line segment from the original line becomes a separate line object. No effect on areas or points.

Farthest Neighbor  Assign each object in the Parameter set to the farthest object from it in the drawing and draw a line between them. Exists in standard and Symmetric versions.

Farthest Pair  Find the two objects that are farthest apart.

Flip Horizontally  Flip objects left / right to their mirror image.

Flip Vertically  Flip objects top / bottom to their upside down image.

Gabriel Network  Creates a Gabriel network on the target point set.

Inner Buffers  Create a buffer zone for each area that is within and smaller than the area by the given distance.

Intersect Lines  Split all lines in the target set into separate lines at intersections and place points at the intersections as well.

Intersection Points  Create points at the intersections of all lines in the target set, including self-intersections.

Join Lines  Join lines with coinciding ends into a new, single line object. Redistribute any data attribute fields according to transfer rules.

Move Horizontally  Move all objects or selected objects the specified distance horizontally. Negative values move objects to the left (West).
| **Move Vertically** | Move all objects or selected objects the specified distance vertically. Negative values move objects down (South). |
| **Nearest Neighbor** | Assign each object in the Parameter set to the nearest object to it in the drawing and draw a line between them. Exists in standard and Symmetric versions. |
| **Nearest Pair** | Find the two objects that are closest together. |
| **Node Points** | Create points at the terminal coordinates of lines, avoiding duplicates at locations where multiple lines terminate. |
| **Normalize Metric** | Fix common flaws in object metrics. |
| **Normalize Topology** | Fix common problems in topology, including snapping lines to nearest points, resolving intersections, resolving overshoots and undershoots and other miscellaneous topological anomalies based on settings in the View - Properties - Precision dialog. Also used to "generalize" drawings to lower precision. |
| **Points** | Create points at all coordinates defining the shape of lines and areas in the target set. Avoids making duplicate points in places where the edges of two areas coincide. |
| **Relative Neighborhood Network** | Relative neighborhood network. |
| **Remove Duplicates** | Remove duplicate objects. Deletes areas, lines or points that appear exactly at the same location. |
| **Reverse Lines** | Reverse the order of coordinates that define a line, thus reversing the "direction" of the line. Used with asymmetric formatting styles so that the style is oriented as desired. |
| **Rotate** | Rotate objects about the approximate center of their minimum enclosing circle by the number of degrees given in the source / argument box. Negative degree values cause counter-clockwise rotation while positive values cause clockwise rotation. Fractional values are allowed. |
| **Scale** | Resize objects by the scale given in the source / argument box. A parameter value of 0.5 resizes objects to half their size. A parameter value of 2 resizes objects to twice their size. |
| **Scale Horizontally** | Resize objects by the scale given in the source / argument box only in their horizontal (East / West) extent. A parameter value of 0.5 resizes objects to half their size. A parameter value of 2 resizes objects to twice their size. |
| **Scale Vertically** | Resize objects by the scale given in the source / argument box only in their vertical (North / South) extent. A parameter value of 0.5 resizes objects to half their size. A parameter value of 2 resizes objects to twice their size. |
| **Segments** | Add redundant coordinates to objects so they are defined using a larger number of coordinates (and thus, segments). This allows preservation of shape when projecting large, simple, vector shapes. |
| **Select Adjacent to** | Select all objects in the target set that are adjacent to any object in the source / argument box set. Objects are adjacent if they have one or more boundary coordinates in common with no other overlaps. |
| **Select Contained within** | Select all objects in the target set that are entirely contained within an object in the source / argument box set. |
| **Select Containing** | Select all objects in the target set that completely contain |
any object in the source / argument box set.

Select Critical Service Centers
Given a set of nodes, called clients, in a network finds the nodes that minimize the maximum path length to any of the clients. This is the classic problem for locating an emergency service center, where at any time one may be called upon to travel from the center to any client. The Select N Critical Service Centers transform uses the source / argument box to set the number of service centers allowed.

Select Euclidean Point Coverage
Select a minimal set of points so that each point from the source set is within the given distance (in the drawing's native measurement units) to at least one point of the result set.

Select Intersecting
Select all objects in the target set that intersect any object in the source / argument box set. Objects intersect if they have any parts in common excluding intersections consisting of common boundary coordinates only.

Select Line Coverage
Select a minimal set of lines so that each line from the source set touches at least one line from the result set.

Select Point Coverage
Given a network, selects a minimal set of points so that each point from the source set is adjacent (through the network) to at least one point of the result set. Normally used with [Selection] in the scope box.

Select Service Centers
Given a set of nodes, called clients, in a network finds the center nodes that minimize the path length to travel from the center to each of the clients and to then return to the center. This is the classic problem for locating a regular or daily service center, where every day one must make the rounds of each of the clients. The Select N Service Centers transform uses the source / argument box to set the number of service centers allowed.

Select Shortest Path
Finds the shortest path between two points in a network.

Select Spanning Tree
Given a network, select lines in the network that make up a minimum spanning tree.

Select Touching
Select all objects in the target set that touch any object in the source / argument box set. Objects touch if they either intersect or are adjacent to each other.

Shape Hull
Tile objects in the drawing with polygonal areas built up out of square tiles using the grid specified in the parameter.

Given a set of points, build a minimum spanning tree network on that point set by adding lines.

Spline
Smooths lines and areas by inserting additional midpoints and using a spline algorithm to replace sharp corners with curves.

Split With
Split target areas and lines using a given set of lines.

Triangulation
Create a Delaunay triangulation consisting of both lines and areas for the selected point set.

Triangulation Lines
Create a Delauney triangulation consisting of lines for the selected point set.

Triangulation Areas
Create a Delauney triangulation consisting of areas for the selected point set.

Union
Combine all areas in the target set into one area object.

Voronoi Diagram
Create area, line and point objects for each Voronoi cell.
Voronoi Lines  Create line objects for each Voronoi cell.

Voronoi Areas  Create area objects for the Voronoi diagram.

Voronoi Points  Create point objects for the Voronoi diagram.

**Automatic Normalization**

This is an advanced subject that assumes the reader is fluent with the internal topological structure of objects.

Manifold maintains automatic cleaning of object metrics. Automatic normalization occurs for those transform operators that require clean object metrics. Before any such Transform toolbar operator begins operation, Normalize Metric automatically will be run on all objects that need to be cleaned.

The automatic normalization is an internal Manifold function that occurs whenever it is required during transform toolbar operation. Due to the caching behavior of Normalize Metric the amount of time for cleaning (if required) will vary depending on whether or not objects in the drawing are marked "clean" or not. A particular transform operator might run very rapidly and then just after **Location Precision** has been changed suddenly run much more slowly during the next run. The slower run occurs because all of the objects have had their "clean" flag cleared as a result of the precision change, so Normalize Metric will have more work to do for that run.

When dealing with imported drawings that may contain specific features of the metric that are to be preserved, users will often choose to begin operations by running the Normalize Topology transform operator on all objects in the drawing. This will clean object metrics while preserving redundant coordinates that are co-located with other objects, and it will mark all objects as having clean metrics. This avoids a situation where Manifold is compelled to run Normalize Metric even though we do not want it run.

When in doubt run **Normalize Topology** once before running other transforms. This can be very time consuming for large drawings, but it is a prudent and necessary step experts will take if they wish to preserve specific metrics.

**See Also**

Transfer Rules for information on controlling how database table information is transferred to new objects that are created by transform operators. For example, when creating centroids the transfer rules within the drawing’s table specify which fields should be transferred to the centroids.
**Transform - Attach to / Attach to Self**

These operators move the coordinates of one object to align to the coordinates of another object or objects. They are mainly used to adjust areas and lines to the shapes of adjacent areas or lines within the same object set or across different object sets.

Both the Attach to and the Attach to Self operators adjust coordinates within the location precision distance parameter that is set for drawings in the View - Properties - Precision dialog. If the location precision parameter is larger than the distance between objects, the objects will be adjusted by moving the coordinate locations that define the objects to the nearest coordinate location of the reference object.

The Attach to operator attaches objects in one object set to objects in a different object set. The Attach to Self operator adjusts objects within the same object set to each other.

**Example**

Consider a map that shows two drawings.

One drawing, called **Lines**, contains a line while the other drawing, called **Areas** contains an area. The location precision has been set to less than the distance between the line and the area.

If we run the transform toolbar using [All objects in Lines] Attach to [All objects in Areas] then the line in **Lines** will be altered to become adjacent to the area in **Areas**.

The Attach to operator works with all types of objects. For example, areas may be attached to other areas.
Suppose we have a drawing called Gray with an area and another drawing called Yellow with another area.

If we used [All objects in Gray] Attach to [All objects in Yellow] the gray area would be adjusted to become adjacent to the yellow area.

Example

The Attach to transform will also move coordinates in parts of objects that are not near the target if the location precision distance is great enough.

Consider a drawing with three area objects, colored differently using thematic formatting to specify a different color for each area.
We will select the upper two objects and create a saved selection called Green.

We select the lower object and create a saved selection called Blue.

We run the transform toolbar with a setting of Green - Attach to - Blue and the areas in the Green saved selection will be attached to the blue object, but if the location precision distance is large enough (as it has been set for the example above) they will also be attached to each other and their other coordinates will be moved as well.

Example

Consider a drawing with three area objects, colored differently using thematic formatting to specify a different color for each area.
We will run Attach to Self using an object set of [All Objects] using three different settings for location precision. In each case we will begin with the drawing above, specify the location precision distance and then run Attach to Self.

As we increase the value of location precision distance (that is, making operations less precise)...  

...coordinates will be moved more aggressively because more of them fall within the location precision distance of each other.
When working with Attach to or Attach to Self the setting used for location precision will be critical, as this value must be set appropriately given the nearness of objects being attached to objects to which they are to be attached.

Although it is theoretically possible to attach objects to themselves using the Attach to operator, if this is what we have in mind we should use the Attach to Self operator which in most cases produces much better results.

View - Properties - Precision
**Transform - Boundaries**

The **Boundaries** operator in the Transform toolbar for drawings will add line objects that exactly coincide with the periphery of every area object in the target set.

In the illustration above, boundary lines have been created for the four Western US states areas. The boundary lines have been selected and moved slightly in the illustration at right to show clearly the addition of lines.

Note that creating a boundary line around each area will create coincident lines along places where the periphery of one area coincides with the periphery of an adjacent area. This may be seen in the above example by dragging apart each of the boundary line objects.

**Tech Tip**

Many transforms automatically run a Normalize Topology transform before running to eliminate common errors that may affect correct operation. The **Boundaries**, Points and Node Points transform operators do not normalize target objects before running. This makes it possible, for example, to segmentize lines with a length threshold of 10 meters, and then use the **Points** transform to place point objects at the locations of resulting inflection points.

The **Boundaries** operator will not split resulting objects if the **Split branches objects after transforms** option is turned off in the Tools - Options dialog.

**See Also**

Transform - Bounded Areas to create area objects from boundary lines.
**Transform - Bounded Areas**

The **Bounded Areas** operator in the Transform toolbar for drawings will add an area object in every region that is enclosed by lines, including those regions created by lines that intersect themselves.

In the illustrations above, four new areas have been created.

**Holes and Islands**

The **Bounded Areas** transform operator will try to resolve regions enclosed by lines within other closed border lines as separate areas. This is a very useful capability when creating lines from closed contours.

Suppose we have one region enclosed by lines that is entirely within another region enclosed by lines. We can select the lines and run the **Bounded Areas** transform operator from the transform toolbar.

By using **Touch Select** and touching both areas in turn we can see that the result is two areas have been created. One area is the inner circle and the other area is the larger circle with a "hole" in it where the inner circle area is located.

**Creating Areas in Drawings**

The **Bounded Areas** operator is frequently used when we import a data set that consists of lines and we would like to have areas. For example, we might import a drawing that outlines lakes or other regions using lines. We can use such drawings to create areas for lakes.
Suppose we've imported a drawing showing Great Bear Lake in Canada drawn as a boundary line. We can select the lines and run the **Bounded Areas** transform operator. The drawing is shown with **Background** turned off in the Layers pane so that the default checkerboard pattern shows through and makes it clear that only lines are involved.

The result is areas created within enclosed lines.

Zooming far into the region in the middle Eastern part of the lake we can deselect the largest area in the lake to see that smaller enclosed regions (representing islands) were created as separate areas by the **Bounded Areas** operator.
If we wished to create a single area for the lake to use within a map we might not want the other areas and can easily (since they are selected) delete them.

**Notes**

Be careful (and skeptical) when working with drawings that have been imported from CAD systems and other topologically unaware software. Such software might create lines that appear to be closed to form a region, but that upon examination at very high zoom levels will be seen to not connect to form closed regions. If the operator yields unexpected results, examine the lines that were thought to be closed for small breaks. For example, if selected contour lines do not result in neat areas it may be possible that the contour lines are not closed figures.

If the lines involved have data attributes, the created areas will acquire the data in accordance with the transfer rules that have been specified for those data columns.

**See Also**

Transform - Boundaries to create boundary lines from area objects.
Transform - Bounding Boxes

Create an area in the form of a rectangular bounding box that encloses each object and is aligned vertically and horizontally with the map window.

In the illustration above we have created a bounding box for the province of Zacatecas in Mexico.

Bounding boxes are created as areas and are selected when they are created. We would normally move them to their own layer so that they can be formatted and placed where desired in the layer stack. If we would like to have bounding boxes as lines we can take the areas and use the Boundaries transform toolbar operator to create lines.

The Common Bounding Box transform operator is like Bounding Boxes, but creates one bounding box about all objects in the scope.

In the example above the green areas were created with Bounding Boxes using the lines and the blue area was created with Common Bounding Box.
**Transform - Buffers**

Create a buffer zone for each object extending outward by the given distance and including the original object. For areas, this is an outer buffer zone.

Units used for the distance value in the source / argument box are taken from the projection of the drawing. If the drawing is in *Latitude / Longitude* projection the units will be degrees. If the drawing is projected, the units will be in meters or feet. It is therefore strongly recommended that the drawing be projected first so that meters or other linear measure can be used instead of attempting to use degrees as a measurement unit.

To see which units are defined for the drawing's projection, click on the Tracker tool and make some measurements. Whatever units are used to show the result of the tracker tool are the units currently in force. The tracker tool is also useful for estimating the desired size range of the buffer zone.

If the drawing uses degrees and meter-based creation of buffer zones are desired, first re-project the drawing into any convenient meter-based projection (such as *Orthographic*) so that meters will be used as the units of measure.

See the Transform - Border Buffers topic for a detailed example illustrating the creation of buffer zones.

**Buffer Zone Variations**

The transform toolbar provides four different buffer zone variations.

Variations are shown based on the area shown above in blue dotted style. All variations were created by showing the resultant buffer zone area as a 50% transparent layer in a map.
The **Buffers** operator creates an outer buffer zone, extending 15000 meters outward from the boundary of the area and including the original area.

**Inner buffer zone**, comprising all parts of the original area except those extending 15000 meters inward from the boundary of the area.

**Border buffer zone**, extending both inward 15000 and outward 15000 from the boundary of the area.

The **Common Buffer** transform operator is like **Buffers**, but creates one buffer zone about all objects in the scope.

In the example above the green areas were created with **Buffers** using the lines and the blue area was created with **Common Buffer**. Note that there are three area objects in the case of the green buffer zones but only a single area object in the case of the common buffer.

**Local Scale and Units of Measure**
Stating that the units used by buffer operators are the units used in the projection is actually an oversimplification. More accurately, the parameter value is taken as the number of local drawing units. Local drawing units are normally the same as the units used by the projection. Local drawing units are the projection units multiplied by the **Local scale** value for the coordinate system specified in the Edit - Change Projection dialog.

Because the **Local scale** value is usually 1, the value used in the source / argument box for buffer operators is usually the same number in local drawing units. Entering 1500 in a meter-based projection thus means 1500 meters. However, if the **Local scale** value is not 1, the value in the source / argument box must be multiplied by the **Local scale** value to get the number of units that will be used to create the buffer. If the **Local scale** value is 10 in a meter-based projection, for example, then entering 50 into the source / argument box is not a command to create a 50 meter buffer, it is a command to create a 500 meter buffer.

An additional subtlety must be considered when this transform operator is used with a drawing layer within a map. If the map component's projection is degree based while the native projection for the drawing is meter based (as, for example, with the **Orthographic** projection) or vice versa, then the transform operator will use whatever units are used by the drawing's projection.

**Tech Tip**

Variations on the basic buffer zone constructions with areas may be easily created by first creating a buffer zone and then using **Clip with (Intersect)** or **Clip with (Subtract)** between the new buffer zone area object and the original area object. For example, using a **Clip with (Intersect)** between a border buffer and the original area will produce a zone that consists only of the defined distance within the area's boundary and that excludes the more inner regions of the original area as well as everything outside of the boundary.

The buffer distance used must be at least four times the size of the location precision factor. If precision has been set to 10 meters then the buffer distance must be larger than 40 meters.

**See Also:**

**Transform - Inner Buffers**
Transform - Centroids

Three related transform operators create centroids for objects using different methods. Centroids are points placed at the "center" of an object. They are used for many reasons but perhaps the most important is to simplify and abstract geographic data in the form of areas or lines into the much simpler form of points. At times we will want the data in a simpler form for export to other programs or to use analytic methods that work with points but which do not work with areas or lines.

Centroids | Create a point at the center of the minimum circle that encloses each object. (areas or lines)
Centroids (Box) | Create a point at the center of the minimum enclosing rectangle for each object. (areas or lines)
Centroids (Inner) | Create a point at the "center" of an area and adjust the position of the point so that it always falls within the area. (areas only)
Centroids (Weight) | Create a point at the approximate center of balance of each object. (areas only)

Centroid operators do nothing for points, since a point is always its own centroid. Two of the three operators can work with lines as well as with areas. When a centroid object is created it inherits the data fields of the object from which it was created. The illustrations above show centroids created for areas with the Centroids operator.

The Common Centroid transform operator is like Centroids, but creates one centroid using the center of the minimum enclosing circle for all objects in the scope.

Examples

In the examples that follow we will use the province of Zacatecas in Mexico as a sample area.

The Centroids (Weight) operator creates a point at the approximate center of balance of the area. It uses a fast algorithm that will usually, but not always, place the centroid point within the area. Very strange area shapes such as horseshoe shapes will cause the centroid point to be placed outside the area.
The **Centroids** operator draws a minimum enclosing circle about each area and creates the centroid at the center of the circle. The illustration above shows the circle centroid in red. Note that the position of the circle centroid is different from the centroid computed for the approximate center of balance.

The **Centroids (Box)** operator draws a bounding box about each area and creates the centroid at the center of the bounding box. The illustration shows a bounding box superimposed above an enclosing circle with the box centroid shown as a small square dot.

**Centroids (Inner)**

We will often encounter areas where the centroid computed using the **Centroids**, **Centroids (Box)** or by the **Centroids (Weight)** transforms will be placed outside an area.

Consider a map of the Southeastern United States.
If we create centroids (green dots) using the Centroids transform we see that the centroid for Florida falls outside of the state. If we were too zoom far into the drawing we would see that the centroid created for Louisiana also falls outside that state.

We can use the Centroids (Inner) transform to create centroids (yellow squares) that are guaranteed to fall within their areas.

**Centroids and Lines**

Because an enclosing circle or a bounding box can be found for lines as well as for areas we can create centroids for lines using the box and circle centroid operators.

This illustration shows four lines with their centroids, computed using Centroids.
If we draw enclosing circles about each line (shown in red selection color) we can see how the locations of the centroids were determined.

Centroids are most frequently created for areas. However, they are also a useful means of "converting" line objects into point data. For example, the above illustration shows lines in a hydrography layer where what appear to be continuous lines are in fact many lines that abut one another.

Using the Centroids operator we can create centroids for each individual line.

As an example of why we would want to do so, suppose for each line segment we have the length of the line. We would like to know the total length of waterways per square kilometer in various regions of the map. We can approximate this by creating a grid where each box is one kilometer square and then creating centroids for each line segment. It is then an easy matter to add up the total "length" values for each centroid point that happens to be in each square kilometer grid box.

In the example above the green points were created with Centroids using the lines and the blue point was created with Common Centroid.

Tech Tip

Many transforms automatically run a Normalize Topology transform before running to eliminate common errors that may affect correct operation. The Centroid Circle, Centroid Box and Common Centroid transform operators do not normalize target objects before running.
Transform - Decompose

Split branched objects into simple (non-branched) objects. For example, a single, branched area object composed of three "islands" will be split into three separate area objects.

Example

Many drawings will show a mainland region and islands as composed of the same area object. If we wish to delete some of the islands we might first want to use decompose to convert the single, complex, branched area object into many unbranched objects. We can then delete the unbranched objects quickly.

Suppose we have such a drawing. If we click with select touch on any of the "areas" we see they are all selected.

All of the "areas" are selected at once because they are all part of the same area object. We can use decompose to split them apart.

To do so, we load up the transform toolbar as seen above and push Apply.

Thereafter, if we click with select touch on any of the areas we see that only the object touched is selected. This is because all of the "objects" we see are now truly separate area objects.

Note: some GIS systems may refer to this function as "explode."
Transform - Decompose to Convex Parts

The **Decompose to Convex Parts** operator splits area objects into smaller areas automatically. Each smaller area created will be a convex hull for the locations it encloses. This operator is often used to split area objects into smaller areas to allow computations or to create centroids that fall within areas.

![Decompose to Convex Parts Example](image)

Given an area at left the **Decompose to Convex Parts** transform will split it into smaller areas as seen at right. Each smaller area is a convex hull for locations it contains. There are many possible decompositions of a larger area into smaller areas in this way. The algorithm generates one such decomposition.

Note that since each smaller area is a convex hull for the locations it contains, the centroid of each of the smaller areas is guaranteed to be located within the area.

![Centroid Example](image)

With some areas, as seen above, the centroid lies outside of the area. If centroids are created to allow transfer of areas to points via the Spatial Overlay dialog (that is, using "point in polygon" operations) for analytic or other purposes, the centroid point might not fall within the desired area. One approach to solving this problem is to split each area into smaller areas and to then use centroids for those smaller areas.

![Decomposed Areas](image)

We can use **Decompose to Convex Parts** to split the area into smaller areas.
The centroids for each will fall within the area. We can now transfer data using spatial overlays knowing that the fields for each area will transfer to a centroid point within that area.

**Notes**

- Use the Centroids (Weight) operator to create centroids that are more centered on each smaller area.
- The transfer of data fields to the new areas will be governed by the Transfer Rules for the fields.
Transform - Decompose to Triangles

The **Decompose to Triangles** operator automatically splits area objects into triangles. The triangles are created using the Delaunay criterion, which seeks to maximize the minimum angle of each triangle. This operator is often used to split area objects into triangles to allow computations or to create centroids that fall within areas. See the discussion of such usage in the Decompose to Convex Parts topic.

Suppose we have an area that we wish to decompose into triangles.

After running the operator the area will be replaced with two triangular areas.

The operator can, of course, be used with considerably more complex areas, such as those representing geographic entities such as the island shown above, located off the coast of Mexico.
Decomposing it into triangles results in many triangles. The triangles are created using the coordinates that define the area as vertices for the triangles.

Notes

- The transfer of data fields to the new triangular areas will be governed by the Transfer Rules for the fields.

See Also

- Triangulation
- Decompose to Convex Parts
The **Distance Network** transform operator creates a network link between all points within the given distance.

In the illustration above we've created a grid of points using the View - Grid tool. The points are 48 meters apart horizontally and vertically.

Setting up the transform toolbar as seen above with a distance of **50** will result in the following network.

Links have been drawn between neighbors in a vertical and horizontal pattern. The diagonals have not been drawn because the hypotenuse between points is greater than 50 meters.

If we delete the selected lines added by the transform and run the **Distance Network** operator one more time with a value of **70** we get the following result:

In this case links have been drawn on the hypotenuse diagonals as well because each point is 69 meters away from the diagonal neighbor (as is easily seen with the Tracker tool).

Note that in both of the above cases, the **Distance Network** operator created **two** links between each point: one in each direction. The extra links can be deleted by selecting all links and then running the Normalize Topology transform operator. This will delete duplicate coincident links.
Units of Measurement

Units used for the distance value in the source / argument box are taken from the projection of the drawing. If the drawing is in Latitude / Longitude projection the units will be degrees. If the drawing is projected, the units will be in meters or feet. It is therefore strongly recommended that the drawing be projected first so that meters or other linear measure can be used instead of attempting to use degrees as a measurement unit.

To see which units are defined for the drawing’s projection, click on the Tracker tool and make some measurements. Whatever units are used to show the result of the tracker tool are the units currently in force.

If the drawing uses degrees and meter-based creation of buffer zones are desired, first re-project the drawing into any convenient meter-based projection (such as Orthographic) so that meters will be used as the units of measure.

When this transform operator is used with a drawing layer within a map the units used by the drawing will be used. If the map component’s projection is degree based while the native projection for the drawing is meter based (as, for example, with the Orthographic projection) or vice versa, then the transform operator will use whatever units are used by the drawing’s projection.
Transform - Enclosing Circles
Create an area in the form of the minimum enclosing circle for each object.

In the illustration above we have created an enclosing circle for the province of Zacatecas in Mexico.

Enclosing circles are created as areas and are selected when they are created. We would normally move them to their own layer so that they can be formatted and placed where desired in the layer stack. If we would like to have enclosing circles as lines we can take the areas and use the Boundaries transform toolbar operator to create lines.

The Common Enclosing Circle transform operator is like Enclosing Circles, but creates one minimum enclosing circle for all objects in the scope.

In the example above the green areas were created with Enclosing Circles using the lines and the blue area was created with Common Enclosing Circle.

Tech Tip

Many transforms automatically run a Normalize Topology transform before running to eliminate common errors that may affect correct operation. The Enclosing Circles transform operator does not normalize target objects before running.
Transform - Enclosing Rectangles
Create an area in the form of the minimum enclosing rectangle for each object, allowing the rectangle to be rotated as compared to the map window.

Given the two lines above, applying the Enclosing Rectangle operator creates the areas shown below. Note that since there are two lines, a minimum enclosing rectangle is created for each.

The Common Enclosing Rectangles transform operator is like Enclosing Rectangles, but creates one minimum enclosing rectangle for all objects in the scope.

In the example above the green areas were created with Enclosing Rectangles using the lines and the blue area was created with Common Enclosing Rectangle.

Tech Tip
Many transforms automatically run a Normalize Topology transform before running to eliminate common errors that may affect correct operation. The Enclosing Rectangles transform operator does not normalize target objects before running.
**Transform - Explode**

Explode lines into multiple line objects where each line segment from the original line becomes a separate line object. This transform operator has no effect on areas or points.

When new lines are created their data attributes will be taken from the original line according to the transfer rules specified for the table's columns.

**Example**

Consider a drawing with one line, that has been selected.

<table>
<thead>
<tr>
<th>ID</th>
<th>Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>16</td>
<td>Hwy 101</td>
</tr>
</tbody>
</table>

In the drawing's table we can see there is only one object. The **N to 1** transfer rule for the **Name** column has been set to **Copy**.

If we run the **Explode** transform, we convert each segment of the line into a separate line object. We can select a few segments to show they are now separate lines.

<table>
<thead>
<tr>
<th>ID</th>
<th>Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>17</td>
<td>Hwy 101</td>
</tr>
<tr>
<td>18</td>
<td>Hwy 101</td>
</tr>
<tr>
<td>19</td>
<td>Hwy 101</td>
</tr>
<tr>
<td>20</td>
<td>Hwy 101</td>
</tr>
<tr>
<td>21</td>
<td>Hwy 101</td>
</tr>
<tr>
<td>22</td>
<td>Hwy 101</td>
</tr>
<tr>
<td>23</td>
<td>Hwy 101</td>
</tr>
</tbody>
</table>

The drawing's table now shows clearly that there are multiple lines. The effect of the **Copy** transfer rule is to copy the value of the **Name** column into each of the new line objects created.
Note also that there is no longer an object with an ID of 16 because the original line object has been deleted. It has been replaced by the newly created lines, one for each of the former segments.
Transform - Join Lines

Join lines with coinciding ends into a new, single line object. Redistribute any data attribute fields according to transfer rules.

In the example shown above, suppose A1, A2, A3, B1 and B2 are all separate line objects. Suppose further that the ends of the lines are exactly coincident and do not have gaps between them as shown in the illustration

Running the Join Lines transform on the selection contain these five line objects will create two new line objects.

One new line object will be made up of A1 + B1 + A2. The other new line object will be made up of A3 + B2.

Technical Note

Given an arbitrary set of lines it can be remarkably difficult to join "coincident" lines. After all, consider that lines can be multi-branched objects like areas. In the case of multi-branched lines what appear to be two different line objects can be the same object. For example, in the illustration above a topologically complex (and weird) drawing could have B1 and B2 both be branches of the same line object and A1, A2 and A3 also be three different branches of the same line object.

Given a set of lines the Join Lines transform creates a network with a link for each branch of each line and then composes another set of lines that collapse chains within the network. Note that chains could consist of parts of different objects). This algorithmic approach combining graph theory and computational geometry provides a flexible, reliable transform operator that can deal with arbitrarily complex topology.

See Also

Dissolve - The Dissolve tool can join lines by data attribute. It uses the Join Lines algorithm to join lines together that have the given data attribute.
T
**Transform - Intersection Points**

The **Intersection Points** operator in the Transform toolbar for drawings will add a point object at every location where lines intersect each other, including self-intersections.

This command does not change the lines in any way. It simply adds points at the places where lines cross each other.

**See also:**

- Transform - Intersect Lines to add points at intersections and also split lines into separate line objects at intersections.
- Transform - Points to add points at all coordinates defining the shape of lines and areas.
Transform - Node Points

The Node Points operator for drawings creates a point object at the end of every line object. If the ends of several line objects coincide, only one node will be created at that location. This transform is used to build true networks out of systems of lines.

Suppose we have three lines that are incident to each other at a location. If we would like to treat these three lines as a network we need to create a point at the ends of the lines.

Applying Node Points creates a point at the end of each line. Only one point is created at the location where all three lines are incident to each other.

Note the difference between the Node Points and the Points transform.

Had we run the Points transform on the initial drawing we would have obtained the result above. The Points transform adds points at every coordinate location that defines the shape of the lines. The Node Points solver adds a point at only the terminal coordinate locations.

Nomenclature

Manifold can treat any system of lines and points as a network. When we discuss network subjects within Manifold, we shift terminology so that points are called nodes and lines are called links. People unfamiliar with networks will often refer to a system of lines such as that in the first illustration above as a "network." However, a network is defined by its nodes, not by its links. Links are simply a way of describing how the nodes of a network are formed into a network. If a drawing (or map) has no points, it is not a network.

Some GIS systems inaccurately use the word node to mean one of the coordinate locations that defines the shape of a polyline. That's a grave error since the world of networking (a considerably larger user population than GIS) in both computers and mathematics uses the word node to mean a point that is a vertex in a network.

Since GIS users will often wish to use a system of lines as a network even if it contains no nodes, Manifold takes a less strict view: default operators in Manifold will treat as a network any system of lines where the endpoints of the lines exactly coincide even if no points exist at the ends of the lines. Use the Node Points transform to add points to create a true network. This will avoid trouble with other software or scripts that may apply sophisticated network mathematics and insist that the "network" in use is a true network.

Tech Tip
Many transforms automatically run a Normalize Topology transform before running to eliminate common errors that may affect correct operation. The Boundaries, Points and Node Points transform operators do not normalize target objects before running. This makes it possible, for example, to segmentize lines with a length threshold of 10 meters, and then use the Points transform to place point objects at the locations of resulting inflection points.

See Also

About Networks
**Transform - Points**

The Points operator in the Transform toolbar for drawings will add a point object at every coordinate location defining the shape of objects in the target box.

![Diagram](image)

When applied to lines, note how a point is created at each of the coordinate locations where the line changes direction.

This command is often used to "convert" areas or lines into sets of points in the shape of those objects.

**Tech Tip**

Many transforms automatically run a Normalize Topology transform before running to eliminate common errors that may affect correct operation. The Boundaries, Points and Node Points transform operators do not normalize target objects before running. This makes it possible, for example, to segmentize lines with a length threshold of 10 meters, and then use the Points transform to place point objects at the locations of resulting inflection points.

**See Also**

Transform - Intersection Points to add points to locations where lines intersect.

Transform - Node Points to add points to systems of lines so that the resulting drawing or map can be used as a true network.
Transform - Clip with (Intersect) / (Subtract)

The Clip with operators in the Transform toolbar for drawings use one or more areas to "clip" other objects, leaving only those parts of the other objects that lie within the areas (Intersect) or removing those parts of the other objects that lie inside the areas (Subtract).

For clarity, the following examples show use of only one clipping area. However, more than one area may be in the "clip with" set. The examples use one area to clip lines. The commands also work when areas are used to clip other areas, no matter how topologically complex the areas involved may be.

Clip with (Intersect)

Using a drawing that shows the state of Texas overlaid with lines forming a grid, we first select the state of Texas and save it within the View - Selections dialog as a saved selection called Texas. We can select the lines and then apply the Clip with (Intersect) command in the Transform toolbar:

The Transform toolbar knows we have made a selection, so the target box is loaded with the selection as the target. We choose Texas in the source / argument box (all of our saved selections will appear as possible choices in the source / argument box) and press Apply.

The result is to split all objects at their point of intersection with the periphery of the Texas area and to discard all objects lying outside of Texas. This is called an "intersection" because it retains all objects where there is an object and there is Texas.

Suppose we have two drawings in a map. Drawing B contains green rectangles and Drawing A contains blue circles (seen with 50% opacity above the rectangles layer).
If we use [All Objects in Drawing B] Clip with [Intersect] [All Objects in Drawing A] in the transform toolbar the result is seen above. Drawing A has been turned off. What is left of the rectangles is the intersection between objects in Drawings A and B. Note that this intersection operation removed everything from the rectangles except the region of intersection. If we wanted to retain the original rectangles as well as the intersections we could have made a copy of Drawing B and used that in the Clip with [Intersect] operation.

Clip with (Subtract)

Beginning once again with Texas overlaid with a grid of lines, we can apply the Clip with (Subtract) command.

The toolbar is the same, except we choose Clip with (Subtract) and hit Apply.

The result is to split all objects at the boundary of Texas and to subtract all objects that lie within Texas.

Clip with Works with All Objects

These commands also work when areas are used to clip other areas, no matter how topologically complex the areas involved may be.
The illustrations above show Clip with (Intersect) and then Clip with (Subtract) applied to two areas using Texas as the "clip with" area.

It is often the case that we have a map showing roads, lakes and other objects throughout an entire region and we wish to make a map that shows only the objects within a part of the region, such as a specific state or province. The Clip with commands are a straightforward means of cutting out only those objects within the desired state or province. Simply use the state or province as an area object with Clip with (Intersect) to cut out only those parts of the objects that are within the desired area.

To keep the illustrations in this topic simple, only illustrations using either lines or areas have been used; however, the commands work perfectly no matter what mix of objects is in the target set.
The transform toolbar includes two operators to find clusters: the Clusters and the Clusters (Zahn) operators. The two operators both find clusters of points but use slightly different approaches. Both employ manifold.net graph theoretic algorithms to find clusters.

- The Clusters form uses relative neighborhood networks to distinguish clusters based on a combination of network and geometric relationships. Applying this operator with a parameter of 0 results in a relative neighborhood network. Relative neighborhood networks incorporate reckoning of the overall arrangement of a point set and are superior to ordinary, local nearest neighborhood methods.

- The Clusters (Zahn) form uses minimum spanning tree networks to distinguish clusters based on minimum path spanning trees. It is named to honor Charles T. Zahn for his work in describing the general use of minimum spanning tree graphs in cluster detection. The links created using this operator are a subset of the links created when a minimum spanning tree is formed. Minimum spanning trees incorporate links based on the minimum traversal of a branched tree that reaches all points, so this form may better reveal clusters arising from spatial propagation.

Clusters are simply collections of points that appear to form groups or to otherwise be related to each other. We may use various mathematical techniques to identify them; however, what counts in most GIS analysis and data mining is the use of cluster-finding methods to identify groups of points for further examination. The essential thing is if the software reveals patterns that make sense to us once we see them but which otherwise could not be found by eye.

The Clusters operators work by creating links between points that are parts of a cluster. The value given in the source / argument box guides the operation. Smaller parameters will result in larger clusters.

Suppose we begin with the set of points shown above. If we apply the Clusters operator with a parameter of 50 it will create lines between points for the clusters found as shown below:
By increasing or decreasing the parameter we can force fewer or more of the unconnected points to be assigned to a cluster.

The (Zahn) form of the operator results in the above clusters when run with a parameter of 50.

**See Also**

Relative Neighborhood Network - The transform operator that creates relative neighborhood networks. This topic includes a note on characteristics of relative neighborhood networks.

**Spanning Tree** - The transform operator that creates minimum spanning trees.

**Notes**

In graph theory, networks are called **graphs**. When searching Internet for information on these topics try searching for words like "relative neighborhood", "graph", "spanning tree", "cluster" and similar. These ideas are applied in an astonishing range of disciplines, from fungal spore distribution patterns to the characterization of finds in archeological sites.
The points for the examples above were created by making centroids for provinces in Mexico using the **Centroids (Weight)** transform operator. The points and results of the transform operators are shown in a map with a drawing of Mexico as a backdrop. We used the centroids as a source set of points because they are dispersed in a geographically interesting way. There is no meaning to the map of Mexico; however, if we were to place one antenna in the geographic center of each province and then we wished to link the antennas in a network we would likely create and study maps such as these.
Transform - Constrained Triangulation

Similar to the triangulation transform, the constrained triangulation transform creates a constrained Delaunay triangulation of a point set by treating the points as nodes in a network and drawing links between them that divides the region between the points into triangular tiles.

There are two differences between triangulation and constrained triangulation:

- Unlike the triangulation transform, the constrained triangulation transform will not draw links through pre-existing line segments.
- The triangulation transform operates only on point objects. The constrained triangulation transform can operate on any object, and will treat the coordinates of lines and areas (inflection points) as points for the triangulation.

There are three transform operators for constrained triangulation:

- The Constrained Triangulation Lines operator creates lines for the triangulation.
- The Constrained Triangulation Areas operator creates areas for the triangulation.
- The Constrained Triangulation operator creates both lines and areas for the triangulation.

See the Transform - Triangulation topic for a general discussion of triangulation.

Example

If we take a set of points as shown above and apply the Triangulation Lines transform operator...

...we can create a triangulation consisting of lines, shown in blue above.
Suppose, however, if we had started with both points and lines (shown in yellow) as seen above and applied the "Triangulation Lines" transform operator.

The result would be the same triangulation, with some of the lines created for the triangulation crossing the pre-existing yellow lines. There are many applications where we would not want a triangulation crossing pre-existing lines. For example, perhaps such lines mark the boundaries between contours or show highways or property boundaries which the triangulation should not cut. We can respect pre-existing lines by using constrained triangulation.

Suppose we start with a set of points and lines and then apply the "Constrained Triangulation Lines" transform operator.
The result shown in light violet color shows that none of the triangulation lines cross any of the pre-existing lines.

We can see the difference between the lines created by triangulation and those created by constrained triangulation by showing the two together as layers in a map with constrained triangulation lines shown in light violet color and triangulation lines shown in thinner blue lines.

The red lines above show lines created in triangulation that are not created in the constrained triangulation.
Constrained triangulation creates a new line, shown in red above, that is not created by regular triangulation.

**Example**

Unlike regular triangulation, which only works with points, constrained triangulation can work with points, lines and areas. The coordinates of lines and areas are taken as points for the purpose of constrained triangulation. This allows us to create constrained triangulations using lines or areas.

The classic example might be creating a triangulation on a set of contour lines. If we begin with the lines seen above and apply the **Constrained Triangulation Areas** operator...
...we create the triangulation seen above, where the triangulation areas are colored in gray. Note that because of the constrained nature of the triangulation no created area cuts across a pre-existing contour line.

**Tech Tip**

Depending on the location of pre-existing segments, the triangulation created by the transform may or may not conform to the Delaunay principle.

**See Also**

- Decompose to Triangles
- Transform - Triangulation

Other types of networks easily created with transform operators:

- Gabriel Network
- Relative Neighborhood Network
- Spanning Tree
**Transform - Convex Hull**

Given a set of points, this operator creates an area about the points using the positions of the extremal points as the bounding coordinates for the area. This is easiest to visualize if we imagine the points to be vertical pegs set on a board and a rubber band is placed around the collection of points to define the shape of the area.

![Diagram of Convex Hull](image)

Running the convex hull transform on the points at left results in the area seen at right. The area line created by this operator will be selected after it is created.

**Tech Tip**

Many transforms automatically run a Normalize Topology transform before running to eliminate common errors that may affect correct operation. The Convex Hull transform operator does not normalize target objects before running.
**Transform - Flip Horizontally**

Flip objects left / right to their mirror image. Because calculations must be made to find the center of the objects to be flipped, it is strongly recommended that drawings be projected before using this operator.

**Example**

We begin with a map of Europe in **Orthographic** projection. The area representing Italy has been selected. Next, load the Transform toolbar with

```
[selection] Flip Horizontally
```

and press **Apply**. This is a command to flip Italy left / right to its mirror image.

This command is most frequently used in CAD-style editing of non-geographic data. It is shown here in a geographic setting to make clear its effect.
Transform - Flip Vertically

Flip objects top / bottom to their upside down image. Because calculations must be made to find the center of the objects to be flipped, it is strongly recommended that drawings be projected before using this operator.

Example

We begin with a map of Europe in Orthographic projection. The area representing Italy has been selected. Next, load the Transform toolbar with

[selection] Flip Vertically

and press Apply. This is a command to flip Italy left / right to its mirror image.

This command is most frequently used in CAD-style editing of non-geographic data. It is shown here in a geographic setting to make clear its effect.
Transform - Gabriel Network

Given a set of points this operator builds a Gabriel network on that point set by creating new lines to serve as the links. **Note:** In a classic Gabriel network, the set of points should not include any co-incident points, that is two points which lie exactly at the same location.

A **Gabriel network** is a network where the links are determined by making a pairwise comparison of points in the context of the points around them. We start with a set of points, and consider all possible pairs of points in the set. For each pair of points, we draw a link between them if there are no other points which lie inside a circle whose diameter is the distance between the points and which is defined by the two points.

The construction above shows a Gabriel network for a set of five points. Note that if any other pairs of points are considered, the circle defined by them would include at least one other point and thus the link is not drawn.

The lines created by this operator will be selected after they are created. It's a good idea to move them to a new drawing to keep the map well organized.

**Example**

Using the set of points above, we can create the Gabriel network seen below.
Note that a subset of a Gabriel network is created by the Relative Neighborhood Network transform operator as seen below:

The Gabriel network is a good way to organize a set of points into a network that maintains a reasonable overall shape of the point set. The relative neighborhood network refines this to create a sparser network that takes greater account of each local point clustering compared to surrounding points. An even sparser network can be created using the Minimum Spanning Tree operator, the results of which are seen below:
The minimum spanning tree removes loops that are present in the relative neighborhood network and creates a network that uses the minimum total length of links between points that connects all of the points.

**See Also**

Relative Neighborhood Network - The transform operator that creates relative neighborhood networks, which are subsets of Gabriel networks. This topic includes a note on characteristics of relative neighborhood networks.

Spanning Tree - The transform operator that creates minimum spanning trees.

Clusters - Transform operators that use relative neighborhood networks and minimum spanning trees to find clusters.

**Notes**

In graph theory, networks are called graphs. When searching Internet for information on these topics try searching for words like "gabriel graph", "relative neighborhood", "graph", "spanning tree", "cluster" and similar. These ideas are applied in an astonishing range of disciplines, from fungal spore distribution patterns to the characterization of finds in archeological sites.

The points for the examples above were created by making centroids for provinces in Mexico using the Centroids (Weight) solver. The points and results of the transform operators are shown in a map with a drawing of Mexico as a backdrop. We used the centroids as a source set of points because they are dispersed in a geographically interesting way. There is no meaning to the map of Mexico; however, if we were to place one antenna in the geographic center of each province and then we wished to link the antennas in a network we would likely create and study maps such as these.
**Transform - Intersect Lines**
Splits lines into multiple line objects at all places where lines intersect.

If two lines intersect, they will be split into four line objects, as shown above.

The second example shows one long line in a spiral shape that is intersected in several places by a diagonal straight line. **Intersect Lines** will split the two lines into fourteen separate lines at the intersection locations marked with red plus characters.

See also: Transform - Intersection Points to add points to locations where lines intersect without altering the lines.
Transform - Move Horizontally / Move Vertically

Move all objects or selected objects the specified distance horizontally or vertically. Negative values move objects to the left (West) or down (South).

Units used for the distance to be moved value in the source / argument box are taken from the projection of the drawing. If the drawing is in Latitude / Longitude projection the units will be degrees. If the drawing is projected, the units will be in meters or feet. It is therefore strongly recommended that the drawing be projected first so that meters or other linear measure can be used instead of attempting to use degrees as a measurement unit.

If the drawing uses degrees and meter-based moves are desired, first re-project the drawing into any convenient meter-based projection (such as Orthographic) so that meters will be used as the units of measure.

Example

We will move Germany in a drawing of Europe. The drawing has been projected into Orthographic projection, so it is a meter-based drawing.

We first select the area representing Germany. Next, load the Transform toolbar with

[selection] Move Horizontally -200000

and press Apply. This is a command to move the area 200 km to the West.

To show vertical movement we load the transform toolbar with

[selection] Move Vertically -300000

and press Apply. This is a command to move the area 300 km to the South.
While it is something of an absurd example to move countries this way, these commands are well-suited to adjusting data sets, such as drawings of wells or other points, that contain systematic errors. They are also useful when using Manifold for CAD editing.

**Tech Tip**

Many transforms automatically run a Normalize Topology transform before running to eliminate common errors that may affect correct operation. The Move transform operators do not normalize target objects before running.
Transform - Nearest / Farthest Neighbors

**Nearest Neighbors:** Given the source set objects in the drawing and a target set of objects in the source / argument box, for each point in the source set finds those points in the target set which are closer to that point than they are to other points in the source set. The neighbors are indicated by a line drawn between them. This is a geometric solver, using straight-line distances, not distances through a network.

This is a general-purpose client-center assignment solver. Suppose we have a number of service centers (the source set) and we also have a collection of customer points (the target set). We would like to assign each customer to the nearest service center. This solver does it automatically: for each service center it finds the "nearest neighbor" from the customer set. It guarantees that no reassignment of a customer to a different service center will reduce the distance between that customer and a service center.

The operator creates lines in the active drawing, which will be selected. It's probably a good idea in most cases to move the lines to a different drawing for better organization.

**Farthest Neighbors:** The same as above, except that for each point in the source set finds those points in the target set which are farther from that point than they are from any other point in the source set.

This solver is used when two classes of things must be kept far apart. Suppose we own a chain of 500 restaurants that are administered through six regional offices. We have a collection of auditors who work with computerized records only, and thus could be located anywhere; however, we have them located in the various regional offices because from time to time they pitch in with other work. We would like to assign each auditor a group of restaurants that are as far away from his region as possible, so that in the course of ordinary business he or she won't get too friendly with the restaurant managers they may be auditing.

Using the Farthest Neighbors solver will make this assignment. It guarantees that no reassignment of an audited restaurant to different auditing manager can increase the distance.

If the points involved have data attributes, the created lines will acquire the data in accordance with the transfer rules that have been specified for those data columns.
Transform - Normalize Metric

Normalize Metric repairs common flaws in object metrics in drawings. Objects in drawings are defined by their coordinates (see the Editing Objects topic). The sequence of coordinates that defines an object is called its metric.

The Normalize Metric operator will fix:

- Self-overlaps
- Self-intersections
- Redundant internal coordinates (duplicate coordinates, unnecessary coordinates)
- Duplicate Coordinates
- Lines with redundant point features in the metric.

Redundant linear features in areas are sequences of internal coordinates that jump from a given coordinate out to some other coordinate and then back to identically the same coordinate before continuing the sequence that defines the area object. A redundant point feature in a line is a repeated coordinate in the sequence defining the line.

Examples

The illustrations above show an area containing a redundant linear feature in the metric. The coordinate sequence defining the area jumps out from a particular coordinate and then back again to exactly the same coordinate. The "line" that appears to exist is a dimensionless phantom.

Normalize Metric will remove the two unnecessary coordinates (one outside the area and a redundant duplicate at the same location in the area boundary).

Optimization

Once Normalize Metric or Normalize Topology is run on an object, the object will be flagged within internal Manifold storage as clean. During future Normalize runs the process will skip examination and normalization of objects that are marked clean. If an object is subsequently modified (through editing by a user or by a script) the "clean" flag will be cleared so that the object will be examined by future passes of Normalize Metric. If the Location Precision property of a drawing is modified via the View - Properties - Precision dialog to a higher value (that is, a less demanding precision) then the "clean" flag for all objects will be cleared.

Because of the caching behavior of Normalize Metric, the amount of time required for the function will vary based on how many objects are been marked "clean." If the Location Precision has just been changed in a large drawing the function will take longer to run. If Normalize Metric has just been run (either explicitly or automatically as part of another transform), the function will run very rapidly since all objects will be marked "clean."
Automatic Normalization

Manifold maintains automatic cleaning of object metrics. Automatic normalization occurs for those transform operators that require clean object metrics. Before any such Transform toolbar operator begins operation, Normalize Metric automatically will be run on all objects that need to be cleaned.

The automatic normalization is an internal Manifold function that occurs whenever it is required during transform toolbar operation. Due to the caching behavior of Normalize Metric the amount of time for cleaning (if required) will vary depending on whether or not objects in the drawing are marked "clean" or not. A particular transform operator might run very rapidly and then just after Location Precision has been changed suddenly run much more slowly during the next run. The slower run occurs because all of the objects have had their "clean" flag cleared as a result of the precision change, so Normalize Metric will have more work to do for that run.

Differences between Normalize Topology and Normalize Metric

Both of these transform operators are used to produce a clean metric; however, the metric produced by Normalize Metric may be slightly different than that produced by Normalize Topology. The main difference between them is that Normalize Metric is run on a per-object basis while Normalize Topology is run on an object set as a whole.

When processing metrics Normalize Topology considers neighboring objects and Normalize Metric does not.

Examples:

- Normalize Topology will detect overlapping areas and will assign the region of overlap to one of the overlapping areas while clipping it from the others. In this same circumstance Normalize Metric will leave the overlaps.
- Normalize Topology will snap points to the nearest object (such as the end of a line) if the distance between the point and the object is less than the location precision. Normalize Metric will leave points unmoved.
- Normalize Topology will detect an intersection between two lines and will split the lines at the intersection. Normalize Metric will leave the lines unchanged.
- Normalize Topology will remove duplicate coordinates as well as other redundant coordinates. Normalize Metric will only remove duplicate coordinates.

Both Normalize Topology and Normalize Metric will remove duplicate coordinates, but Normalize Topology will also attempt to remove redundant coordinates. Normalize Topology will leave any redundant coordinates that are also coordinates in any other object. This is done to guarantee that a common border between any two adjacent objects is exactly the same in both objects. Note that Normalize Metric can not do the same since it operates only on single objects.

How should one choose between Normalize Topology and Normalize Metric? In most cases, we would like any adjustments to object metrics to proceed with the entire object set in mind so in most cases one would use Normalize Topology in preference to Normalize Metric.

When dealing with imported drawings that may contain specific features of the metric that are to be preserved, users will often choose to begin operations by running Normalize Topology. This will clean object metrics while preserving redundant coordinates that are co-located with other objects and it will mark all objects as having clean metrics. This avoids a situation where Manifold is compelled to run Normalize Metric even though we do not want it run.

If some other transform operator (such as Clip Intersect) is run on a drawing that has not been yet normalized with either Normalize function Manifold has no choice but to run Normalize Metric to guarantee a clean metric. By running Normalize Topology first we pre-empt the running of Normalize Metric by other transforms in self-defense. The main reason for running Normalize Topology first is to prevent the deletion of redundant coordinates that are co-located with other objects. A secondary (rare) reason is to prevent redundant coordinates from being deleted when we are working at a location precision that may cause coordinates to be judged "redundant" that are really needed to prevent gaps from emerging between formerly adjacent objects.

Why do the other transform operators run Normalize Metric instead of Normalize Topology if objects need cleaning before processing? Transform operators are frequently run on subsets of objects. If Normalize Topology were used automatically the usual workflow of running transforms on subsets of objects would quickly lead to a clustered drawing, different parts of which have been normalized with respect to different sets of objects. That would defeat the global normalization that is usually a key objective of Normalize Topology.
To summarize, when in doubt run **Normalize Topology** once before running other transforms. This can be very time consuming for large drawings, but it is a prudent and necessary step experts will take if they wish to preserve specific metrics.

**See Also**

**Transform - Normalize Topology**
Transform - Normalize Topology

Normalize Topology alters drawings in many ways at once by making fine adjustments in the positions and coordinate points defining points, lines and areas. If objects fall within the distance specified in Location Precision in the View - Properties - Precision dialog, they will be adjusted to topologically sensible positions.

This operator includes several functions that are executed simultaneously:

- Snap lines to nearest points - Used to prepare drawings for use as networks.
- Resolve overshoots and undershoots - Truncate overshoots and extend undershoots.
- Adjust area boundaries - Clip overlaps and extend areas to fill in gaps.
- Split lines at intersections.
- Remove redundant coordinates in object metrics that are unshared with other objects.
- Move defining coordinates to the nearest positions consistent with the Location Precision parameter and remove any redundancies.

This latter function leads to the use of Normalize Topology for "generalizing" drawings to a lower resolution by altering the Location Precision parameter in the View - Properties - Precision dialog of a drawing and then running Normalize topology.

Normalize Topology can handle any mix of points, lines and areas, including branched areas. Lines and points are pulled to neighboring areas and then lines and points are adjusted between themselves. Normalize Topology considers neighboring objects when making adjustments. It will automatically make fine adjustments so that small gaps do not appear between neighboring areas, for example.

See the Normalize Metric topic for illustrations of redundant metrics.

Use with Multiple Map Layers

To run Normalize Topology across map layers, run it on [All Objects] or on [Selection] if the selection includes objects in multiple map layers.

For better results (both speed and accuracy) make sure that all map layers and the map are in the same projection and all layers use the same location precision.

Optimization

Once Normalize Metric or Normalize Topology is run on an object, the object will be flagged within internal Manifold storage as clean. During future Normalize runs the process will skip examination and normalization of objects that are marked clean. If an object is subsequently modified (through editing by a user or by a script) the "clean" flag will be cleared so that the object will be examined by future passes of Normalize Topology. If the Location Precision property of a drawing is modified via the View - Properties - Precision dialog to a higher value (that is, a less demanding precision) then the "clean" flag for all objects will be cleared.

Because of the caching behavior of Normalize Topology, the amount of time required for the function will vary based on how many objects are been marked "clean." If the Location Precision has just been changed in a large drawing the function will take longer to run. If Normalize Topology has just been run (either explicitly or automatically as part of another transform), the function will run very rapidly since all objects will be marked "clean."

Comparison to Simplify

The Simplify command is similar to the Normalize Topology operator. However, the Simplify command is aimed at simplification on a per-object basis while the Normalize Topology operator considers relationships between objects when simplifying them. We can see the difference by running both commands on a drawing of Mexico.
We begin with a drawing of Mexico that's been projected into Orthographic projection.

Running Simplify with a Distance setting of 25000 meters results in the simplification of areas. However, each area is simplified without considering any relationships with adjacent areas. This provides an optimal simplification when each area is considered by itself but also results in overlaps and gaps between areas.

If instead of using Simplify we used Normalize Topology, we would first use View - Properties - Precision to set the Location Precision to 25000 meters and then we would run Normalize Topology.

Normalize Topology takes a lot longer to run than Simplify, but the result in the end is free of overlaps and gaps. Each area has been adjusted both on the basis of capturing its own shape as well as to match its neighbors. However, it could be said that the resulting shape for each individual object (without regard to neighboring areas) is not as "optimal" a simplification as is done by Simplify.

When simplifying a single object it is probably best to use Simplify since the result is obtained much faster. When simplifying many objects for which adjacency must be maintained it is best to use Normalize Topology.

Differences between Normalize Topology and Normalize Metric

Both of these transform operators are used to produce a clean metric; however, the metric produced by Normalize Metric may be slightly different than that produced by Normalize Topology. The main difference between them is that Normalize Metric is run on a per-object basis while Normalize Topology is run on an object set as a whole. When processing metrics Normalize Topology considers neighboring objects and Normalize Metric does not.
Examples:

- **Normalize Topology** will detect overlapping areas and will assign the region of overlap to one of the overlapping areas while clipping it from the others. In this same circumstance **Normalize Metric** will leave the overlaps.

- **Normalize Topology** will snap points to the nearest object (such as the end of a line) if the distance between the point and the object is less than the location precision. **Normalize Metric** will leave points unmoved.

- **Normalize Topology** will detect an intersection between two lines and will split the lines at the intersection. **Normalize Metric** will leave the lines unchanged.

Both **Normalize Topology** and **Normalize Metric** will remove redundant coordinates, but **Normalize Topology** may leave some redundant coordinates that would be removed by **Normalize Metric**. **Normalize Topology** will leave any redundant coordinates that are also coordinates in any other object. This is done to guarantee that a common border between any two adjacent objects is exactly the same in both objects. Note that **Normalize Metric** cannot do the same since it operates only on single objects.

How should one choose between **Normalize Topology** and **Normalize Metric**? In most cases, we would like any adjustments to object metrics to proceed with the entire object set in mind so in most cases one would use **Normalize Topology** in preference to **Normalize Metric**.

One of the rare cases where we might prefer **Normalize Metric** over **Normalize Topology** is when we must deal with a seriously inaccurate drawing that is known to contain many redundancies in object metrics, which we would like to quickly fix so that all subsequent operations are faster. In this case we could first run **Normalize Metric** at, say, one-fourth of the usual Location precision and then run **Normalize Topology** at the normal value of Location precision.

When dealing with imported drawings that may contain specific features of the metric that are to be preserved, users will often choose to begin operations by running **Normalize Topology**. This will clean object metrics while preserving redundant coordinates that are co-located with other objects, and it will mark all objects as having clean metrics. This avoids a situation where Manifold is compelled to run **Normalize Metric** even though we do not want it run.

If some other transform operator (such as **Clip Intersect**) is run on a drawing that has not been yet normalized with either **Normalize** function Manifold has no choice but to run **Normalize Metric** to guarantee a clean metric. By running **Normalize Topology** first we pre-empt the running of **Normalize Metric** by other transforms in self-defense. The main reason for running **Normalize Topology** first is to prevent the deletion of redundant coordinates that are co-located with other objects. A secondary (rare) reason is to prevent redundant coordinates from being deleted when we are working at a location precision that may cause coordinates to be judged "redundant" that are really needed to prevent gaps from emerging between formerly adjacent objects.

Why do the other transform operators run **Normalize Metric** instead of **Normalize Topology** if objects need cleaning before processing? Transform operators are frequently run on subsets of objects. If **Normalize Topology** were used automatically the usual workflow of running transforms on subsets of objects would quickly lead to a clustered drawing, different parts of which have been normalized with respect to different sets of objects. That would defeat the global normalization that is usually a key objective of **Normalize Topology**.

To summarize, when in doubt run **Normalize Topology** once before running other transforms. This can be very time consuming for large drawings, but it is a prudent and necessary step experts will take if they wish to preserve specific metrics.

**Tech Tip**

To prevent **Normalize Topology** from moving coordinates about (snapping points to the ends of lines, etc.), one simply sets the location precision to a very small value. The "small value" should be some value considerably less than any possible distance between distinct coordinates that occur in objects. For example, in a drawing originating from a USGS DLG where the normal accuracy is ten meters using a location precision of .001 meter will assure that no coordinates are moved by **Normalize Topology**. The procedure is:

- Launch the View - Properties dialog for the drawing and set Location Precision to a very small value.
- Launch Tools - Options dialog, go to Miscellaneous page and uncheck the Split branched objects after transforms checkbox.

Simplify
Transform - Normalize Metric
Transform - Relative Neighborhood Network

Given a set of points, builds a relative neighborhood network on that point set by adding lines.

A relative neighborhood network is a subnetwork of a Gabriel network (see the Gabriel Network topic). The links of a Gabriel network are drawn based on no points being within the circle defined by any pairwise point comparison, where the diameter of the circle is given by the distance between the points in the pair. In contrast, the relative neighborhood network draws a link if no other points appear in the area of intersection of two circles drawn centered on the points of the pair where the radius of the circles is the distance between the points of the pair.

In the figure above, the inner red circle shows the exclusion circle applied when drawing a Gabriel network. The area indicated in gray color shows the exclusion area applied when drawing a relative neighborhood network. Note that since the relative neighborhood network excludes links to nodes in a larger prohibited area, the relative neighborhood network will have fewer links than the Gabriel network.

The lines created by this operator will be selected after they are created. It's a good idea to move them to a new drawing to keep the map well organized.

Relative neighborhood networks are very useful because they not only consider the distance between two points considered as a pair, they also take into account the distance between that pair of points and all of the rest of the points. The two points are "relative neighbors" only if they are as least as close to each other as they are to all of the other points. Relative neighborhood networks therefore include a built-in reckoning of the overall arrangement of the point set in addition to local considerations. For this reason, they tend to reveal better cluster relationships than do simple local measurements such as nearest neighbors.

Example

Using the set of points above, we can create the relative neighborhood network seen below.
Note that a superset of a relative neighborhood network is created by the Gabriel Network transform operator as seen below:

See Also

**Spanning Tree** - The transform operator that creates minimum spanning trees.

**Clusters** - The transform operator that uses relative neighborhood networks to find clusters.

Notes

In graph theory, networks are called graphs. When searching Internet for information on these topics try searching for words like "relative neighborhood", "graph", "spanning tree", "cluster" and similar. These ideas are applied in an astonishing range of disciplines, from fungal spore distribution patterns to the characterization of finds in archaeological sites.

The points for the examples above were created by making centroids for provinces in Mexico using the Centroids (Weight) transform operator. The points and results of the transform operators are shown in a map with a drawing of Mexico as a backdrop. We used the centroids as a source set of points because they are dispersed in a geographically interesting way. There is no meaning to the map of Mexico; however, if we were to place one
antenna in the geographic center of each province and then we wished to link the antennas in a network we would likely create and study maps such as these.
Transform - Remove Duplicates

Remove duplicate objects. The **remove duplicates** operator deletes areas, lines or points that appear exactly at the same location. It is best used when field contents (if any) are not an issue, since this transform simply removes the most recently-created objects.
Transform - Reverse Lines
Reverse the order of coordinates that define a line, thus reversing the "direction" of the line. For multi-branched lines, the Reverse Lines transform will also reverse the order of branches so the first branch becomes the last and vice versa. Used with asymmetric line formatting styles so that the style is oriented as desired.

Directed Line Styles

Some line styles are asymmetric in that their appearance depends on the direction of the line. All lines in Manifold have a "direction" that is implied by the order in which they are drawn from the first coordinate that defines the line to the last.

A triangle line style is one such style. When looking along the direction of the line from the beginning to the end the triangles point to the left in this style. This can be seen by drawing a line.

We can use this style with the Insert Line tool to draw a new line by clicking at the left and then clicking at the right in the direction shown by the red arrow.

The result is a line drawn in triangles with the triangles pointing to the left along the direction of the line.

Suppose we draw a second line in the opposite direction as indicated by the red arrow.
In this case, the triangles will point in the opposite direction.

We can see that the orientation of the lines depends upon their direction, as shown by the red arrows. To switch the direction of a line (and thus the orientation of any asymmetric line style) select the line and use the Reverse Lines operator.

**Tech Tip**

Many transforms automatically run a Normalize Topology transform before running to eliminate common errors that may affect correct operation. The Reverse Lines transform operator does not normalize target objects before running.
Transform - Rotate (Drawings)

Rotate objects about the approximate center of their minimum enclosing circle by the number of degrees given in the source / argument box. Negative degree values cause counter-clockwise rotation while positive values cause clockwise rotation. Fractional values are allowed. For example, a parameter value of -45.5 rotates objects counter-clockwise by 45.5 degrees and a parameter value of 90.5 rotates objects clockwise by 90 degrees.

It is strongly recommended that drawings be projected before using this operator to provide maximum accuracy in rotation.

Rotation Example

We will rotate Germany within a drawing of Europe. The drawing has been projected into Orthographic projection.

![Maps showing rotation example](image)

We first select the area representing Germany. Next, load the Transform toolbar with

[selection] Rotate -45.5

and press Apply. This is a command to rotate Germany by 45.5 degrees counter-clockwise.

This command is most frequently used in CAD-style editing of non-geographic data. It is shown here in a geographic setting to make clear its effect.

Tech Tip

Many transforms automatically run a Normalize Topology transform before running to eliminate common errors that may affect correct operation. The Rotate transform operator does not normalize target objects before running.
Transform - Scale / Scale Horizontally / Scale Vertically

Resize objects by the scale given in the source / argument box. A parameter value of 0.5 resizes objects to half their size. A parameter value of 2 resizes objects to twice their size. The Scale Horizontally and Scale Vertically operators resize objects by the scale given in the source / argument box only in their horizontal (East / West) or vertical (North / South) extent.

It is strongly recommended that drawings be projected before using these operators to provide maximum accuracy in scaling.

**Scale Example**

We will resize Germany within a drawing of Europe. The drawing has been projected into Orthographic projection.

We first select the area representing Germany. Next, load the Transform toolbar with

```
[selection] Scale 0.5
```

and press Apply. This is a command to resize Germany to half the former size.

**Scale Horizontally Example**

We will now resize Germany only in its horizontal extent.

We first select the area representing Germany. Next, load the Transform toolbar with

```
[selection] Scale Horizontally 0.5
```

and press Apply. This is a command to resize Germany to half the former size in the horizontal (East / West) direction. All vertical extents will remain the same.

**Scale Vertically Example**

We will now resize Germany only in its vertical extent.
We first select the area representing Germany. Next, load the Transform toolbar with

[selection] Scale Vertically 0.5

and press Apply. This is a command to resize Germany to half the former size in the vertical (East / West) direction. All horizontal extents will remain the same.

These commands are most frequently used in CAD-style editing of non-geographic data. They are shown here in a geographic setting to make clear their effect.

Tech Tip

Many transforms automatically run a Normalize Topology transform before running to eliminate common errors that may affect correct operation. The Scale transform operators do not normalize target objects before running.
Transform - Segments

The **Segments** operator is used to insert additional coordinates into objects to allow preservation of shape when the objects are re-projected into a different coordinate system. The segmentize operator takes each straight line segment that comprises lines and areas and inserts additional coordinates, so that the single straight line segment will consist of many more straight line segments. These additional coordinates will be redundant in the existing coordinate system, but they may be necessary to preserve shape when re-projecting the drawing into a different coordinate system.

The transform toolbar version of this command adds the number of given segments, whereas the Segmentize command in the Drawing menu adds segments so that each segment is no greater than a given **Distance** parameter.

See the Segmentization topic for illustrations and explanation of the segmentization process.

**Tech Tip**

Many transforms automatically run a Normalize Topology transform before running to eliminate common errors that may affect correct operation. The **Segments** transform operator does not normalize target objects before running. Also, the **Segments** operator will not split resulting objects.
**Transform - Select Adjacent to**

Select all objects in the target set that are adjacent to any object in the source / argument box set. Objects are adjacent if they have one or more boundary coordinates in common with no other overlaps.

Suppose we have a saved selection called *Durango* that selects the province of Durango in Mexico.

Running **Select Adjacent** selects all other provinces that share a boundary with Durango.

**Tech Tip**

If **Select Adjacent** fails to select some "adjacent" areas but Select Touching does select those areas, carefully examine the region of adjacency to see if there is any overlap between the objects.

**See Also**

Select Contained / Containing
Select Intersecting
Select Touching
Transform - Select Contained / Containing

Select Contained within will select all objects in the target set that are entirely contained within an object in the source / argument box set. Select Containing will select all objects in the target set that completely contain any object in the source / argument box set.

Suppose we have a saved selection called Durango that selects the province of Durango in Mexico.

Select Contained within

Running Select Contained within selects the two points and the line that are entirely within Durango.

Select Containing

Suppose we have another layer in the map containing circular areas. Running Select Containing selects the large circular area that entirely contains Durango.

Select Touching
**Transform - Select Euclidean Point Coverage**

Selects a minimal set of points so that each point from the source set is within the given distance to at least one point of the result set. The distance is given in the drawing’s native measurement units.

This is a very useful operator when locating antennas for some types of wireless services.

**Example**

Suppose we have a network created from roads in a town. The drawing is in Orthographic projection, which by default uses meters as the projection unit.

A point has been placed at the end of each line using the Points operator. Duplicate points have been removed with the Remove Duplicates operator. We could now delete the roads, since we no longer need them, but we will keep them for display purposes.

We can run the **Select Euclidean Point Coverage** operator in the transform toolbar on all objects using a parameter of 500. Because the drawing uses meters in its projection coordinate system, we are asking Manifold to construct the Euclidean point coverage using a distance of 500 meters.
The result of the operator is that four points have been selected and shown in red selection color.

If we draw circles about each red point that are 500 meters in radius, we can see that Manifold has selected four points such that every other point in the network lies within 500 meters of one of the four points.

The point coverage selected is **minimal**, because no fewer than four points can be selected such that all other points are within 500 meters of a selected point. We cannot choose only three points, for example, within 500 meters of all the other points. Four points are minimal, because five points are not necessary.

The point coverage is said to be **Euclidean** because the distances between points that are measured to be 500 meters or less are computed using straight line, Euclidean distance. They are not distances as measured through the network.

Note that the point coverage selected by Manifold is not guaranteed unique. There may be a different set of four points that also covers the other points to a distance of 500 meters. The guarantee is simply that there is no set of three or fewer points that is also a coverage to 500 meters of this particular network, and that the selected set of four points is a coverage to 500 meters.

Note that the illustration suggests a practical usage for this operator. Suppose we have a road network within a region that we would like to saturate with wireless service, such as wireless communications between centralized polling stations and reporting nodes. If each wireless antenna can cover a 500 meter radius and we would like to locate antennas only at nodes (to take advantage of the ease of trenching roads or pulling cable through existing conduits) we can use the **Select Euclidean Point Coverage** operator to find possible coverages with the minimal number of antennas required.

**Units of Measurement**

Units used for the distance value in the source / argument box are taken from the projection of the drawing. If the drawing is in **Latitude / Longitude** projection the units will be degrees. If the drawing is projected, the units will be in meters or feet. It is therefore strongly recommended that the drawing be projected first so that meters or other linear measure can be used instead of attempting to use degrees as a measurement unit.

To see which units are defined for the drawing's projection, click on the Tracker tool and make some measurements. Whatever units are used to show the result of the tracker tool are the units currently in force.

If the drawing uses degrees and meter-based creation of buffer zones are desired, first re-project the drawing into any convenient meter-based projection (such as **Orthographic**) so that meters will be used as the units of measure.
When this transform operator is used with a drawing layer within a map the units used by the drawing will be used. If the map component’s projection is degree based while the native projection for the drawing is meter based (as, for example, with the Orthographic projection) or vice versa, then the transform operator will use whatever units are used by the drawing’s projection.

About Networks
Drawing Networks
Not All Maps are Networks
Transform - Select Intersecting
Select all objects in the target set that intersect any object in the source / argument box set. Objects intersect if objects from both sets have some parts in common (excluding intersections consisting of common boundary coordinates only) and also have some parts not in common. Excluded, therefore, are cases where objects are entirely contained within other objects, or where some objects entirely contain others.

Suppose we have a saved selection called Durango that selects the province of Durango in Mexico.

Running Select Intersecting selects three lines that are partially inside Durango. Note that it does not select the two points and line that are entirely within Durango.

Select Adjacent to
Select Contained / Containing
Select Touching
Transform - Select Shortest Path

Given a selection that includes a system of lines that can be treated as a network plus two points this transform operator selects those lines that form the shortest path through the network between the two points.

Example

We begin with a map with three drawing layers:

- A background map of Mexico. This has been set to low opacity so it is faint and unobtrusive.
- A drawing called Nodes that contains points. These were created for this example by running the Centroids transform operator on the Mexican province areas.
- A drawing called Links that contains lines. These were created for this example by running the Relative Neighborhood Network transform operator on the points in the Nodes layer.

In the Nodes layer we select two points. If we like, we can save this selection in the Selections pane so we can later select exactly these two points again.
In the Links layer we select all of the lines. This may be done rapidly by enabling Edit - Select Objects - Lines (or simply pushing in the Select Lines button) and then choosing Edit - Select by Type.

Run the Select Shortest Path transform using the [Selection] as the scope. Press Apply to select those lines that comprise the shortest path between the two points through the network.

The result is that the lines on the shortest path are selected, and highlighted in red selection color. (In the illustration above we have also used the saved selection to select the two points as well.) We will often save this selection, or copy the lines involved and paste them into a new drawing.

**Troubleshooting**

When running this transform operator and getting unexpected results, check the following:

- Are you using an object set that contains only the two points between which you want a shortest path? Running this operator on a set of objects that contains more than two points will select two random points and select a shortest path between them.
- Do the lines in use form a network? That is, are they contiguous or are there breaks in the lines? Use Normalize Topology to make sure the various ends of lines are coincident with the beginnings of the next lines.
- Are the points in use coincident with the ends of the lines? If not use Normalize Topology to make sure they are coincident.

Transform - Select Service Centers

Manifold includes four transform operators to find optimal locations for service centers. These include:

- Select Critical Service Centers
- Select N Critical Service Centers
- Select Service Centers
- Select N Service Centers

The operators solve two types of network tasks: to find regular service centers and to find critical, or emergency service centers. Both types of task occur in two forms: to find just one location for a service center or to find an \( N \) number of that type of service center.

**Regular Service Centers**

Given a set of nodes, called clients, finds the "central" node that minimizes the path length to travel from the center to each of the clients and to then return to the center. This is the classic problem for locating a regular or daily service center, where every day one must make the rounds of each of the clients. A real life example would be locating an industrial bakery that every morning must send a truck to deliver bread to the stores and restaurants that resell its baked goods. Every day the truck visits the same clients. The job is to place the bakery so that the overall distance travelled is minimized.

**Critical Service Centers**

Given a set of nodes, called clients, finds the "central" node that minimizes the maximum path length to any of the clients without regard to return travel. This is the classic problem for locating an emergency service center, where at any time one may be called upon to travel to a given client. A real life example would be locating a fire station that is equipped with regional facilities for fighting certain types of hazardous chemical fires. The possible clients are those factories that use such hazardous chemicals, but it is not known in advance at which factory an accident requiring the specialized equipment will occur. Thus the task is to place the fire station to minimize the distance to any one of the factories at which an accident might occur.

**Variations**

Clearly, both of the above examples are somewhat artificial. However, the general idea of minimizing distance for regular service or minimizing distance for emergency service can be applied to many network problems besides the siting of bakeries or fire stations. The Manifold transforms are deliberately kept fast and simple so they are easy to use. The main option is the use of the source / argument box in the Transform toolbar to specify the number of different service centers that are to be found. The \( N \) versions of the operators will find a dispersed pattern of the given number of service centers, placing each to optimize the service overall. The non-\( N \) version of the operators assumes we really intend to place only one service center, but it provides several backup options that are less optimal near the central location found.

**Requirements**

All four of the service center solvers require a connected network to function. In a connected network each point is exactly placed at the end of a line and all lines that are incident to other lines have their end coordinates exactly coincident. There are no gaps, points that are not located exactly on the lines, or lines that are intended to be incident but where the ends don't exactly coincide.

**Examples**

We begin with drawing of a network that has nodes at the ends of all links.
To find the four best locations for regular service centers, we run the **Select N Service Centers** operator with a parameter of 4 in the transform toolbar.

The operator selects the four optimal nodes. We could then copy these nodes and paste them into a new drawing if we wanted to record our findings.

The selection made by the **Select Service Centers** operator run with a parameter of 4 is seen above. The assumption is we are looking for only one regular service center but we want to have a choice of the four best candidates.

Running the **Select N Critical Service Centers** operator with a parameter of 4 creates the selection above. Note that although the nodes selected are similar to those selected for the regular centers, there is one node that is different from the similar node selected by the regular centers algorithm (blue arrow).
The Select Critical Service Centers operator with a parameter of 4 provides very different results than the regular service centers operator. These are the best four choices if an unpredicted dispatch must be made to any other node.

If the results for four centers seem counter-intuitive, consider the result for a parameter of 2. The lower of the two selected nodes is the best (determined by running the transform with a parameter of 1), while the upper one is second best. This shows the power of graph theory to reveal solutions that one might not pick out by eye.
Transform - Select Touching
Select all objects in the target set that touch any object in the source / argument box set. Objects touch if they either intersect or are adjacent to one another.

Suppose we have a saved selection called Durango that selects the province of Durango in Mexico.

Running Select Touching selects the two points and line that are entirely within Durango as well as three additional lines that are partially inside Durango. It also selects the areas that are adjacent to Durango.

Select Adjacent to
Select Contained / Containing
Select Intersecting
Transform - Shape Hull

Tile objects in the drawing with minimum enclosing polygonal areas built up out of square tiles using the grid specified in the parameter. Use a value greater than 1 in the parameter.

Given the two lines above, applying the Shape Hull transform operator with a parameter of 50 creates the area shown below. Decreasing the parameter results in a more stair-stepped, coarser enclosing area while increasing the parameter results in a finer enclosing area.
Transform - Spanning Tree
Given a set of points, builds a minimum spanning tree network on that point set by adding lines.

A spanning tree is a network that connects all of the points in the point sets without forming any loops. A minimum spanning tree connects points so that if the lengths of all the links are added up there is no way to connect all of the points using links with a lower total length. If we wish to connect all the points using fiber optic cable the minimum spanning tree will use the least total amount of cable.

Although points sets will often have one and only one spanning tree arrangement that results in the lowest distance, regularly arranged point sets (such as those in orthogonal grids) can have many different spanning tree networks drawn that will all have the same, lowest, total length of links. The minimum spanning tree transform simply guarantees that no tree can be drawn that uses less material than the spanning tree it finds.

Given the point set above, the minimum spanning tree operator would create the network shown below:

Minimum spanning trees are very important in a very wide range of disciplines. Because they show how to connect points with the least connecting material they are obviously important in any analysis that requires short distances between connected items and minimization of overall connection distances.
Given a network, this operator selects those lines in the network that make up a minimum spanning tree.

We can create the network above by inserting points into a drawing and then running the Relative Neighborhood operator.

If we then run the Select Spanning Tree operator it will select those lines that participate in a minimum spanning tree.

See Also

Clusters - The transform operator that in the Clusters (Zahn) form uses minimum spanning trees to find clusters.

Relative Neighborhood Network - The transform operator that creates relative neighborhood networks, which are subsets of Gabriel networks. This topic includes a note on characteristics of relative neighborhood networks.

Notes

In graph theory, networks are called graphs. When searching Internet for information on these topics try searching for words like "relative neighborhood", "graph", "spanning tree", "cluster" and similar. These ideas are applied in an astonishing range of disciplines, from fungal spore distribution patterns to the characterization of finds in archeological sites.

The points for the examples above were created by making centroids for provinces in Mexico using the Centroids (Weight) transform operator. The points and results of the transform operators are shown in a map with a drawing of Mexico as a backdrop. We used the centroids as a source set of points because they are dispersed in a geographically interesting way. There is no meaning to the map of Mexico; however, if we were to place one
antenna in the geographic center of each province and then we wished to link the antennas in a network we would likely create and study maps such as these.
Transform - Spline
Smoothes lines and areas by inserting additional midpoints and using a spline algorithm to replace sharp corners with curves. The value in the source / argument box determines the number of midpoints inserted into each segment.

Example

Consider a drawing containing a line and an area.

After running the Spline operator on [All Objects] with a source / argument box value of 5 both the line and the area have been smoothed.

Smoothing will preserve common boundaries between adjacent areas.
For example, suppose we have two adjacent areas like the above.

Running the Spline transform (again, with a parameter value of 5) creates the above smoothed boundary between the two areas.

**Notes**

*Spline* is a great way to provide a more natural, rounded appearance to vector drawings in GIS. It is similar to how Bezier curves are used to provide rounded curves.
Transform - Split With

Split target areas and lines using a given set of lines. The transform takes the given set of lines and cuts into separate objects any line and area objects that are intersected by the lines.

Example

Suppose we have a drawing with an area and a line.

We select the line and in the Selections pane save this selection as a saved selection called line.

We next select the area and in the Selections pane save this selection as a saved selection called area.

We can now set up the transform toolbar with the Split with operator as seen above and press Apply

The result is that the area object is split into two areas, neatly cut by the line. We can select the rightmost area.
If we press **Delete** the area disappears, proof that what was once one area was split into two areas.

**Comments**

The **Split with** operator uses any set of lines to split any combination of areas or lines. The example above shows just one line being used to split a single area. We can use the transform in far more significant ways. For example, we could use lines showing streets to split a background area and thus create areas within the various streets that could be used as city blocks, or we could use the boundary of Switzerland to "cookie cutter" VMAP 1 lines and areas that cross the border.
Transform - Triangulation

A Delaunay triangulation of a point set treats the points as nodes in a network and draws links between them that divides the region between the points into triangular tiles.

If we take a set of points as shown above and apply the Triangulation Lines transform operator we can create a triangulation consisting of lines.

The result is a set of lines that show the boundaries of triangular tiles that completely cover the region between the points. Had we wished to create tiles in the form of area objects, we could have used the Triangulation Areas transform operator. Using the Triangulation operator would simultaneously create both Triangulation Lines as well as Triangulation Areas.

There are many different algorithms that may be used to decide how a point set should be triangulated. Manifold's transform toolbar Triangulation operators use Delaunay triangulation (also spelled the Delone triangulation). The Delaunay triangulation is closely related to the Voronoi tiling of a region, as can be seen from the following illustration that shows both a Voronoi tiling as well as a triangulation.

The blue lines show the borders of Voronoi tiles. The green lines show the Delaunay triangulation. To make the triangulation we draw a line between every two points that share a border line in the Voronoi tiling.

Triangulations can be used for many purposes. They are a natural way of creating a network by connecting points that allows "travel" between points. Triangulations have great use in interpolation as well.
For example, if we begin with a set of points shown above we can create a triangulation as seen below:

Transfer Rules

The triangulation operators except will transfer column data from source to target (created) objects using whatever transfer rules are in force for the data attribute columns.

Transform - Constrained Triangulation

Other types of networks easily created with transform operators:

Gabriel Network
Relative Neighborhood Network
Spanning Tree

Historical Note - A Tale of Two "Delaunays":
Through an accident of translation of a Russian name into Latin characters, the wrong mathematician is often credited with the invention of "Delaunay" triangulation.

Charles-Eugene Delaunay was the French mathematician and astronomer who often is given credit for the triangulation method bearing this name. However, he is the wrong "Delaunay".

Charles-Eugene Delaunay (1816 - 1872)

Educated at the Ecole des Mines in engineering and at the Sorbonne in astronomy, the French mathematician and astronomer Charles-Eugene Delaunay is best known for his contributions to the theory of lunar motion. He is honored with a lunar crater named for him as well as several street features in Paris. These include the Square Delaunay, the Rue Delaunay and (perhaps especially amusing to GIS beginners) the Impasse Delaunay. Delaunay drowned in 1872 in a boating accident in the English Channel near Cherbourg.

Boris Nikolaevich Delone (pronounced "Delaunay" and often spelled that way in English as well) is the Russian mathematician who invented the triangulation method now universally used throughout computational geometry.

BORIS NIKOLAEVICH DELONE

Boris Nikolaevich Delone (1890 - 1980)

Boris Delone was born in St. Petersburg on March 15, 1890 and lived a long life as a mathematician and mountain climber. He persisted in the study of algebra even after the utilitarian transformation of society in the wake of the October revolution discouraged the study of abstract mathematics. After graduating from Kiev University in 1913 Delone taught at the Kiev Polytechnic Institute. He moved to St. Petersburg in 1922 to join the faculty at Leningrad University. In 1932 he worked in the Mathematics institute of the Academy of Sciences. In 1935 he became a professor of Mathematics at the University of Moscow (MGU) from 1935 to 1942. His work in triangulation arises from his work in mathematical crystallography. He also worked in computational geometry, the theory of numbers, and the history of mathematics as well as continuing his life-long researches in algebra. Delone became an Academician in 1929.

Delone's fame as a mountain climber within that sport was equal to his fame as a mathematician in scientific circles. He climbed numerous peaks of the highest difficulty in the wilds of the Caucasus, Central Asia and the Altai. He wrote of his life in mountaineering: "Mountain climbing in my life was not simply a sport or the source of a good mood. It is a worldview that asserts simple truths, glorifying the good things: bravery and comradeship, the desire to know and the desire to help, a devotion to purpose, a sense of and joy in daring, keenness and striking courage ".

Pronunciation

"Delaunay" is normally pronounced in the French style, with stress on the final syllable: "Deh - lah - NAY". The name is pronounced with "short" vowels in the first two syllables and a long "a" in the last syllable.
The Cyrillic for "Delone" is pronounced the same way as "Delaunay". It is an oddly French-sounding surname within the Russian world. Due to pronunciation conventions in English it strikes us as odd that the Latin spelling of "Delone" would be so pronounced. For this reason it is often spelled "Delaunay" in English texts, the convention adopted here.
**Transform - Union**

The **Union** operator in the Transform toolbar for drawings combines into a single area all areas in the target set. If the areas being combined do not touch, a multi-branched area object will be created.

In the illustration above, four Western US states areas have been combined into a single area object using **Union**.

**See Also**

**Dissolve** - A method of combining objects using the values of data attributes.
Transform - Voronoi Operators

These operators create a Voronoi diagram for the points in the active drawing.

Suppose we have a drawing of points. A Voronoi diagram divides the drawing into regions around each point that are shaped so that the borders of the regions are equidistant from the two nearest points.

By drawing lines to mark out Voronoi cells (or drawing areas in the shape of those cells), we divide up (or tile or tessellate) the drawing into regions. Every location within a Voronoi cell is closer to the point about which that cell is drawn than it is to any other point. Voronoi diagrams are very important for dividing drawings into regions associated with points.

- **Voronoi Diagram**: Create area, line and point objects for each Voronoi cell.
- **Voronoi Areas**: Create area objects for each Voronoi cell.
- **Voronoi Lines**: Create line objects at the border of each Voronoi cell.
- **Voronoi Points**: Create point objects at the intersections of the borders of the Voronoi cells. Rarely used.

The illustration seen above shows the effect of the Voronoi Lines operator.

The Voronoi Diagram operator, as seen above, creates area, line and point objects for the Voronoi diagram. Note that points appear at the intersection of the borders of the Voronoi cells. These points are created by the Voronoi Points operator.

The areas, lines or points created by this operator will be selected after they are created. It's a good idea to move them to a new drawing to keep the map well organized. Move them by using Edit - Cut and then Edit - Paste into a new drawing or Edit - Paste As a new drawing in the project pane.

**Example**

Suppose we have a few hundred environmental sampling stations scattered throughout a region. We also have a dozen data collection centers, numbered 1 through 12, within the region.
We would like to assign each sampling station to the nearest collection center. To do this we first use a drawing of the data collection centers to create a **Voronoi Area** surrounding each center.

![Voronoi Diagram](image)

We can then use the Spatial Overlay dialog to transfer the identification number of each data collection center to the Voronoi cell that encloses it. Next, we can use **Spatial Overlay** once more to transfer the identification number from each Voronoi cell to all of the sampling station points within each cell. The result is that each sampling site will have a field that contains the data collection center number that services it.

**Transfer Rules**

All of the Voronoi operators except **Voronoi Lines** will transfer column data from source to target (created) objects using whatever transfer rules are in force for the data attribute columns.

**Historical Note:**

Voronoi diagrams are also known in some cultures as Dirichlet or Thiessen tessellations. Although individual investigators have used this powerful concept informally at least as far back as Descartes in 1644 the key researchers formally developing this concept were Dirichlet and Voronoi.
Dirichlet used a special form of the Voronoi tessellation in his study of positive quadratic forms. Dirichlet was born in a part of the French Empire long disputed back and forth between France and Germany, studied in Paris and settled down to an overworked and productive career in Germany. Voronoi later published a generalization of Dirichlet's concept that would apply to higher dimensions and so introduced the concept in its modern form.

Georgi. F. Voronoi (1868 - 1908)

Voronoi was born in Russia on 28 April 1868 and graduated from the University of St. Petersburg in 1889, winning the Bunyakovsky prize for his Master's thesis and again a second time for his Doctor's thesis. He was a lecturer at Warsaw University and contributed to the theory of algebraic numbers and the geometry of numbers.

At times Voronoi wrongly is claimed to be a German mathematician (an error repeated in some web sites). Even more inaccurately, some people refer to Voronoi's work by crediting the concept to Thiessen, a German meteorologist. Both errors appear to arise from the dominance during the inter-war years of German researchers in crystallography and other subjects in which Voronoi diagrams are used.

Thiessen used the idea of Voronoi diagrams much later than either Dirichlet or Voronoi, beginning only in 1911 to apply them to the study of meteorology. Thiessen quite likely felt he had independently derived the concept (as have many workers in the years since Voronoi's publications).

As a meteorologist Thiessen probably would not have had full awareness of all that was done in mathematics by professional mathematicians such as Dirichlet or Voronoi. But is unfortunate that some writers who certainly knew of Voronoi's work would deny either Voronoi or Dirichlet credit while advancing Thiessen as the inventor of a concept that Voronoi developed both more fully and at an earlier date, not to mention Dirichlet's earlier work as well.

Whatever the reason for the original misattribution, in modern times if we are not to inadvertently repeat the error we should use the term "Voronoi" or "Dirichlet" tessellations for this concept. The term "Voronoi" is used by Manifold because it was Voronoi who presented the mathematics of this notion in the contemporary form used within Manifold.

Pronunciation

"Voronoi" is pronounced by English speakers as "Vo - ro - noi" with a short "o" sound, like the "o" in "or", for the first two syllables. The third syllable is pronounced like the "noi" in "noise". The stress is on the third syllable. Russian speakers will pronounce the name with such a short "o" in the first two syllables that it sounds like "uh" or even "ah".
The Business Tools package is an optional extension to Manifold System that provides additional commands for working with drawings. The extension adds functionality in several areas:

- **Districts (Advanced)** - Redistricting using a condensed, expert level dialog.
- **Districts (Visual)** - Redistricting via an easy-to-use visual, interactive dialog.
- **Drive-Time Zones** - Computation of drive-time zones via an easy-to-use, interactive dialog.
- **Optimal Route** - Finding an optimal route to designated locations using a condensed, expert level dialog.
- **Optimal Route (Visual)** - Finding an optimal route to designated locations via an easy-to-use, interactive dialog.
- **Send Email** - Automatically send email to map objects. Used to send spatially-targeted email.
- **Topology Factory** - An interactive dialog to view and repair common topological errors in drawings.
- **Expanded programmatic access to routing and other functions.**

If you do not have the optional Business Tools package enabled you will not have the above capabilities enabled within Manifold System. This documentation describes these commands but they will not be enabled if you do not have the Business Tools package enabled.

### Installing Business Tools

The Business Tools package is built into your Manifold System installation and becomes enabled for use when activated. Activate it by providing a Business Tools serial number and Activation key that turn on Business Tools functionality. The process of activating the Business Tools extension is very similar to that used to activate Manifold System. See the Activation Keys and Serial Numbers topic and the Installing and Activating a Manifold Extension topic for details.

Some Manifold product options, such as Universal Edition or Ultimate Edition, use a single serial number and Activation key to enable permanent installation of both Manifold System as well as extensions. If you have activated Universal Edition or Ultimate Edition you do not need to individually turn on Business Tools or Geocoding Tools or Surface Tools. Activating Universal Edition or Ultimate Edition will also automatically turn on all three extensions.

### Turning on Business Tools

If you have licensed Universal Edition, you do not need to turn on Business Tools. The Business Tools extension is automatically enabled with a Universal Edition serial number.

If you have not licensed Universal Edition and you wish to add Business Tools functionality to your installation, begin by acquiring a Business Tools license from manifold.net, which will provide you with a Business Tools serial number.

2. Launch Manifold System. Close any projects that may be open.
3. Choose Help - Activate Extension
4. Enter the Business Tools serial number. Enter it exactly as it was issued to you by manifold.net. Do not change upper case to lower case. Do not replace hyphens with space characters or make any other changes to the serial number. If desired, you may also enter an Activation key for the serial number as well. Press Accept.
5. Manifold will then exit. When re-launched, the Business Tools package will be enabled.
6. Using the serial number alone the Business Tools package may be run for 30 days from the date the serial number was issued. After that, an Activation Key must be fetched and provided to the Help - Activate Extension dialog together with the serial number. Once an Activation Key and a serial number have been provided to the Help - Activate Extension dialog the extension will be permanently installed. Don't forget to login as Administrator when permanently activating the Business Tools extension.

### Status of Extensions
The Help - About dialog shows all extensions that have been installed. If a serial number only has been used to install an extension, the number of days left before an Activation key is also required will be shown.

Districts (Advanced)

The Drawing - Districts (Advanced) menu selection is enabled when the optional Business Tools extension has been installed and the focus is on a drawing window or on a drawing layer in a map window that contains areas. If you have not activated the Business Tools extension with a valid Business Tools serial number you will not be able to use the Districts (Advanced) command.

The Districts (Advanced) command takes a set of areas and automatically assigns each area into as many districts as desired. For example, if four districts are desired each area in the set will be assigned to one of the districts. Areas will be assigned so districts will be made up of areas that are grouped together into the district as reasonably as possible. The districts commands in Manifold are used to create districts that represent sales territories, voting districts or other groupings of areas, which might be states, postal code areas, voting precincts or other regions.

The Districts (Advanced) command will also assign areas based on the content of a numeric data field so districts can be balanced by the sum total of that field. For example, areas can be assigned into districts based on the content of a Population field so that the resultant districts all have approximately the same population. Options allow balancing not only so that each district has the same total value of the balancing field but that some districts can have proportionately more or less. For example, the command may be used to create four districts, one of which has twice the population of all the rest.

Using this command, Manifold can either create districts by assigning areas to them without any preconditions, or we can specify which areas must be in which district.

The Districts (Advanced) command is a text dialog-driven command that works with values in the drawing’s table. For a more visual, interactive districting function, see the Districts (Visual) command.

</tr>
</tbody>
</table>

To assign areas into districts:

1. Open a drawing that contains areas.
2. Choose [All Objects] to assign all areas in the drawing to a district.
3. If districts are to be created based on some data attribute field, choose the field to use in the Balance box. If not, choose none.
4. Choose a column in the Save to box into which each district identification number will be written. The default choice of [New Column] will create a field called District and will write the district number for each area into that column.
5. If formatting is to be modified to show each district in a different color, choose Modify formatting (the default).
6. In the **Districts** box enter a number followed by a comma for each district to be created. For example, the default of "1, 1" tells Manifold to create two districts. To create four districts we would enter "1, 1, 1, 1" in this box. Press **OK**.

The command will add a column called **District** to the drawing’s table and place the district number in that column for each record. District numbers are integers beginning with 1 so that after the **Districts (Advanced)** command operates all areas in the first district will have the number 1 in the **District** column, all areas in the second district will have the number 2 in the **District** column and so on.

If the table already has a **District** column the **Districts (Advanced)** command will use the values in the column to control its activity. All area records with a 0 in the **District** column will be assigned to districts. All area records with a non-zero value in the **District** column will retain that value as their district assignment. For example, if some areas have a value of 1 and others have a value of 2 with all the remainder having 0 then when we run the **Districts (Advanced)** command to create two districts those areas having a value of 1 will be assigned to district 1, those with a value of 2 will be assigned to district 2 and all other areas will be assigned to either district 1 or 2. Placing pre-existing values in a **District** column is a handy way of forcing some areas to be assigned to given districts.

The series of numbers separated by commas in the **Districts** box specify how many districts to be assigned and also specify the relative weight for each. For example, a 1, 1, 1 string tells Manifold to create three districts, each of which is approximately the same size considering the total value of the field specified in the **Balance** box. A 1, 1 string tells Manifold to assign two districts of equal size and a 1, 1, 1 string tells Manifold to create four districts of equal size.

The size of the number in the series specifies how large that district should be relative to the others. For example, a string of 1, 3.5, 1, 1 tells Manifold to assign four districts, the second of which is to have three and a half times the total value of the other districts. A string of 1, 2, 2, 2 tells Manifold to create four districts, the first of which is one half the size of the others. Note that the values are purely relative. We could express the same effect with 0.5, 1, 1, 1 or 2, 4, 4, 4.

**Example**

Consider a drawing showing a group of adjacent areas. The example drawing shows areas formed of triangles and other straight edged polygons, but it could just as easily be an area showing countries, postal code districts or some other real geographic drawing.

![Areas](image)

Our task is to assign each area in the drawing to one of four districts. Ideally, we would like the districts to be reasonably compact in shape, so that areas in the same district are adjacent to each other.
If we open up the drawing's table we can see that it has no columns in it except the default system ID column.

With the focus on the drawing, we launch the Districts (Advanced) dialog. We will balance using the intrinsic field Area (I), which will result in districts all having approximately the same area. We use the string 1, 1, 1, 1 in the Districts box to create four districts of the same size. We leave the Modify formatting box checked (the default) so that right away we can see how the areas are assigned into different districts. Press OK.

Right away, the drawing is reformatted to show the new districts that have been assigned. Manifold has attempted to assign areas to districts so that the total area of each district is approximately the same and that areas assigned to each district are adjacent to each other.
If we look at the drawing's table we can see that a new District column has been added to the table. Each value in the District column specifies to what district that area object has been assigned.

For example, if we select one of the areas in the drawing…
…we can see it has a value of 3, meaning it has been assigned to district number 3.

<table>
<thead>
<tr>
<th>Field</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>IC</td>
<td>555</td>
</tr>
<tr>
<td>District</td>
<td>3</td>
</tr>
</tbody>
</table>

If we would like to change the assignment of the area, we can double-click on the area in the drawing and in the Object Fields dialog change the value of the District field to 1.

The formatting of the object will change to the color for district 1...

<table>
<thead>
<tr>
<th>ID</th>
<th>District</th>
</tr>

</tbody>
</table>

…and the value in the table, of course, will also now be 1.
Although the Districts (Visual) dialog is much easier to use for interactive changes in the assignment of areas to districts, we can show some more intricate work with the Districts (Advanced) dialog to illustrate how the assignment of areas to districts is nothing more than the assignment of a District number to each record.

For this example we will take four areas that are each assigned to a different district, and then reorganize all the other areas into districts about them. We being by selecting four areas, one from each district, which we want to force to be in each of the four districts.

In the table we can see that some of the records have been selected.
If we choose **Edit - Select Inverse** (or simply press **CTRL-I**) we can invert the selection so that all records previously unselected are now selected.

The table now shows that all records except the four areas we chose are now selected. We did this so we can change the **District** value in each of these records to 0. To do so, double-click into the **District** cell of any of the selected records and change the **District** value to 0.
All of the District values in the selected records will also change to zero. This is a very useful facility within Manifold that often comes in hand. We've deselected the records to provide a clearer illustration.

If we take a look at the drawing we see that there now remain only four areas assigned to areas with all of the other areas formatted in default gray.

We now launch the Districts (Advanced) dialog once more. This time we will use a Districts string of 1, 1, 2.5, 1, which tells Manifold to create four districts where district 3 is two and a half times larger than the other districts. In executing this command, Manifold will be constrained by the four areas we have already assigned to districts 1, 2, 3 and 4 because of the non-zero values they already have in their Districts column.
When we press OK we can see how Manifold copes with the command. It has assigned areas so that districts 1, 2 and 4 have about the same area and district 3 has approximately two and a half the area of the other districts.

Examining the table, we can see that those areas which previously had 0 in the Districts column now have numbers from 1 to 4 in the Districts column, representing their assignment to one of the four districts.

**Notes**

In the above examples we balanced districts using the Area (I) intrinsic field. This balances the total area of each district. If the drawing's table had other fields, such as the population of each area, we could have used one of those fields to balance the districts.

In "real life" situations we often want to use fields such as population or total sales to balance areas such as counties or zip code regions to form districts. In a law enforcement application we might want to assign territories to detectives such that the total number of crime incidents is balanced (the objective being so that the investigative workload on each detective's territory is about the same). In a public health application for medical services in rural regions, we might want to assemble districts to balance population, so that the medical staff assigned to each district has the same workload as other districts.

In such applications, quite often it is the case that some areas must be assigned to given districts because the district headquarters is already located there. We can use techniques like the example above to force some areas to be assigned to given districts and to then let Manifold optimize the allocation of other areas between districts.
Manifold will do its best to balance districts as directed; however, given the granularity of the balancing field and the constraint to have reasonably connected districts it may not be possible to have districts that are exactly balanced given the proportions desired.

Districts (Visual)
The **Drawing - Districts (Visual)** menu selection is enabled when the optional Business Tools extension has been installed and the focus is on a drawing window or on a drawing layer in a map window that contains areas. If you have not activated the Business Tools extension with a valid Business Tools serial number you will not be able to use the **Districts (Visual)** command.

The **Districts (Visual)** command provides an interactive dialog that allows specifying districts using a point and click visual user interface. In the main display pane the dialog shows a visual preview of the drawing in which districts are assigned. The dialog also lists the districts and relevant data for each district in a districts list pane.

To operate the dialog, add the number of districts desired into the district list pane (which opens by default with two districts), choose a field to use for balancing the districts and press **Assign**. Districts may then be modified by clicking as desired in the visual preview pane or in the districts list pane. Press **OK** to apply the districts to the drawing and **Cancel** to exit the dialog without making any changes.

To make manual adjustments, choose one of the districts in the districts list pane by clicking on that row to highlight the district. Clicking on an area in the visual preview pane will now assign it to that district, or if it is assigned will remove it from the district (clicking an area will toggle its membership in the district). The toolbar buttons just above the districts list pane affect the highlighted district in the visual districts pane. For example, to remove a district from the list, click on it to highlight it and then press the **Delete** button.

**Controls**

- **(Visual preview pane)** Displays the drawing either in default gray color or as colored by districts assigned with the **Assign** button.
  - **Zoom To Fit** - Zoom so that the entire drawing fits within the preview pane.
  - **Zoom In** - Magnify the view as if seen from a closer distance.
  - **Zoom Out** - Reduce the view as if seen from farther away.
  - **Zoom Box** - Zoom to the size of the cursor box drawn with the mouse.
  - **Center Point** - Pan the view so that the spot clicked is centered.
**Grabber** - Interactive pan: click and drag with the grabber hand. The scene will be panned so that the initial point is moved to the spot where the drag is released.

**(Districts list pane)** A list of districts to which areas may be assigned. The first number gives the relative weight of each district. Use the default weight of 1.00 so that each district will be created the same size (that is, the same total value of the Balance field). Click on a district to highlight it. Double-click into either the weight cell or into the color well to change the weight or color used for that district.

**New** - Add a district in the district list pane.

**Delete** - Delete the highlighted district from the districts list pane.

**Move to Top** - Move the highlighted district to the top of the district list pane.

**Move Up** - Move the highlighted district up one position in the district list pane.

**Move Down** - Move the highlighted district down one position in the district list pane.

**Move to Bottom** - Move the highlighted district to the bottom of the district list pane.

**Fill** - Assign all unassigned areas to the highlighted district.

**Clear** - Toggle to unassigned all areas in the highlighted district.

**Clear All** - Clear all district assignments from all areas.

**Show Counts** - Push in to show the number of areas in the district for each district in the districts list.

**Show Values** - Push in to show the sum total of the Balance value for all areas in the district for each district in the districts list.

**Show Value Percentages** - Push in to show the percentage of the total value for all areas being districted of each district in the districts list.

**Assign** Assign all unassigned areas to districts using the given settings. Areas that are already assigned to districts will not be re-assigned.

**Scope** Objects to be districted. [All Objects] or [Selection] or a saved selection.

**Balance** Choose a numeric field to use to balance districts. Manifold will add up the totals in this field when assigning areas so that each district has the same total value for this field. Choose none to balance districts by no field but just by the number of areas in each.

**Save to** The name of a numeric column to use for district identification numbers.

**Load Districts** Enabled if the drawing already has a numeric field called District or some other field that can be used to store district numbers. Pressing the Load Districts button will load district assignments into the dialog from the values in
the District field or from whatever field has been chosen in the Save to dialog. This is used when districts have already been assigned in a drawing and the dialog is re-launched to make changes.

Modify formatting Check to modify the formatting of areas so that areas in the same district appear in the same colors.

Create contiguous districts Use a networking algorithm to try to assign areas to districts so that areas in the same district are adjacent to each other. On by default. If this option is turned off, the system can work much faster but areas might be assigned to districts in such a way that not all areas in the same district are adjacent to each other.

OK Accept the current assignment and update the drawing with the districts as seen in the preview pane and reported in the districts list pane.

Cancel Exit the dialog without making any changes to the drawing.

Pre-Assigning Areas to Districts

To force an area to be assigned to a give district, highlight that district in the districts list pane and then click on the area. When the Assign button is pressed the district assignment will keep that area assigned to that district and will attempt to build the district around that area.

Example

Let’s consider an example using the sample drawing of Mexican provinces on the Manifold CD. We will assign different provinces to different districts.

When we open the drawing we see it rendered in default gray formatting. The drawing shows provinces in Mexico as areas.
If we open the drawing’s table we can see it has numerous fields. Visible in the illustration above is the ID field giving the internal object identifier, a SQMI field that gives the area of each province in square miles, a SQKM field that gives the area in square kilometers and a POBL_1990 field that gives the 1990 population of each province. There are more fields in the table outside the view shown in the illustration above.

With the focus on the drawing window, we choose **Drawing - Districts (Visual)** in the main menu.

The dialog launches as seen above. This illustration and other illustrations in this example that show the preview pane are shown in a reduced view to more easily fit into this documentation. The dialog has a visual preview pane at the top that shows the drawing, a districts list pane in the lower left that lists districts with information about each district, and a group of options to the right.

Looking more closely at the districts list pane we see it opens by default with two districts, colored yellow and blue, that at present have no areas assigned to them.

Looking more closely at the options we see that the dialog opens using the **Area (I)** intrinsic field as the balancing field by default. This is simply because the **Area (I)** intrinsic field is the first column in alphabetical order of the columns available in this drawing’s table.

We shall create districts based on the number of square miles of each province. To do so, we will change the **Balance** field to **SQMI**.
Click into the **Balance** box and choose **SQMI**.

The dialog is now set up to create two districts of approximately equal size, assigning areas so that total value of **SQMI** in each district is approximately the same. To assign districts, we press the **Assign** button. The system will compute for a while (potentially a long while with complex drawings that have many areas) and will assign areas to districts.

The illustration above shows a reduced view of the preview pane and part of the districts list pane.

We can see in the visual preview pane that each area has been colored yellow or blue depending the district to which it has been assigned. In the districts list pane we can see that 13 areas have been assigned to the yellow district, for a total **SQMI** value of 410588.96 and that 19 areas have been assigned to the blue district for a total **SQMI** value of 411531.37. Manifold helpfully tells us the total percentage of **SQMI** in both the yellow and the blue districts. We can see that with the yellow district having 49.94% and the blue district having 50.06% the assignment of areas to districts worked out very well for the objective of having about the same total **SQMI** in each district.
It’s not always possible, of course, to assign areas to districts so that the value being balanced works out so evenly. However, Manifold will do its best and will usually assign areas to districts with much better accuracy than can be done by hand. The task is especially difficult if the **Create contiguous districts** box is checked (the default) so that not only must districts be balanced but they must also have all areas in contiguous contact with each other.

We can try a different arrangement of districts. To do so, we first press the **Clear All** button to clear all assignments.

The visual preview pane will go back to the default unassigned gray for all areas and the districts list will clear all values for the two districts.

**Create contiguous districts**

We can next try creating districts again, but this time unchecking the **Create contiguous districts** box to see the effect of relaxing this constraint. Once more we press **Assign**. This time, the assignment process happens virtually instantaneously since relaxing the requirement to create contiguous districts allows Manifold to work much faster.
With the *Create contiguous districts* box turned off, the districts created are rather similar, but we can see from the districts list pane that the balance is not quite as good. In this case, the percentages are 47.95% and 52.05%, not quite as even as with the *Create contiguous districts* box checked on. This shows a secondary effect of this option box, in that it not only directs Manifold to form contiguous districts but as a side effect of the algorithm used to form contiguous districts it will often end up with slightly better balancing.

**Using Three Districts**

![Create contiguous districts checkbox]

Let's check the *Create contiguous districts* box once more, and let's add a third district and assign the provinces into three districts instead of only two. We press the **Clear All** to clear district assignments and make way for new assignments.

To add a third district, click the **New** button in the districts list pane toolbar.

This adds a third district to the districts list, by default colored red. If we would like to change the colors of any of the districts, we can double-click into the district's color well to change the color.

After adding the third district we press **Assign**.

Manifold will compute optimal assignments for three districts and assign each area to a red, yellow or blue district. We can see from the percentages that districts have been assigned quite evenly, with approximately 33% of the total SQMI area in each district.
How would the districts look if we unchecked the Create contiguous districts box?

We uncheck the Create contiguous districts box, press Clear All to clear district assignments and then press Assign.

The result is not quite as good as with the Create contiguous districts box checked. Note that the percentages are not as close to an even 33% for each district and also that one of the areas in the red district is not adjacent to the others. Note also that Manifold has switched the colors of districts assigned, with the blue district now occurring in the North.

In general, when we ask Manifold to assign districts from a blank slate the system has a free hand in how areas are assigned. If we would like to control the assignment of areas to districts, we can do so.

Manual Assignment of Districts

Let's begin by checking the Create contiguous districts box once more so contiguous districts are created. We will also press Clear All to start with a blank slate once more.
To assign an area to a district, click on the district in the districts list pane to highlight it and then click on any area in the preview pane. If an area is unassigned or has been assigned to a different district, clicking on it will assign it to the highlighted district. If an area has already been assigned to the highlighted district, clicking on it will clear the assignment. In the illustration above we have highlighted the red district in the districts list pane and have already clicked on two unassigned areas to assign them to the red district. The districts list shows statistics for two areas in the red district.

As areas are added to or removed from each district the districts list pane will show updated statistics. The districts list pane now shows statistics for three areas in the red district.

To assign areas to a different district, click on that district in the districts list pane to highlight it. In the illustration above we have clicked on the yellow district in the districts list pane and then we’ve clicked on three areas in the preview pane to add them to the yellow district. Note that the districts list pane has been updated with information on the three areas in the yellow district as well.
We can click on the blue district and then click on five areas in the preview pane to assign them to the blue district.

The areas that are assigned to a district will stay assigned if we now press the Assign button to assign the remaining areas to districts. Pre-assigning areas manually is a way of forcing them to be part of a desired district and to compel Manifold to do the best job it can of balancing the remaining areas into districts.

If we press the Assign button Manifold will balance the remaining districts as seen above. By pre-assigning some areas to the red, yellow and blue districts we can guide the desired shape of a district, perhaps at some cost to the optimization of balancing.

Re-balancing Districts

We can also clear some districts and force Manifold to re-balance them while retaining existing districts.
To clear a district, highlight the district in the districts list and then press the **Clear** button. In the illustration above we have highlighted the red district and will now **Clear** it.

The result is that all areas formerly in the red district have now been unassigned.

We can also highlight the yellow district and then press the **Clear** button to clear all areas in the yellow district as well.
If we press the **Assign** button Manifold will assign all unassigned areas to the three districts. Note that in making this assignment Manifold added two small areas to the blue district in addition to those areas that were already assigned to the blue district. When areas are pre-assigned Manifold will never remove them from the district but it is always possible that Manifold will add some areas to a district.

### Districting with Different Weights

So far this example has assigned areas to districts where each district had a weight of 1. This means that the objective has been to create districts that all have the same total value of the balancing field. If desired, we can change the weights on districts so that, for example, one district is created three times larger than the other districts.

We will now re-balance the districts so that the red district is three times larger than the yellow or blue districts.

We begin by pressing the **Clear All** button. Next, we double-click into the 1.00 weight in the red district's line and change it to 3.00.
When we press **Assign** Manifold will attempt to assign areas to districts so that the red district is three times larger than the yellow or blue districts. As we can see above, the assignment is remarkably close to the ideal. At almost 60% the red district is indeed three times larger than the other districts, which are approximately 20% each.

However, we might not be happy with the shape of the red district. Perhaps we would be willing to sacrifice some of the accuracy of the numeric balancing in order to get districts that are more compact. If desired, we can adjust the districts manually.

For example, we could highlight the blue district and then move two of the areas assigned to the red district into the blue district by clicking on them.

Next, we could highlight the yellow district and then click on one of the blue areas to move it into the yellow district. The net result of these changes is a more compact shape to our districts but at the cost of increasing the share of the smaller districts to about 25% each and decreasing the share of the larger district to about 53%.
Working with districts is often a tradeoff between having districts that are numerically close to an ideal value and having districts that are compact or otherwise have a desired shape. We rarely have the opportunity to assign districts that have exactly the shape as well as the numeric balance desired. Manifold’s Districts (Visual) dialog is therefore generally used interactively to change options, pre-assign some districts and otherwise develop the assignment desired.

Results

So far, all work has happened within the Districts (Visual) dialog. If we press OK, the formatting will be transferred to the drawing and the drawing will be updated with a new Districts field that contains the number of each district for each area.

When we press OK the drawing is updated with the formatting used in the dialog.

<table>

</tr>
<tr>
<td>6</td>
</tr>
<tr>
<td>7</td>
</tr>
</tbody>
</table>

If we open the drawing's table, we will not initially see a District field because it is hidden by default.

To make it visible we choose the Table - Columns dialog and click the District field on. In the illustration above we have also used the Move Up button to move this field near the top of the table.
The **District** field will then appear. We can see that each area has been assigned to one of districts 1, 2 or 3. If an area was not yet assigned it would have a value of 0 in the **District** field.

### Using the Load Districts Button

If a drawing's table already has a districts field (which could be called **District** or some other name) with district assignments for each area we can load those assignments into the dialog by choosing the field in the **Save to** box and then pressing the **Load Districts** button.

### Performance

Assigning areas to districts can be computationally very intensive if the **Create contiguous districts** box is checked, as we would normally want it to be. It is possible to redistrict a drawing with approximately a thousand areas in less than fifteen minutes on modern machines with adequate memory, however larger drawings can take longer.

### Note

This example has balanced districts using the **SQMI** field in the drawing, which gives the area of each province in square miles. We've used this field because it makes it immediately visually obvious what is being balanced, the total size of each district. However, districts are more frequently balanced using some other field, such as total population or total number of customers, that does not have a direct relationship with the surface area of the areas being assigned.

### Tech Tip

In the illustration above, we have created districts that are balanced using the **POBL_1990** field that gives the population for each province. Each district has approximately the same population, remarkably close to 33.33% for each district. The districts have unequal geographic area because much of Mexico's population is concentrated within densely populated provinces near Mexico City.
It is frequently the case that we would like to give districts names such as "North," "Central," and "South" instead of using numbers. There are two ways of approaching this. The first is to change the type of the District field to a text type and then in the table select all records with District equal to 1, change them to "North" (easy to do when they are all selected because changing one changes them all) and so on. However, that loses the formatting and district information from the numeric District field, since the Districts (Visual) dialog works only with numeric fields. If we take this approach we will have to manually format the area colors using a thematic format based on unique text values of the District field.

Another approach is to create a new text column in the table, perhaps called District Name or some other convenient name and to then use the transform toolbar to copy the values from the District column to the District Name column. Manifold will automatically translate type on the fly from numeric to text. We can then select all records with District Name equal to 1, change them to North and so on. This will retain the original numeric District field and formatting while also providing us with a text field that can be used for labels and so on.

See the Editing Data in Tables topic for information on selecting cells in records and changing all selected items at once.

Districts (Advanced)

Districts
Drive-Time Zones

The **Drawing - Drive-Time Zones** menu selection is enabled when the optional Business Tools extension has been installed and the focus is on a drawing window or on a drawing layer in a map window that contains lines and at least one point (which can be used as a center). If you have not activated the Business Tools extension with a valid Business Tools serial number you will not be able to use the Drive-Time Zones command.

Manifold's Drive-Time Zones command can find zones from one or more points, called Centers from which travel occurs. A drive-time zone is the distance that can be traveled through the road network (and possibly off road as well) in the given time.

The drawing of road lines used must be a true road network that is a connected network. If there are small breaks between the road lines or if the ends of adjacent lines are not exactly coincident the drawing cannot be used as a road network. The drawing used must be **projected** so that accurate measurements can be made.

**Controls**

**Center** Choose a set of points (usually the [Selection] or a saved selection) that are to be used as centers for the drive time zones. **Very Important:** Points to be used as centers must be exactly coincident with the end of one of the lines in the road network.

**Roads** Choose a set of lines to be used as a road network. Usually [All Objects] to use all lines in the drawing, or might be a saved selection of lines to use only some lines from a very large drawing if we know that the drive time zones will end up being reasonably local.

**Length** Choose a field to use that gives the length of each line in the road network. Choose the unit of measure used for the value in the field. Use the intrinsic field Length (I) if there is no explicit length field. On large road networks for which drive-time zones may be repeatedly calculated, it is more efficient to create a "length" field in the table and to copy into that length column the contents of the Length (I) intrinsic field using the transform toolbar for tables. This will avoid a recalculation of Length (I) on the fly for each run and will improve performance.

**Speed** Choose a field to use that gives the speed of travel for each line in the road network. Choose the units of measure used for the length and time values in the field, for example, miles per hour or kilometers per hour. By default, if a column named Speed is available in the drawing's table it will be automatically loaded into the Speed box.

**Split roads at intersections** If checked, split road lines into separate lines at intersections with other roads.

**Method** Choose **Buffer**, **Hull** (default) or **Zone** as follows:

**Buffer** - Find all portions of roads that may be reached in the given time and then build a buffer zone area about each road line that extends out the given distance. Specify the distance desired and the units to be used (meters, feet, etc.) for the distance. **Use with care**, since phenomenally complex buffer zones can be created in urban areas that may take a long time to compute.

**Hull** - Find the most distant spot on each road that may be reached in the given time and create an area that is the convex hull enclosing the most distant points. This is the usual "drive time zone" polygon created by ordinary GIS systems.

**Zone** - Find the most distant spot on each road that may be reached in the given time as well as the additional area that may be reached by travelling from each reachable spot at the given Off-road speed. The Off-road speed value is specified using whatever units of
linear measure are used in the coordinate system of the projected drawing and whatever units of time measure are used for the Speed combo. For example, if the drawing is in a meter-based projection like Orthographic and the Speed value is in miles per hour the value for Off-road speed will be in meters per hour. The Zone method serves the classic task of trying to find how far someone can get in a given time if they travel either/or by road or by leaving the road and travelling over the ground off-road (often used for law enforcement search planning).

**Zones**
The drive time for each zone and the units of measure (hours, minutes, etc.). For example, to create a single drive time zone enter 60 for the distance reachable in that time. Enter 60, 120, 180 to create three drive time zones each of which is reachable in times of 60, 120 and 180. **Note:** this requires the Tools - Options - Miscellaneous - Use English measurement units option to be set the same as the linear units of measure used by the coordinate system.

**To create a drive time zone from a single center:**

1. Open a projected drawing that contains lines that form a connected road network and at least one point. Lines should have a field that can be used as the Speed field. If all roads are to be treated as having the same speed, simply create a “speed” field and fill it with 1 for all lines.
2. Select a point on the road network (lying exactly at the end of one of the lines that make up the network) that will be the center of the drive-time zone. Launch the Drive-Time Zones command.
3. Choose [Selection] for the Center value.
5. Choose Length (I) to use as the Length value as well as the unit of measure.
6. Choose the name of the field giving the speed value in the Speed combo as well as the units of measure.
7. Choose the desired Method.
8. In the Zones field, choose the time desired for each zone plus the unit of time measurement. Press OK.

When choosing Method, it is a good idea to start with a simple method, such as Hull, to see just how much of a region will be covered by a given set of parameters in a drive-time zone. This will reveal situations where settings accidentally result in very large drive-time zones that may cover many streets in an urban area. In such cases, use of the Buffer method may create extremely complex buffer zone areas that can take a long time (many hours) to compute. It is a good idea to test the desired parameters using a rapidly computed method such as Hull before launching a more compute-intensive method such as Buffer.

**Example**

We begin with a drawing of streets that has several points, one of which has been selected. The drawing is in an Orthographic meter-based projection so that distances are in meters and may be measured accurately.
The streets (as usual) consist of many lines with the end points of the lines coincident to form a connected network, that is a real network without any gaps or overshoots between the lines. The points are located exactly at the ends of lines so that they two are part of the network.

</tbody>
</table>

If we open the drawing’s table we see that most lines have a speed of 10 marked on them with some lines having higher speeds. In the drawing, lines with faster speeds have been thematically formatted so they are in different colors. The drawing’s table also has the Length (I) intrinsic field showing as well as a Length field that we created and populated by copying the contents of the Length (I) intrinsic field. We could use the Length field if we had a really big network and wanted the calculations to go slightly faster, but it is not used in this example.

Launching the Drive-Time Zones command with the above settings will create a drive-time polygon in the shape of a convex hull about the selected point that was used as the Center.

Note that the units used are mixed, with meters, miles per hour and minutes in use. The Length parameter is in meters, since the use of Orthographic projection cast the native dimensions in use in this drawing in meters. The units used for Speed are simply whatever is intended by the values in that column in the drawing. The example drawing is of a location in the United States, where speeds are recorded in miles per hour.
Manifold simply reaches out from the center point as far as is possible to go through the road network and then draws a polygon to enclose the most distant spots reachable. Because the two colored roads have much faster speeds than the smaller streets around them, by far the greatest reachable distance is over the faster roads. The maximum distance reachable in the given time over the faster roads thus marks the corners of the resultant drive-time zone.

If we delete the convex hull drive-time zone area and re-run the command using the same central point but using the **Buffer** option, we can create a drive-time buffer using a setting of **30** meters.

The result is more interesting than using the **Hull** option. What we see is how far we can get from the center point along all of the roads in the given time, plus a buffer zone that extends out 30 meters from each reachable spot. Note that because of the great difference in speed between the main roads and the smaller streets, we can get only a small distance down any of the side streets in the given time.
The **Buffer** option is often used to find which addresses can be reached in a given time from a central location. Addresses are often placed in drawings using the geocoder and so they are often not exactly on the street line but close to the street line. By creating a buffer zone as a drive-time zone, we can find which address dots are located within the resultant buffer zone area.

Using the **Buffer** option provides a very rich display, but it can be very computationally intensive. In a road system with many roads, even a slight increase in the drive time distance can result in a considerably more complex buffer area with a surprisingly large increase in computation time required. Use this option with great care, scaling up in small steps to avoid launching Manifold on a job that could take days to compute.

A third option is to use the **Zone** option as seen in the dialog above, using an **Off-road** speed of 3200 to represent 3200 meters per hour, approximately 2 miles per hour. The linear units for the **Zone** speed are taken from the projection, in this case **meters** from the Orthographic projection and the time units of measure are the same as are specified for the **Speed** parameter, in this case being **hours** from the miles per hour speed values.

The resultant drive-time zone is very interesting. It shows how far one can travel from the central point using a combination of travel on the roads and travel off the road. For regions far from the central point the zone shows those spots reachable when travelling all the way or almost all the way by car at the given road speed. That's why the zone is elongated along the lengths of fast main roads.

Closer in to the central point the zone covers those spots that are reachable if we go a short way by the road network and then get out of the car and travel off-road over the ground at the given off-road speed for whatever time is left. Therefore, close to the central point the regions between roads get filled in because they can be reached within the given time by off-road travel.
If we had re-run the command using an off-road speed of 5 we would have obtained the result above. It shows that if our off-road speed is faster, we can get to even more regions in between roads.

The Zone option is often used by law enforcement or search and rescue services to define an area to search when a period of time has elapsed and the target person may be travelling on or off roads. For example, suppose some people in a four-wheel drive vehicle are lost in a semi-desert region where it is not clear if they stayed on the road during their travel or ventured off-road into the desert. If we know where they started and how much time has elapsed we can make reasonable guesses at their speed on the road network and their speed off-road. We can then use the Zone option to find the region to search, consisting of that region that they could reach through any combination of on-road and off-road travel.

**Troubleshooting**

Simple errors that may cause problems:

- Points to be used as locations are either not on lines or are not within the drawing's precision factor distance of a line. Since the default precision factor for a projected drawing is 0.000001 meter (about one thousandth of a millimeter) it is highly unlikely that points placed in drawings using anything other than Snap functions will be adequately close to a line to be considered "on" the line.
- The drawing of roads might not be a real network, that is, the ends of adjacent lines may not be coincident, there may be dangles or undershoots, breaks in the lines or other disconnects that prevent the lines shown from being used as a real network. Use Normalize Topology to "clean" the road network if need be, but keep in mind that poorly drawn road drawings might not be repairable even with the Normalize Topology tool.
- The units of measure used in the dialog do not correspond with the units of measure used in the drawing or used in the Speed or Length fields. For example, if a drawing has been projected using a foot-based projection the use of meters to interpret a Length (I) intrinsic field will be inaccurate.
- The drawing is not projected and covers a sufficiently large area that errors arise. Always use a drawing that has been projected using a projection appropriate to the region of interest. For small regions (say, the size of a state or province in most countries), Orthographic is a fine meter-based projection that is a good bet.
- Changing the setting of requires the Tools - Options - Miscellaneous - Use English measurement units option to be different from the linear units of measure used by the projection / coordinate system will cause inaccurate results. If the projection is in meters, that option should be unchecked. If the projection is in feet, the option should be checked. It is possible to leave the option in an incompatible state and to multiply the Zones values by the ratio feet to meters or meters to feet and still get an accurate result, but that is difficult to keep in mind and not recommended.

**Note**

Strictly speaking, a drawing used for drive-time zone computation need not be projected. However, since degrees of Latitude vary in size from the Equator to the Poles any task that requires accuracy should use only projected drawings.

**See Also**

Network User's Introduction
Optimal Route

The Drawing - Optimal Route menu selection is enabled when the optional Business Tools extension has been installed and the focus is on a drawing window or on a drawing layer in a map window that contains lines and at least two points (between which a route can be selected). If you have not activated the Business Tools extension with a valid Business Tools serial number you will not be able to use the Optimal Route command.

The Optimal Route tool is a less-interactive version of the Optimal Route (Visual) tool. It simply finds the best route through a given set of locations (the selection or a saved selection), taking the locations in free order. To learn how to use this tool, see the Optimal Route (Visual) topic.

The drawing of road lines used must be a true road network that is a connected network. If there are small breaks between the road lines or if the ends of adjacent lines are not exactly coincident the drawing cannot be used as a road network.

The Optimal Route tool is provided for expert use as a specialized shortcut. In almost all cases for interactive work it is better to use the Optimal Route (Visual) dialog. However, the parameters used in Optimal Route are directly analogous to those used in the programming model when scripting optimal routes. The Optimal Route dialog is therefore especially useful to programmers who are learning to work with Manifold's optimal route capabilities via the scripting interface.

Controls

- **Locations**: Points to use for locations. [All Objects] or [Selection] or a saved selection.
- **Roads**: Objects to be used for road lines. [All Objects] or [Selection] or a saved selection.
- **Length**: Choose a field to use that gives the length of each line in the road network. Choose the unit of measure used for the value in the field. Use the intrinsic field Length (I) if there is no explicit length field. On large road networks for which optimal routes may be repeatedly calculated, it is more efficient to create a "length" field in the table and to copy into that length column the contents of the Length (I) intrinsic field using the transform toolbar for tables. This will avoid a recalculation of Length (I) on the fly for each run and will improve performance. Lines with a zero or negative value for Length will be ignored and will not be used in the route.
- **Speed**: Choose a field to use that gives the speed of travel for each line in the road network. Choose the units of measure used for the length and time values in the field, for example, miles per hour or kilometers per hour. By default, if a column named Speed is available in the drawing's table it will be automatically loaded into the Speed box.
- **Split roads at intersections**: If checked, split road lines into separate lines at intersections with other roads.
- **Save report**: Check to create a comments component in the project that contains a driving directions report.
- **Names**: Field to use for road names in the driving directions report. If [None] is selected, the report will be created using a format without road names. By default, if a column named Name is available in the drawing's table it will be automatically loaded into the Name box.
- **Turns**: Choose the writing style used to report turns. none results in no turns reported. The other two styles allow choice of turns using either compass directions (for example, to turn North or South at a given intersection) or relative directions (for example, to turn right or left at a given intersection).
OK  Find and optimal route and add a line object to the
drawing representing the route. Add a comments
component with driving directions if the Save report box
has been checked. If no route has been as yet created
using the Locate Route button, pressing OK is the same
as Cancel.

Cancel  Exit the dialog without making any changes to the
drawing.

Units of Measure used by Intrinsic Fields

The units of measure used by the Length (I) and Area (I) intrinsic fields depend upon both the projection of the
drawing and the Tools - Options setting for the Use English measurement units option as follows:

- If the drawing is in Latitude / Longitude (that is, unprojected) Length (I) is reported in degrees and
  Area (I) is reported in square degrees.
- If the drawing is projected and the Use English measurement units option is turned off, Length (I) is
  reported in meters and Area (I) is reported in square meters.
- If the drawing is projected and the Use English measurement units option is turned on, Length (I) is
  reported in feet and Area (I) is reported in square feet.

Troubleshooting

Simple errors that may cause problems:

- Points to be used as locations are either not on lines or are not within the drawing's precision factor
distance of a line. Since the default precision factor for a projected drawing is 0.000001 meter (about
one thousandth of a millimeter) it is highly unlikely that points placed in drawings using anything other
than Snap functions will be adequately close to a line to be considered "on" the line.
- The drawing of roads might not be a real network, that is, the ends of adjacent lines may not be
  coincident, there may be dangles or undershoots, breaks in the lines or other disconnects that prevent
  the lines shown from being used as a real network. Use Normalize Topology to "clean" the road
  network if need be, but keep in mind that poorly drawn road drawings might not be repairable even with
  the Normalize Topology tool.
- The units of measure used in the dialog do not correspond with the units of measure used in the
  drawing or used in the Speed or Length fields.
- The drawing is not projected and covers a sufficiently large area that errors arise. Always use a
drawing that has been projected using a projection appropriate to the region of interest. For small
regions (say, the size of a state or province in most countries), Orthographic is a fine meter-based
projection that is a good bet.

Network User’s Introduction
Optimal Route (Visual)
Optimal Route (Visual)

The **Drawing - Optimal Route (Visual)** menu selection is enabled when the optional Business Tools extension has been installed and the focus is on a drawing window or on a drawing layer in a map window that contains lines and at least two points (between which a route can be selected). If you have not activated the Business Tools extension with a valid Business Tools serial number you will not be able to use the **Optimal Route (Visual)** command.

The **Optimal Route (Visual)** command provides an interactive dialog that allows choosing locations within a road network so that an optimal route between the locations may be found through the road network, taking into account the length of the roads and speed limits on the roads. In the main display pane the dialog shows a visual preview of the drawing in which locations are selected and routes are found. The dialog also lists the locations to be traversed and relevant options for the road network.

Locations to be visited may be selected from any point in the drawing meeting one of the following criteria:

- The point is located exactly at the endpoint of a line.
- The point is located exactly at one of the coordinates that defines a line.
- The point is located closer to the line than the distance given in the drawing’s location precision property (open the drawing, click on View - Properties and then the Precision […] button).

The drawing of road lines used must be a true road network that is a connected network. If there are small breaks between the road lines or if the ends of adjacent lines are not exactly coincident the drawing cannot be used as a road network.

To operate the dialog, open a drawing that has a road network of lines as well as points on the lines that are to be visited. Launch **Optimal Route (Visual)** and then in the preview pane click on the points to be visited to add each point as a location. As each point is clicked, it will be highlighted with red selection color and added to the list of locations to be visited in the lower left pane of the dialog. The start location will be shown with a larger red dot and the end location will be shown with a larger red diamond. Clicking a point that has been already selected will deselect it from the route.

By default, the system will find an optimal path through all of the locations from the first location to the last location regardless of the order in which locations between the first and the last appear in the list. To force the system to find an optimal path through the locations in the order in which they appear in the locations list, check the **Use list order** box before locating a route. To order the locations within the list, either click them in the preview pane in the desired order or change the order in the list. To re-order locations in the list use the up and down buttons in the locations list pane’s toolbar.

If any points are selected in the drawing when the **Optimal Route (Visual)** dialog is launched they will be automatically added to the locations list for the route. A start location may then be designated by highlighting it in the locations list and clicking the **Move to Top** button and an end location may be designated by highlighting it in the locations list and then clicking the **Move to Bottom** button. If the dialog is re-run in a drawing and no points are selected, the dialog will launch with whatever was the last used list of locations. This makes it easy to re-run the dialog without having to re-click points into the locations list.

Locations will be listed in the locations list pane using their object ID numbers. If each point has a field called “Name” pressing the **Show Name** button will show the contents of the Name field for each location in the list. Using the **Show Name** button provides a much more user friendly list of locations than just using the object ID's.

Options in the lower right section of the dialog allow choosing which field specifies the length of the roads, the field specifying the speed of travel over each road and the units of measure. If desired, a report can be created using a variety of styles that provides driving directions for the route.

When all options have been selected, pressing the **Locate Route** button will identify the optimal route between the points to be visited. The route will be shown in red selection color. Pressing the **Trace Route** button will launch an animation that shows a small dot travelling over the route. When a route has been located, we can click the **Save Report** button to save a report of driving directions as a comments component in the project under whatever name we like.

When happy with the located route, press **OK** and the route will appear in the drawing as new line object that traverses the route. The new line object will be selected. To avoid creating duplicated objects in the drawing it is a good idea to **Cut** the new route line object and to **Paste** it into a new drawing.
To find an optimal route between locations:

1. Open a projected drawing that contains lines that form a connected road network and at least two points. Lines should have a field that can be used as the Speed field. If all roads are to be treated as having the same speed, simply create a "speed" field and fill it with 1 for all lines. Launch the Optimal Route (Visual) dialog.

2. In the preview pane, click on the point that is to be the starting point for the route. Next, click on each point that is to be visited in order. All points must be on the road network (that is, lying exactly at the end of one of the lines that make up the network). The clicked points will appear as locations to be visited in the locations list.

4. Choose Length (l) to use as the Length value as well as the unit of measure. The unit of measure will depend on the projection in use and is normally meters (for meter-based projections like Orthographic) or feet (usually used only in US specific projections).

5. Choose the name of the field giving the speed value in the Speed combo as well as the units of measure (the default is meters per hour, which quite likely will be changed to miles per hour or kilometers per hour).

6. Press the Locate Route button to see a preview of the route in the preview pane. To animate the route, press the Trace Route button.

7. If a driving instructions report is required, choose the report options desired and click the Save report button. This will create a new comments component in the project that reports the driving instructions for the route.

8. If happy with the route, press OK. A new line object will be created in the main drawing and highlighted in red selection color. The line object is a single line that includes all coordinates traversed in the route. To save this line, Cut it, create a new drawing and then Paste it into the new drawing. It is usually useful to save the new line that represents the route so that it may be used together with the original drawing in a map, with the new route line formatted to make the route obvious (using a thicker line, etc).

9. If the Save report option was chosen, the system will generate a report and save it into a new comments component.

Controls

(Visual preview pane) Displays the drawing in default gray color.

- **Zoom To Fit** - Zoom so that the entire drawing fits within the preview pane.
- **Zoom In** - Magnify the view as if seen from a closer distance.
- **Zoom Out** - Reduce the view as if seen from farther away.
- **Zoom Box** - Zoom to the size of the cursor box drawn with the mouse.
- **Center Point** - Pan the view so that the spot clicked is centered.
- **Grabber** - Interactive pan: click and drag with the grabber hand. The scene will be panned so that the initial point is moved to the spot where the drag is released.
- **Trace Route** - Animate the route using a moving black dot to trace out the route.

(locations list pane) A list of locations to be visited in order by the route. The starting location is at the top of the list and the end location is at the bottom of the list. Location are identified by their internal Manifold ID numbers and, if desired, by the contents of a Name field in the drawing's table if the Show Names button is pushed in.

- **Delete** - Delete the highlighted location from the locations list pane. Clicking a location that has been already selected will also deselect it from the route and delete it.
from the locations list pane.

- **Center** - Center the highlighted location in the window.

- **Ping** - Locate the highlighted location by drawing converging circles to it. A great way to see what the highlighted location is.

- **Move to Top** - Move the highlighted location to the top of the locations list pane.

- **Move Up** - Move the highlighted location up one position in the locations list pane.

- **Move Down** - Move the highlighted location down one position in the locations list pane.

- **Move to Bottom** - Move the highlighted location to the bottom of the locations list pane.

- **Show Names** - In the locations list display names for locations taken from a Name column for the point in the drawing's table.

**Use list order**

If checked, Manifold will create an optimal route that goes through all of the locations in the locations list in order. If not checked (the default) Manifold will begin at the first location and end up at the last location but will find an optimal route that goes through all of the other locations at least once in the best possible way.

**Locate Route**

Enabled when two or more points have been selected in the preview pane and added to the locations list. Press to create an optimal route between the locations in the desired order. **Note:** until the OK button is pressed, the located route is only a preview.

**Roads**

Objects to be used for road lines. [All Objects] or [Selection] or a saved selection.

**Length**

Choose a field to use that gives the length of each line in the road network. Choose the unit of measure used for the value in the field. Use the intrinsic field Length (l) if there is no explicit length field. On large road networks for which optimal routes may be repeatedly calculated, it is more efficient to create a "length" field in the table and to copy into that length column the contents of the Length (l) intrinsic field using the transform toolbar for tables. This will avoid a recalculation of Length (l) on the fly for each run and will improve performance. Lines with a zero or negative value for Length will be ignored and will not be used in the route.

**Speed**

Choose a field to use that gives the speed of travel for each line in the road network. Choose the units of measure used for the length and time values in the field, for example, miles per hour or kilometers per hour. By default, if a column named Speed is available in the drawing's table it will be automatically loaded into the Speed box.

**Split roads at intersections**

If checked, split road lines into separate lines at intersections with other roads.

**Save report**

Enabled when a route has been located. Press to create a comments component in the project that contains a driving directions report.

**Names**

Field to use for road names and location names in the driving directions report. If [None] is selected, the report will be created using a format without road names or
location names. When names are used, the report will note all points that are passed by the route even if they are not in the locations list. By default, if a column named Name is available in the drawing’s table it will be automatically loaded into the Name box.

**Turns** Choose the writing style used to report turns. none results in no turns reported. The other three styles allow choice of turns using either compass directions (for example, to turn North or South at a given intersection) or relative directions (for example, to turn right or left at a given intersection), of both relative and compass (the default).

**OK** Accept the current route shown in the preview pane and add a line object to the drawing representing the route. If no route has been as yet created using the Locate Route button, pressing OK is the same as Cancel.

**Cancel** Exit the dialog without making any changes to the drawing.

**Example**

Let's use the Optimal Route (Visual) dialog to find a route between locations.

We begin with a drawing of roads that has several points in the drawing as well. The points have been exactly located at the ends of lines using snap mode to snap to the ends of lines when creating points.

</tbody>
</table>

If we open the drawing's table we can see that each line has a Name and a Speed for the road represented by that line. The speed shows the actual speed used on that road which in some cases is substantially larger than the posted speed limit. We have the Length (ft) intrinsic field turned on for display so that at a glance we can see the length of each road line.
If we select the points and view the drawing's table with the Selection Filter button pushed in so that only the selection is visible, we can see that the each point also has a Name value describing the point.

When we launch the Optimal Route (Visual) dialog it shows the drawing in a preview display in the upper pane. Points in the drawing are shown in bright green color by default. Any color desired may be specified in the Tools - Options - Color page.

We begin building a route by clicking the start location in the dialog's preview pane.
When we click the first location desired, it appears as a larger red diamond. The red color indicates it has been selected as part of the route and the larger diamond indicates it is the end location of the route (with only one location selected the initial location is also the end location).

In the locations list pane a new location is listed using the Manifold object ID number.

If we press in the Show Names mode button the locations list pane will report the Name for that location as well.

To add the next location we click on it in the preview pane.
When clicked it also appears as a larger red diamond. The larger diamond indicates it is the end location for the route. The initial location has changed to a larger red dot. The larger dot indicates it is the start location for the route.

In the locations list pane the new location appears below the first location.

We can add a third location by clicking on it in the preview pane.

The last location added appears as a larger red diamond to indicate it is the end location. Note that the previous end location (now the middle location of the route) appears as a smaller red dot, the red color indicating it has been selected as part of the route.
The third location added to the route also appears at the bottom of the locations list.

We can continue in this way to add two more locations to the route. The start location and the end location are shown as a larger dot and a larger diamond respectively and the intermediate locations appear as smaller red dots.

Each location also appears in the locations list.

Before finding routes we set up options. For the length of the road lines we will use the Length (I) intrinsic field. Since the drawing is in Orthographic projection and Use English measurement units is turned off in our installation, we use meters as the unit of length. The speeds are given in miles per hour using the Speed field in the table. For the report, we will use the absolute style of directions, using compass directions.
If we press the **Locate Route** button a route will appear in the preview pane. If we press the **Trace Route** button we can see how the route passes through the various locations from start location to end location. Some of the road segments are used more than once.

We can also press the **Save report** box so that a comments component giving driving directions will be generated.

If we press **OK** to accept the route, a new line object is generated in the drawing and a comments component containing driving instructions is added to the project. The new line, shown in red selection color, might be difficult to see in the drawing. We use **CTRL-X** or **Edit - Cut** to **Cut** the new line object out of the drawing. We then paste it into the project pane as a new drawing.
We can then show the new drawing in a map together with the original roads drawing as seen above. We've formatted the new drawing with thicker lines so that the red selected route line is more visible.

Start at Fire Station.
Turn South-East on Middlefield.
  Drive for 2 minutes (2.30 mi).
Arrive Park.
Continue South-East on Middlefield.
  Drive for 1 minute (1.58 mi).
Turn North-East to California.
  Drive for 3 minutes (0.54 mi).
Arrive Middle School.
Turn South-West on California.
  Drive for 3 minutes (0.54 mi).
Turn North-West to Middlefield.
  Drive for 1 minute (1.58 mi).

The driving directions (fragment shown above) enumerate each segment of the route in text form. The driving directions also show the total time, total distance and average speed over the route. The illustration above shows driving directions using the "absolute" Turns style.

Start at Fire Station.
Take Middlefield.
  Drive for 2 minutes (2.30 mi).
Arrive Park.
Keep straight on Middlefield.
  Drive for 1 minute (1.58 mi).
Turn left to California.
  Drive for 3 minutes (0.54 mi).
Arrive Middle School.
Make U-turn on California.
  Drive for 3 minutes (0.54 mi).
Turn right to Middlefield.
  Drive for 1 minute (1.58 mi).

The illustration above shows driving directions using the "relative" Turns style.

Start at Fire Station.
Take Middlefield.
  Drive for 2 minutes (2.30 mi).
Arrive Park.
Keep straight on Middlefield (South-)
  Drive for 1 minute (1.58 mi).
Turn left to California (North-East)
  Drive for 3 minutes (0.54 mi).
Arrive Middle School.
Make U-turn on California (South-West)
  Drive for 3 minutes (0.54 mi).
Turn right to Middlefield (North-West)
  Drive for 1 minute (1.58 mi).

The third illustration above shows the default style, which uses both compass absolute and relative turns driving directions.
Which style is desired is a matter of taste. The absolute style uses compass directions and so is less ambiguous than the relative style in case of errors where the driver gets off a route and must rejoin it at some later point. However, the relative style is easier for most ordinary people to follow when driving. The both style is the default because it is completely unambiguous.

It is often the case that a road shown in a drawing is made up of multiple lines laid end to end. Manifold will collapse the driving directions for such end-to-end lines of identical name into a single line in the report. However, if the road changes name along the end-to-end sequence of lines the driving directions will note the newly named road as a new line in the report.

**Units of Measure used by Intrinsic Fields**

The units of measure used by the Length (I) and Area (I) intrinsic fields depend upon both the projection of the drawing and the Tools - Options setting for the Use English measurement units option as follows:

- If the drawing is in Latitude / Longitude (that is, unprojected) Length (I) is reported in degrees and Area (I) is reported in square degrees.
- If the drawing is projected and the Use English measurement units option is turned off, Length (I) is reported in meters and Area (I) is reported in square meters.
- If the drawing is projected and the Use English measurement units option is turned on, Length (I) is reported in feet and Area (I) is reported in square feet.

**Troubleshooting**

Simple errors that may cause problems:

- Points to be used as locations are either not on lines or are not within the drawing's precision factor distance of a line. Since the default precision factor for a projected drawing is 0.000001 meter (about one thousandth of a millimeter) it is highly unlikely that points placed in drawings using anything other than Snap functions will be adequately close to a line to be considered "on" the line.
- The drawing of roads might not be a real network, that is, the ends of adjacent lines may not be coincident, there may be dangles or undershoots, breaks in the lines or other disconnects that prevent the lines shown from being used as a real network. Use Normalize Topology to "clean" the road network if need be, but keep in mind that poorly drawn road drawings might not be repairable even with the Normalize Topology tool.
- The units of measure used in the dialog do not correspond with the units of measure used in the drawing or used in the Speed or Length fields.
- The drawing is not projected and covers a sufficiently large area that errors arise. Always use a drawing that has been projected using a projection appropriate to the region of interest. For small regions (say, the size of a state or province in most countries), Orthographic is a fine meter-based projection that is a good bet.

**Notes**

Strictly speaking, a drawing used for optimal route computation need not be projected. However, since degrees of Latitude vary in size from the Equator to the Poles any task that requires accuracy should use only projected drawings.

When showing route lines in maps, using a line style with directional arrows is an easy way to show direction.

What do we do if our drawing is in Orthographic or other meter-based projection but we would like to have length units in miles? We can turn on the Use English measurement units option and then create an Active Column that converts the Length (I) intrinsic column from feet to the equivalent distance in miles and then use the Active Column in the Length box.

**Tech Tip on Performance**

The task of locating an optimal route through a given number of locations in optimal order is NP-full. That is, solving the task can be mathematically shown to require examination of all possible permutations of the source data to achieve an absolute optimum. Therefore, the task is not solvable for any number of locations above 10 to12 because the required computing time expands so enormously beyond that number of locations.
A computation strategy for locating optimal routes when there are more locations is to use an heuristic algorithm that gives good results even if the results are not a mathematically perfect optimal route. Manifold uses this strategy. When there are ten or fewer locations Manifold will compute an exact solution. With eleven or more locations, Manifold uses an heuristic algorithm to find the optimal route.

It sometimes comes as a surprise to network newbies that finding an optimal route through a number of locations is much harder if the system must find the best route through them when they are taken in any order than if locations are visited in a given list order. The reason is that finding an optimal route through many locations in a given order is a simple matter of repeatedly finding the shortest path between only two locations: from the first location to the second, from the second to the third and so on.

In contrast, finding a route that minimizes travel time through many locations in free order requires solving the entire problem before even the second location to visit can be determined.

Optimal Route
Send Email

The Drawing - Send Email menu selection is enabled when the optional Business Tools extension has been installed and the focus is on a drawing window or on a drawing layer in a map window that contains points, lines or areas. The command is also available when the focus is on a table window. If you have not activated the Business Tools extension with a valid Business Tools serial number you will not be able to use the Send Email command.

Manifold's Send Email command adds direct email capability to Manifold System. If you have data that contains an email address in some data attribute field, you can automatically email to objects using those email addresses. Send Email works by sending email through the Windows MAPI email layer. If applications that also use MAPI such as Outlook or Outlook Express have been installed the email will end up being routed through the Outlook or Outlook Express outbox.

Using a computer that already has Microsoft Outlook or Outlook Express installed is recommended because Outlook provides a simple means of checking that your system has been configured to correctly send email. Before attempting to operate Send Email make sure you can send email from Outlook. If you can't send email with Outlook, please fix that problem first.

Controls

From Enter an email to appear as the "from" email. When emailing on a system that has Outlook installed, whatever is the default email sending account for Outlook will appear in the "from" header in the emails regardless what is entered into this From field.

To Choose the field that contains email addresses. For example, if we have a drawing of points representing customers where the drawing's table has an "email" field that contains each customer's email address, we would choose the email field.

Email addresses must be in the form username@domain, for example, sales@manifold.net

Addresses in the form "Manifold Sales" <sales@manifold.net> will not work.

Skip duplicates Email only once to each email address if more than one selected record has the same email address. Checked by default.

Subject Enter text to appear as the subject field for each email.

Message Enter a text message to appear as the body of each email. If we have a longer email, it may be more convenient to compose the message as a text file and to then copy from the text file and to paste into the dialog. A Manifold project might have several email texts on hand in the form of comments components that can be copied and pasted into the Message dialog box as desired.

Expand column references Expand escape sequences containing column names to column values. Checked by default.

OK Send the emails.

Cancel Exit without sending email.

The Subject and Message texts can contain the names of columns in square brackets [ ]. Sending email messages will automatically replace the column names with data from those columns from the relevant table records.

To send email from Manifold:

1. Open a drawing or table that contains a field with an email address.
2. Select the objects in the drawing or the records in the table to which email should be sent.
3. Choose Send Email from the main Drawing or Table menu.
4. Fill in a value for the From field (will be overridden by the Outlook default From account setting if Outlook is used).
5. Choose the column name that contains email addresses for the To setting.
6. Enter whatever text is desired for the Subject and Message boxes and press OK.
7. Email message will automatically be created for each selected object and loaded into the Outbox for Outlook.

Example

Let's imagine that John's Gas Stations is a company operating a chain of gas stations in Northern California. The company wishes to send an email message to each congressional representative in whose district they operate a gas station to urge opposition to a proposed law that would force the company to raise prices.

We begin with a map that has two layers: a drawing layer called Congress showing congressional districts and containing the email address for each congressional representative, and a drawing layer called Facilities that shows the location of our gas stations.

With the focus on the Congress layer, we select the desired districts in the Congress layer using the above settings in the transform toolbar.

The result is that each congressional district containing one of our gas station facilities has been selected.
If we open the Congress drawing's table (with the selection filter button pushed in so that only selected records appear) we can see the data for the selected districts. Note that a field called Email contains the email address for each representative.

We launch the Send Email command and fill it the boxes as seen above. Note the use of field names in square brackets [ ] that will be substituted for each email with the appropriate value for that record. For example, the subject text in the email sent to congressman Pete Stark will have the Subject text of

**Important Message for Pete Stark**

and the Message body in the email will begin

**Dear Representative Stark,**

The use of square brackets and appropriate data fields provides a degree of personalization for what might otherwise be read as an impersonal mass mailing.

When we press OK the system will create six email messages, one for each selected object, and will pass them through the Windows MAPI layer for sending. If we have Outlook installed, the messages will end up in the Outlook mailbox, ready for sending.

**Emails Must be Valid**

Send email can only work with email addresses that are correct email addresses. If the table used contains an invalid email address, the send email process will stop with an error message when it hits that record.

For example, if sending email to sales@manifold.net a typographic error that inserts an unnecessary space as in **sales@manifold.net** or **sales@manifold.net** would result in an invalid email address that will stop the send email process.
An easy way to find invalid email addresses is to use the Query Toolbar with the not button pushed in and the Containing Match to search for the regular expression given below:

```
({\w.\!$%\-+}+@[A-Za-z0-9\-]+(\.[A-Za-z0-9\-]+)+)
```

Pressing Select in the query toolbar will find all records that do not have valid email addresses. Using the selection filter in the table to show only selected records, the malformed email addresses may then be corrected or their records deleted.

As an alternative, we can use the Edit - Find command with the regular expression box checked to search through email field using the regular expression given above.

Copy and paste the above regular expression from this Help topic into the Find box. The regular expression will select records that have valid email addresses. Using Edit - Select Inverse we can invert the selection to find all those records not matching the above regular expression.

**Using Outlook and Outlook Express**

When sending a lot of mail, the system works much faster if Outlook or Outlook Express has already been launched before Send Email begins sending mail messages.

The emails will be created and placed in the Outlook Outbox. They will be sent the next time Outlook sends and receives mail. If you have Outlook set up to automatically send and receive mail using a full-time Internet connection, the email will go out with the next send/receive operation. If you are using a dial-up line, connect to your ISP and check mail as you normally would and the emails will go out at that time.

Emails will be passed to Outlook and Outlook will do the actual mailing. If you look in the Outbox before the mail gets sent and see a name instead of an email address for a record, check your Outlook Contacts to see if you have that particular email address entered as a Contact with a different name in your Outlook installation. In such cases Outlook is taking the email address passed by Manifold and substituting a name based on the Contacts information. The mail will still be sent properly; Outlook is just trying to be helpful by showing you the name associated with that email address.

When Outlook is installed, the From field will be inherited from however you have set up Outlook. There are methods to alter the From field by establishing an account with a fake originator address and (temporarily) setting this account to be the default for Outlook; however, if you are planning on doing such things you already know how to do this. Please don't use such techniques for spam purposes.

Outlook and Outlook Express may raise a confirmation box when Send Email is used to confirm that the user allows sending of email from a different program. This is an anti-spam measure that is intended to prevent viruses or other malign programs from using a computer's Outlook installation to send spam without the user realizing it. However, such confirmation boxes can be highly annoying when sending lots of email using Send Email.

Mail confirmation message boxes displayed by the Outlook Express can be disabled by checking off the "Warn me when other applications try to send mail as me" option in the Outlook Express Tools - Options - Security menu. Unfortunately, Outlook XP does not appear to have the same option (a good reason to use Outlook Express when working with Send Email).

**Paging**

Keep in mind that the ability to send email is also the ability to page someone via email. If we keep the right pager email addresses in the map's data fields, we can use Send Email to page people. Cool!

It is important to know the terms and conditions the pager service provider has for their email to pager service. An email paging service may require us to know the pager's PIN number as well as one or more numeric identifiers for that pager. For example, to send a page, one might be required to use an email address in the form

```
8007208398.9801155@pagercompany.com
```

Pay attention to the maximum message lengths acceptable to the pager service provider. Some providers will take long messages and split them into multiple pages sent to the pager. In such cases, the messages we send to the pager should be kept short.

Not all email to pager services can handle all of the fields that may appear in a normal email message. Some services cannot handle a Subject: line while others encourage it.

Note that not all pager companies allow pages via email. Some companies provide this service only to national customers and do not offer it to regional pager service customers. Other companies do not provide it at all. Some companies say they have an “email to pager” service, but it is a restricted service that does not allow general email as is commonly used throughout civilized society.

Examples of annoying restrictions include required use of proprietary pager company email packages, special web mail forms on web pages or the purchase of a special email account from the vendor. Some companies say they have “email to pager” service when what they have is only a form on their Internet web page but no access from normal email. Paging services are a highly competitive market. If your pager service company does not have true email capability, dump them and sign up with a company that provides the service you want.

If you are having trouble sending a page from within Send Email, try using the same addresses and body text from the same machine using Outlook. If you cannot use Outlook to send a message to the desired pager, this indicates a problem with your computer’s Outlook configuration, with your Internet connectivity, or with the email to pager service. If Outlook cannot send an email to the pager, Send Email will not be able to either.

A Request from manifold.net

GIS has played a key role in the development of “direct mail” in snail mail. GIS will also play a key role, for better or for worse, in the development of sophisticated geo-targeting methods for email as well as snail mail. We’d like to ask our colleagues and customers to use Send Email only for beneficial uses and in situations where the recipient wants to be contacted. Please do not use Send Email to spam people.

Send Email can be used for many good purposes. Emergency coordinators can be notified if a storm threatens their community. Volunteer fire department members in rural areas can be paged to deal with a specific fire threat. Companies can send email to representatives or dealers within a certain drive time of a proposed new product tour. The possibilities for good are endless.

Targeted email for those who want to receive it is good. Spam is bad. Please, let us all make sure that we in the GIS community will not be the ones who ruin a good thing.

Notes

The John’s Gas Stations example is fictional. Perhaps the most fictional aspect of the example is the use of email addresses for congressional representatives. Very few of the representatives have published emails for the public to use. Most hide behind a web form and do not allow direct emails.
**Topology Factory**

The **Drawing - Topology Factory** menu selection is enabled when the optional Business Tools extension has been installed and the focus is on a drawing window. If you have not activated the **Business Tools** extension with a valid serial number you will not be able to use the **Drawing - Topology Factory** command.

The **Drawing - Topology Factory** command provides an interactive dialog to view and repair common topological errors in drawings. To use Topology Factory, open a drawing and then launch Topology Factory. The system will scan the drawing and report any incidents found in a list, grouping incidents of the same type together. If a selection is present, Topology Factory works only on the selected objects.

Selecting a particular type of incident, such as **Lines intersecting other lines** will choose that set of incidents for repair. If there is more than one such incident of that type, the system will choose the first incident of that type and will make one of the lines involved in the incident red and the other line blue.

Clicking **Center incident** will zoom into the current incident. Clicking **Previous**, **Next** or **Last Incident** will choose one of the other incidents of that type.

Clicking **Fix Incident** will repair the incident using the method specified, where **auto** tells Manifold to choose which line to edit, and choosing **modify blue** or **modify red** will specify which line is to be modified so that the two lines do not intersect each other.

Topology Factory will report many relationships between objects as incidents that may or may not be errors depending on the intent of the drawing. For example, if we intend that some lines will intersect areas or that some areas are to overlap other areas then such incidents are not errors. On the other hand, if we do not want any areas to overlap other areas then such incidents are errors to be repaired. Since Topology Factory does not know what we intend it reports all incidents within the repertoire of incidents for which it scans.

To make it easy to see detected incidents out of a list of many possible types of incidents, Manifold provides four buttons to control sort order that may be used to rapidly bring relevant incidents to the top of the incidents pane.

**Location Precision**

The **Location precision** parameter in the **View - Properties - Precision** dialog guides Topology Factory in deciding when an object is sufficiently "near" another object to trigger an incident. The **Location precision** factor should be set to a distance value so that proximity of objects over distances smaller than the specified distance will be detected as an incident. For example, if desired, the **Location precision** factor may be relaxed to a higher value while working with Topology Factory to detect and correct incidents and then set back to a smaller value for more detailed work. For convenience, Topology Factory provides a **Precision** box to specify precision within Topology Factory.

Note that lowering the value of the location precision parameter (making it a smaller number) will increase the precision, that is, it will cause Topology Factory to examine smaller details. Increasing the value of the location precision parameter (making it a larger number) will cause Topology Factory to examine incidents over larger details. Setting the location precision parameter to a larger value, for example, will cause Topology Factory to ignore incidents where lines overshoot areas by very small distances that are less than the large size of the location precision parameter.

As with the case when working with any automated tool, keep in mind that making sweeping changes with Topology Factory using a precision parameter that is significantly larger than the precision with which the drawing was originally created may make undesirable changes in the drawing. For example, lines that intersect at a very acute angle may have their point of intersection moved. To avoid unintended changes in such cases, take a moment to save the project before making changes. Examine incidents carefully and make changes only after viewing each incident. Although Topology Factory is quite good at identifying incidents based on the precision parameter in use, it cannot read our minds to know in all cases what we intend. That is why an interactive dialog is provided to make it easy for the user to review incidents and to decide what should be done in each case.

**Controls**

(Visual preview pane) Displays the drawing with the current incident marked in red and/or blue selection color.
Zoom To Fit - Zoom so that the entire drawing fits within the preview pane.

Zoom In - Magnify the view as if seen from a closer distance.

Zoom Out - Reduce the view as if seen from farther away.

Zoom Box - Zoom to the size of the cursor box drawn with the mouse.

Center Point - Pan the view so that the spot clicked is centered.

Grabber - Interactive pan: click and drag with the grabber hand. The scene will be panned so that the initial point is moved to the spot where the drag is released.

Center Incident - Pan and zoom the display to the current incident.

First Incident - Choose the first incident for repair of a set of incidents.

Previous Incident - Choose the previous incident for repair of a set of incidents.

Next Incident - Choose the next incident for repair of a set of incidents.

Last Incident - Choose the last incident for repair of a set of incidents.

(fix method box) Choose a method to repair this particular incident: auto - Manifold chooses. modify blue - modify the object shown in blue. modify red - modify the object shown in red.

Fix the current incident using the selected method.

Fix all incidents of the highlighted type using the default fix method (auto).

(Incidents list pane) A list of incidents found in the drawing, with like incidents grouped together in the same type of incidents. Incident types with more than one incident will be shown in boldface together with the number of such incidents. If the repair of a given incident may affect other incidents, the number of incidents for such possibly affected types will be shown with an asterisk to indicate that they should be refreshed.

Alphabetic - Sort the incidents list pane by alphabetic order.

Alphabetic, Blanks Last - Sort the incidents list pane by alphabetic order, grouping detected incidents at the top of the list.

Recommended - Sort the incidents list pane by items Manifold recommends we should inspect.

Recommended, Blanks Last - Sort the incidents list pane by items Manifold recommends we should inspect, grouping detected incidents at the top of the list.

Refresh Re-scan the drawing for possible incidents that need to be repaired.
Types of Incidents

Topology Factory identifies the following:

**Areas near other areas**  Areas that are within the precision parameter of other areas, including overlaps.

**Areas near themselves**  Areas where any portion comes near itself within the precision parameter. Often will flag multi-branched areas with islands or holes when these disjoint portions of the same area are "near" each other.

**Areas overlapping other areas**  Areas that overlap other areas where the overlap is at least the precision parameter.

**Areas overlapping themselves**  Areas that overlap themselves (possible to do with pathological topology) where the overlap is at least the precision parameter.

**Areas with multiple islands**  Areas with multiple branches that form disconnected islands. Holes in multi-branched areas are not islands.

**Areas with redundant or invalid metric**  Areas where the sequence of coordinates defining the area is either redundant (for example, repeated identical coords) or forms an invalid metric. Multi-branched areas are flagged as possible invalid metric, so areas with islands or holes will be reported.

**Lines intersecting areas**  Lines that cross over areas, having an intersection of at least the precision parameter.

**Lines intersecting other lines**  Lines that cross over other lines.

**Lines intersecting themselves**  Lines that cross over themselves.

**Lines near areas**  Lines within the precision parameter of an area.

**Lines near other lines**  Lines within the precision parameter of another line.

**Lines near themselves**  Lines for which any portion comes near itself within the precision parameter. Often will flag multi-branched lines when these disjoint portions of the same line are "near" each other.

**Lines overlapping other lines**  Lines that coincide with another line.

**Lines overshooting areas**  Lines where the end of the line extends past the boundary of an intersected area.

**Lines overshooting other lines**  Lines where the end of the line extends past an intersection with another line.

**Lines overshooting themselves**  Lines where the end of the line extends past an intersection with a different portion of the same line.

**Lines undershooting**  Lines where the end of the line does not quite reach the boundary.
areas of an area.

Lines undershooting other lines
Lines where the end of the line does not quite reach another line.

Lines undershooting themselves
Lines where the end of the line does not quite reach a different portion of the same line.

Lines with contiguous branches
Multi-branched lines where some branches coincide.

Lines with multiple separate branches
Multi-branched lines where branches do not coincide.

Lines with redundant metric
Lines composed of sequences of coordinates where some coords are repeated or are otherwise unnecessary.

Points coinciding with other points
Points that are located at exactly the same position as another point.

Points near areas
Points that are located within the precision parameter of an area.

Points near ends of lines
Points that are located within the precision parameter of the end of a line.

Points near lines
Points that are located within the precision parameter of any part of a line.

Points near other points
Points that are located within the precision parameter of another point.

Incident List Sorting

The incident list may be sorted using the four buttons immediately above it as follows:

Pressing the Alphabetic button sorts incidents by alphabetic order.

Pressing the Alphabetic, Blanks Last button sorts incidents by alphabetic order, bringing found incidents to the top of the list.
Pressing the **Recommended** button sorts incidents by priority in which Manifold recommends they be fixed.

**Example**

Consider a drawing with two areas and two lines. The two areas are colored in different colors using thematic formatting.

The areas have been drawn so they overlap.
When we launch **Drawing - Topology Factory** the dialog opens showing the first highlighted incident centered at higher zoom so we can easily see the incident. When two objects are involved in an incident Topology Factory will draw one of them in red and one of them in blue so that we can easily choose which object we would like to modify to resolve the incident.

We have configured the incidents list using the **Alphabetic, Blanks Last** sort option so that found incidents are displayed at the top of the list. We have highlighted the **Areas overlapping other areas** incident.

In the upper right corner of the dialog we choose **modify blue** and then click the **Fix Incident** button.
Manifold will redraw the display, showing the object that has been modified in green. We can click **Refresh** to recompute topological relationships (which might have changed as a result of the modification).

After the refresh, we can see that the blue area has had the overlapping portion removed.

If we take a look at the incidents list, we see that there is no longer a report of overlapping areas. Instead, the first item on the list is **Areas near other areas**, which makes sense because the two areas are now adjacent.
In the above way we can proceed through the list of all incidents reported by Topology Factory, examining each and deciding how we would like each reported incident to be resolved.
Images

Images in Manifold are usually the familiar sorts of image that almost everyone has viewed or edited with applications such as Microsoft Paint, Microsoft Image Editor, Adobe PhotoShop, Microsoft Photo Editor and similar programs.

Such images are commonly stored as TIF, BMP, GIF, JPG or various other common image formats. Existing images may be imported into a Manifold project using the File - Import - Image command. New images may be created in Manifold and then exported into common image file formats using File - Export.

Creating a New Image

1. Open a project or create a new project with File - New.
2. Choose File - Create - Image to launch the Create Image dialog.
3. Provide a name for the image, the desired size in pixels and the type of image and press OK.

The File - Create - Image dialog takes the projection parameters for the new image from whatever window is active at the time the new image is created. If the project pane is active, the image will be created using the system default projection of Orthographic centered at the 0,0 world latitude/longitude origin. If a map window or other image window is active when the new image is created, the new image will be created using whatever projection is used by that active window. This context-sensitive setting of default projection parameters makes it much easier to create new images using projection parameters that are hassle-free by default.

Linked Images

An image that is imported into Manifold is stored within the Manifold .map project file. An alternative to importing images into Manifold is to link images into the project using the File - Link - Image command. Images may be linked into a Manifold project from a variety of sources outside of the .map file. When images are linked into a Manifold project the .map project file does not contain the actual image but rather contains a pointer to the source of the image, which remains stored outside of the project file.

See the Linked Images topic for additional information.

Image Fundamentals

Images are made up of pixels ("picture elements") arranged from left to right in a series of equal rows. They are often referred to as raster files in older GIS applications. ("Raster" is the old television word for the sweep of an electron gun across a series of rows used to create an image.)

Although images are normally photographic or scanned images that represent visual images of the world around us, images in Manifold can also be abstract data sets that are saved as pixels in a raster arrangement. For example, a multi-spectral satellite sensor might create an "image" of a continent from space where each pixel contains numbers representing temperature, reflectance, height above sea level as well as other information. Pixels in such an image may be colored according to their data values to convey the data content of the raster data set in a visual way.

Let's begin by explaining images in the context of familiar sorts of photographic images.
Images are fundamentally different from drawings in several ways:

- Images are made up of a sea of pixels and contain no "objects." Any objects we perceive in an image are the sole result of our psychological interpretation of regions of pixels of like color to be distinct things. Zoomed up close the image is a blur of pixels. Zoom far enough into the image above and it is unclear where the "sky" ends and the "monument" begins. In contrast, drawings contain true objects that are defined by precise sets of geometric coordinates for each object.

- The appearance of an image is highly dependent upon the zoom level. At zooms greater than 100%, the individual pixels will become visible as the image becomes ever more like a coarse mosaic. Drawings, on the other hand, are always razor sharp no matter how high the zoom. Objects in drawings will not change their appearance when zooming in or out: if a point is formatted as a small dot the dot will appear to be the same no matter what the zoom. In a drawing an intersection between lines will always be razor sharp.
whereas in an image what might appear to be a sharp intersection will at high zoom be seen as clumps of pixels.

- Images have no intrinsic coordinate system embedded in the image but rather depend upon an implied coordinate system suggested by the relationship of pixels to each other that is defined by their arrangement in rows. Drawings have an implicit coordinate system implied by the coordinates that define the objects. If an image is to be used within a coordinate system, it must first be referenced to that coordinate system.

- When drawings are re-projected the number of objects stays the same even though their shape may be different. When images are re-projected pixels are always created or deleted through interpolation as the images is projected into a different shape.

**Compressed Images**

Compressed images are a special type of image that is dynamically reconstituted as needed from compressed data. Although they may appear to consist of pixels and may be described as consisting as a certain number of pixels in width and height, they are dynamically created as necessary and do not actually consist of a fixed number of pixels. Compressed images are used for very large images where display must be fast and storage requirements reduced to accommodate the very large size of the image. In exchange for fast speed and reduced storage, compressed images are limited to display only functions and may not be edited.

**Georegistering Images**

Georegistering is the process of telling Manifold where a particular image is to be located on Earth. See the Coordinates Tutorial for more information on the concepts behind this process. Georegistration is closely related to the idea of projecting an image.

By default, images in Manifold are taken to be in Orthographic projection located at zero degrees latitude and zero degrees longitude, with each pixel in the image assigned a true geographic location based on the given size of pixels or DPI used when the image was created or imported. It does no harm to assume a geographic location for images that will be used in a purely abstract way (like PhotoShop), and having a built-in assumption about projection and location is very useful when images will be used in a geographic context.

See the Georegistration topic for information on how to georegister an image for use within a map. See the Projections and Images topic for more information on use of projections with images.

**Different Types of Images**

Because images can involve very large numbers of pixels and each pixel can involve several numbers to describe its color, images can require very large amounts of storage space. Many methods have been invented to save space when storing images. The more popular methods have become so prevalent that most image processing systems, including Manifold, allow working with images that are internally structured using several different standard methods. These appear in the system as several standard types:

- **Grayscale Images** - These are coded using one number per pixel representing one of 256 different gray tones ranging from black to white.

- **Palette Images** - These are images coded using one number per pixel, where the number specifies which color in a palette of up to 256 different colors should be displayed for that pixel. The colors in the palette can be True Color RGB colors. Palette images save space at the cost of a reduced total number of colors available for use in the image.

- **RGB Images** - These images use three numbers for each pixel, allowing possible use of millions of colors within the image at the cost of requiring three times as much space as grayscale or palette images. They are often called True Color RGB images in Microsoft applications.
• **RGBa Images** - These images are RGB images with a fourth number added for each pixel that specifies the transparency of that pixel in the range 0 to 255. RGBa images are used when combining multiple images in maps for elaborate graphics composition or creation of special visual effects in maps.

• **Compressed Images** - Compressed images use sophisticated wavelet compression technology to not only compress the amount of data an image requires but also to reconstitute the image on the fly on demand. At any given zoom level the desired view of the image is reconstituted from the compressed data store. Compressed images in general may be viewed but not altered or otherwise manipulated.

In addition Manifold can import data from multi-spectral raster data images that contain many channels. When importing from formats that support many channels Manifold will import each channel into one of the above image types (most normally, as a grayscale image). Operations on multi-spectral raster data sets can then proceed by choosing those images/channels to use. For example, three of the imported images can be combined into a single RGB image to create a "false color" image that uses three images/channels as R, G and B channels in a single image.

For many operations the various types of images will seem equivalent, except that compressed images cannot be edited or manipulated. We can select a rectangular region of pixels in an non-compressed image using Select Box, for example, without it mattering what type of image is involved. Some operations will only work for certain types of images. For example, the Hue / Saturation command only works with RGB or RGBa images and so this command will be disabled whenever the focus is on a grayscale image.

We can always convert a grayscale or palette image to RGB in order to use a particular command and then convert it back. To convert an image from one type to another, use the Image - Convert To dialog.

**Transparency in Images**

Drawings consist of empty space in any region that is not occupied with a point, line or area. In contrast, images have no empty space. Every part of an image is filled with pixels. To allow "see through" regions in images, Manifold images may have invisible pixels through which any items in lower layers may be seen. Invisible pixels are simply placeholders that do not appear. It is if there are no pixels in that part of the image. Invisible pixels are often used to give the appearance that images are not rectangular but consist of some irregular, non-rectangular shape. However, every image is rectangular because every image consists of a series of equal-width rows of pixels.

To make part of an image transparent, we select the desired region and then Delete those pixels. Invisible pixels may be used with any of the four types of images.

Any image layer can be made partially transparent by changing its opacity from 0% to 100% in steps of 1 percent using the controls in the Layers pane. This is a great way to create spectacular effects. Transparent layers work with all types of images.

In addition, RGBa images can have each individual pixel assigned a percent pixel transparency value. This is normally accomplished through partial erasers and other tools. When combined with Manifold image editing tools this effect can be used to compose amazing images by combining many layers of other images. See the Layers topic for an example.

To summarize, there are four types of transparency that may be found in a map:

- Drawings are transparent in empty space not occupied by an area, line or point.
- Any image may be made fully transparent in regions of invisible pixels.
- Each pixel in an RGBa image may be partially transparent using RGBa pixel transparency.
- Any image layer may be made partially transparency using layer transparency.

**Image Windows vs. Map Windows**

An image may always be popped open in an image window to show the image by itself using the native projection used for that image. This is a handy way to see the image in its native state if there is any confusion about how it appears in a map.

Map windows are the normal user interface for working with images mainly because of the layer capabilities of maps. Maps can include many image layers and thus allow the use of many simultaneous images. In graphics...
composition we will often work with many image layers at the same time to compose an image by stacking elements.

The illustration above shows four image layers above several drawing layers in a map. The Manifold logo and text are both in separate layers and their shadows underneath are drop shadows in RGBA image layers created using Gaussian Blur. Both drop shadow layers have had opacity decreased so their shadows are not so obvious.

**Using the Layers Pane with Images**

The Layers pane is used to control the appearance of images within image windows. The layers pane includes checkboxes for two system "layers" - a background color layer and a border layer that shows an enclosing box about the height and width of the image.

By default, images are shown using the checkerboard background Manifold uses to provide a backdrop for any transparent regions. The layers pane is shown to the right of the image window. Illustrated is the standard **bronze** image with regions other than the monument selected and then deleted into Invisible Pixels.
Checking the **Border** box will draw a one-pixel border around the height and width of the image. This is a good way to see the actual extent of an image that contains regions of invisible pixels.

Checking the **Background** box in the layers pane will replace the checkerboard background with whatever is the default background color. This is a good way to see the actual extent of an image that contains regions of pixels that are the same color as the background (usually white).

Note that only maps can have true "layers" in Manifold in the sense that they can layer more than one component within the same map window. The border and background "layers" in the Layers pane for images are not true layers even though they appear in the Layers pane in the same manner as do layers in maps. These are simply system controls that take advantage of the Layers pane as a conceptually convenient user interface.

Checkboxes show above other than **Border** and **Background** are explained in the Images and Channels topic.

**Layouts and the Layers Pane**

If an image has any Layouts created they will appear as "layers" in the layers pane for that image. Checking the box for one of these print layout layers will cause a layout rectangle to appear in the image that shows the region covered by the layout.

Right clicking onto the hatched border of one of the layout rectangles in the image will cause a context menu to appear with controls based on that layout rectangle. For example, we can **Zoom** to a given layout rectangle, **Print** it or change its **Properties**. If a layout is empty (for example, if the layout scope is set to **selection** and no pixels are selected in the parent image) zooming to the layout will do nothing.
Use **Tools - Options - Colors - Layout Rectangle** to change the color in which layout rectangles are shown. The default color is black.

**Nomenclature**

Transparency and opacity are two terms that mean the same concept viewed from different directions. When something is completely opaque it is not at all transparent. When something is perfectly transparent it may be said to have zero percent opacity.

Which word is used depends on the discussion. When imagining layers stacked up above each other like transparent sheets it is conceptually clearer to use the word **transparency**. When discussing a specific percentage of light transmission to be applied via a slider bar in a dialog most applications use the word **opacity**.

The convention in the graphics arts editing software industry is to adjust layer transparency with controls that set a number from 0% to 100% opacity, so that an image with 100% will be fully opaque and not allow any view of an image underneath it. **Manifold** follows this convention. This convention persists in the graphics arts industry even though the technical implementation of transparency effects is done using an **alpha** channel within RGBA images where the higher the value of the alpha channel (from 0 to 255) the higher the transparency.

One therefore encounters the slight conceptual dissonance of increasing opacity with higher numbers (up to 100%) in dialogs and other user interfaces while the internal data sets use numbers (alpha channel values) in which opacity decreases with higher numbers. Since we rarely set alpha values by hand this is not so bad. Alpha values are normally set using various tools, such as erasers, or masks. In the case of masks, the darker the mask region the lower the alpha value is and thus the higher the opacity. From a casual conceptual view this is very acceptable because it leads to an effect where black regions of masks cause full opacity and white regions of masks cause full transparency. Since we are used to thinking of "white space" as being transparent this works well as a natural mnemonic for the effects of masks.

**Images can be Huge**

Images are often saved on disk in compressed file formats such as .tif or .jpg or even within a project saved in **Manifold’s compressed .map** format. However, once the image is loaded into Manifold it must be uncompressed so that every pixel is available for viewing, selection and possible manipulation or alteration as a result of editing or georegistration or other processes. A 50MB, compressed .tif file can easily be expanded into a 150MB uncompressed image within Manifold when it is uncompressed from the storage format.

One way to get an idea of the active size of images is to consider their size: RGB images require 4 bytes for each pixel. A 6000 x 6000 pixel RGB image therefore requires 144 megabytes. When working with four such images at once we will have almost 600 megabytes of image space even before any temporary files are considered.

One strategy to manage very large images is to use compressed images, a special type of image that always remains compressed and is dynamically reconstituted as necessary. Compressed images require much less space either in the **Manifold** project or when saved on disk, and they allow very fast redisplay. However, the cost of using **compressed images** is that they can only be displayed - they cannot be edited or otherwise manipulated.

Unless the images are compressed images, to work with large images you **must** have large amounts of RAM and large amounts of free space on disk. You should also use a reliable operating system such as Windows XP or Windows 2000 that can adequately handle large amounts of RAM. Older Windows editions such as Windows ’98 have so many memory-management bugs that they cannot reliably be used for tasks that require large amounts of RAM. Since RAM is very inexpensive, load your computer with enough RAM so that the entire project can fit in RAM memory. Ideally, load a full two gigabytes or more.

For **Manifold** to work your machine must have adequate RAM, an operating system that can handle the necessary RAM, or adequate disk space. If any of these factors are not present your system will report various error messages when working with images or other large tasks.

Projections and Imported Components - Discussion of projections issues and formats when importing images plus simple explanation of channels.

**Palettes** - How palette images work.
RGBa Pixel Transparency - RGBA explained, with examples.
Projections and Images - More advanced discussion of projection issues with images. Read after reading the Projections and subsequent projection and coordinates topics.
Compressed Images - Compressed images are used for display of very large images.
Linked Images - Linked images are dynamically created from queries or tables.
About the Sample Images provides notes on the bronze monument and other sample images.
Image Window Menus and Controls

This topic lists default menus and controls that appear when an image window is active. These will also appear when an image tab is active in a map. Image commands are all listed under the Image menu. Some commands are organized under submenus called Adjust and Effects. These somewhat arbitrary categories are used so Manifold users who are familiar with Adobe PhotoShop will find the menu structure more familiar when seeking analogous commands.

This list also calls out the most popular menu items, such as from the View - Panes menu, that are especially relevant to use with images.

Many image editing commands work only with RGB or RGBa images. See the Image Types topic. Image editing commands are not available for compressed images. To edit a compressed image, first convert it to an RGB or RGBa image, edit it and then convert it back to a compressed image.

Edit Menu

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cut</td>
<td>Windows clipboard cut operation. Copy pixels to the windows clipboard and delete them from the image.</td>
</tr>
<tr>
<td>Copy</td>
<td>Windows clipboard copy operation. Use this to copy pixels from the image onto the clipboard for pasting elsewhere.</td>
</tr>
<tr>
<td>Paste</td>
<td>Paste the contents of the Windows clipboard into the image and deletes any selected pixels. Creates new pixels in the image.</td>
</tr>
<tr>
<td>Paste Append</td>
<td>Paste the contents of the Windows clipboard into the image without deleting any selected pixels. Creates new pixels in the image.</td>
</tr>
<tr>
<td>Delete</td>
<td>Permanently delete selected pixels from the image.</td>
</tr>
<tr>
<td>Delete All</td>
<td>Permanently delete all pixels from the image.</td>
</tr>
<tr>
<td>Assign Projection</td>
<td>Used with drawing, image, labels and surface windows to change the interpretation of the data. This is a specialized function that is applied only when manually specifying the projection of a component imported from a format that does not correctly store projection information. To change the native projection of any component other than a map, use the Edit - Change Projection command.</td>
</tr>
<tr>
<td>Change Projection</td>
<td>Used with components like drawings and images to re-project the component and thus permanently change the data.</td>
</tr>
<tr>
<td>Select All</td>
<td>Select all pixels in the image.</td>
</tr>
<tr>
<td>Select None</td>
<td>Deselect all pixels in the image.</td>
</tr>
<tr>
<td>Select Inverse</td>
<td>Invert selection: those pixels that were selected will be deselected while those pixels that were not selected will be selected.</td>
</tr>
<tr>
<td>Select Mode</td>
<td>Choose the selection mode to be used for mouse selection:</td>
</tr>
<tr>
<td></td>
<td>Replace - Any selection made with the mouse will replace the previous selection.</td>
</tr>
<tr>
<td></td>
<td>Add - Any selection made with the mouse will be added to the previous selection.</td>
</tr>
<tr>
<td></td>
<td>Subtract - Any selection made with the mouse will be subtracted from the previous selection.</td>
</tr>
<tr>
<td></td>
<td>Invert - Any selection made with the mouse will be inverted with the previous selection.</td>
</tr>
<tr>
<td></td>
<td>Intersect - Any selection made with the mouse will be</td>
</tr>
</tbody>
</table>
intersected with the previous selection.

**Modify Selection** Changes the shape of regions of selected pixels.
- **Border** - Select those pixels on the border of the selected region(s).
- **Contract** - Uniformly contract selected region(s) by given number of pixels.
- **Expand** - Uniformly expand selected region(s) by given number of pixels.
- **Smooth** - Provide a smoother edge to the region(s) of selected pixels.

**Snap To** Enable / Disable snap modes:
- **Graticule** - Snap to graticule intersections if a graticule is displayed.
- **Grid** - Snap to grid intersections if a grid is displayed.

**Save Mask/Channel** Create masks from the current image or save channels as grayscale images.

**Load Mask/Channel** Load a mask or a channel from a grayscale image.

**Go To** Go to the entire image or to a selection.

**View Menu**
- **Back** Go back one view.
- **Forward** Go forward one view.
- **Zoom In / Out** Zoom in brings us closer to the image while zoom out moves us farther away.
- **Zoom To Fit** Zoom so that the image fits the existing window size.
- **Zoom To** Zoom to a specified zoom level.
- **Graticule** Show a graticule (latitude / longitude lines).
- **Grid** Show a grid that may be used to measure or to align editing and snap commands.
- **Legend** Display a legend showing formats.
- **North Arrow** Display a North arrow.
- **Scale Bar** Display a scale bar.
- **Display Options** Enabled for compressed images. Enables choice of which channels will be used as R, G, B and alpha channels.
- **Panes** Call a dialog that allows displaying or hiding all panes.
- **Full Screen** Show the image over the entire monitor area.
- **Refresh Data** Update a linked image with the latest data from the controlling geocoded table.
- **Refresh View** Update the visual appearance of the image with any changes made since the last refresh. Enabled only if **Autorefresh View** is off and some change (such as a selection) has been made that might affect the visual appearance of the image.
- **Autorefresh View** Automatically update the image whenever any changes are made that might affect the visual appearance of the image. Turn this option off when working with very large
images where there is no desire to take the time to show, say, a selection when it is made (repainting a very large image on every selection step might take longer than desired). When **Autorefresh View** is off, we can always cause a refresh on demand using the **Refresh View** command.

**Properties** View the properties dialog for this image.

**View - Panes Menu** Panes of special interest when working with images include:

**Layers** When used with image windows, the layers pane turns individual R, G, B or alpha channels on and off and also controls whether the image border or background is displayed. See also the Images and Channels topic.

**Selection** Save and recall regions of selected pixels.

**Tool Properties** Specify characteristics of image editing tools, such as the opacity of a paintbrush.

**Image Menu**

**Open Palette** Enabled for palette images. Open the palette for this

**Open Data Source** Open Database Console focused on the data source of a linked image.

**Dither** Uses a smaller number of colors in an image while preserving a perceptual effect through the use of dither patterns.

**Quantize** Convert image to the specified number of colors using enhanced or standard methods.

**Resize** Change the size of the image using desired interpolation method.

**Convert To** Convert images between grayscale, palette, RGB, RGBA or compressed images.

**Image - Adjust Menu**

**Color Balance** Adjust RGB color values for Shadows, Midtones or Highlights

**Brightness / Contrast** Change brightness and contrast.

**Hue / Saturation** Alters hue, saturation and lightness.

**Invert** Invert pixel channel value. Creates a "photographic negative".

**Equalize** Alters individual pixel brightness so there is an equal number of pixels at all brightness levels.

**Gamma** Change mid-tone color brightness.

**Threshold** Forces grayscale pixels to white, black or unchanged based on a histogram.

**Threshold Color** Like **Threshold** but applies to each RGB channel individually.

**Posterize** Convert image to a limited number of colors for a "poster"
Image - Effects Menu

- **Colorize**: Adjust saturation and hue while keeping intensity the same, as if a color were applied to a grayscale version of the image.
- **Gaussian Blur**: Apply Gaussian bell curve blurring to create shadows, halos and transitions.
- **Motion Blur**: Streaked effect in the desired direction.
- **Diffuse**: Moves pixels by swapping them in a "random walk."
- **Filter**: Applies convolution filters, either custom filters or a choice from numerous presets.
- **Fluoresce**: Alter saturation and lightness in asymmetric ways to cause some colors to appear unusually bright.
- **Noise**: Add random monochromatic or color pixels.
- **Relief**: Add highlights and shadows to give a 3D effect to 2D images.
- **Simplify**: Aggregates pixels into larger clumps for a pointillist or mosaic tile effect. Can also remove small dots in cartographic work.
- **Tile**: Convert image into rectangular tiled regions of
- **Relink**: Re-links a linked image to a data source.
- **Unlink**: Converts a linked image to a local image with no connection to the originating data source. Linking and then unlinking an image is equivalent to importing it.
- **Create Index Drawing**: Creates an index drawing for an image library.
- **Download**: Downloads intermediate levels of an image linked from a Manifold image server, OGC WMS server or TerraServer.

Transform Toolbar

- **Operators**
  - **Add Margin**: Add to the rectangular size of the image by the given number of pixels at the margin.
  - **Add Noise**: Add color noise as set by the source / argument box.
  - **Add Noise (Mono)**: Add monochrome noise as set by the source / argument box.
  - **Auto Contrast**: Automatically adjust contrast to balance contrast non-linearly throughout the entire image considering the overall intensity of each pixel.
  - **Auto Level**: Balance contrast throughout the entire image by balancing contrast within each channel individually.
  - **Blur**: Blur image by fixed amount. Blurs both features and colors. For a "blur" effect that does not mix colors, use the Median filters.
  - **Blur (parameter)**: Blur image by the number of pixels given in the source / argument box. This blur is implemented as a matrix operator where the value of the source / argument box is the weight of the center pixel with weights of all other pixels set to 1. Increasing the value therefore produces a lesser blur.
Brightness  Adjust brightness by source / argument box amount.
Contrast  Adjust contrast by source / argument box amount.
Crop  Crop image size to the selection.
Crop Margin  Crop the rectangular size of the image by the given number of pixels at the margin.
Desaturate  Reduce saturation to zero for all color values. Remains RGB.
Difference East  Detect and emphasize edge transitions to the East. See the Filters topic for general discussion of convolution matrix filters like this one.
Difference North  Detect and emphasize edge transitions to the North.
Difference North-East  Detect and emphasize edge transitions to the North-East.
Difference North-West  Detect and emphasize edge transitions to the North-West.
Difference South  Detect and emphasize edge transitions to the South.
Difference South-East  Detect and emphasize edge transitions to the South-East.
Difference South-West  Detect and emphasize edge transitions to the South-West.
Difference West  Detect and emphasize edge transitions to the West.
Diffuse  Migrate pixels by swapping them in a "random walk." Reapplying Diffuse several times will move pixels further and further away from their original positions.
Equalize  Equalize image to value given in source / argument box.
Flip Horizontal  Flip image left / right to mirror image.
Flip Vertical  Flip image top / bottom to upside down image.
Gamma  Alter gamma value by source / argument box.
Gaussian Blur  True Gaussian probability function blur by given amount.
Grayscale  Cast all colors into gray tones by intensity. Remains RGB.
High Pass 1  Emphasize rapid transitions between pixels. Good edge detection with horizontal and vertical lines.
High Pass 2  Stronger emphasis on rapid transitions between pixels with strong edge detection on lines of all angles.
High Pass 3  Edge detection with crisp vertical and horizontal and fuzzy lines at other angles.
Invert  Invert pixel values so that 0 becomes 255 and 255 becomes 0. See the Invert topic for information on Invert At.
Laplace 1  Good edge detection with emphasis on horizontal and vertical changes.
Laplace 2  Strongest changes at point of intersection of horizontal and vertical lines, resulting at a small \( X \) pixel pattern at the point of intersection. Fuzzy...
detection of linear features at other angles.

**Low Pass 1** Strong blur, with strong suppression of large pixel to pixel changes.

**Low Pass 2** Blur, with medium suppression of large pixel to pixel changes.

**Low Pass 3** Blur, with least suppression of large pixel to pixel changes. Removes graininess in some images.

**Median Cross** Evens out color tending to preserve horizontal and vertical features. A "blur" that ignores perfectly horizontal and vertical linear features.

**Median Square** Evens out color looking at a 3 x 3 matrix surrounding each pixel. A "blur" effect that preserves prevailing color.

**Median Square 5** Strong evening out of color looking at a 5 x 5 matrix surrounding each pixel. Results in removal of isolated pixels of color differing greatly from surrounding pixels. A stronger "blur" effect that preserves prevailing color.

**Motion Blur** Four options in diagonal, horizontal and vertical directions to blur image as if moved in that direction by given amount.

**Posterize** Converts the image to a limited number of colors for a "poster" effect. Very low (2, 3 or 4) parameter values give the most obvious effect.

**Rotate** Rotate image given number of degrees. Negative degrees are taken as counter-clockwise rotation.

**Sharpen** Emphasize transitions to give images a sharper appearance.

**Sharpen (parameter)** A Sharpen with selectable value for degree of sharpness. This sharpen is implemented as a matrix operator where the value of the source / argument box is the weight of the center pixel with weights of all other pixels set to 1. Increasing the value therefore produces less sharpening.

**Sharpen More** Enhanced sharpness compared to standard Sharpen.

**Threshold** Converts an image into black and white based on whether each pixel is above or below the given value in intensity.

**Threshold Black** Like **Threshold**, but forces all pixels below the intensity value into black while leaving all pixels above that value unchanged.

**Threshold White** Like **Threshold**, but forces all pixels above the intensity value into white while leaving all pixels below that value unchanged.

**Tile** Divides image into tiles of given X and Y extent and then averages pixel values within the tiles. This is used for aggregating and interpolating raster data images into larger tiles and for creating "pixelated" artistic effects.

**Tile Median** Equivalent to **Tile** command with **Preserve Colors** checkbox checked.
**Image Types**

Manifold works with several standard types of images:

**Grayscale Images** - These are coded using one number per pixel representing one of 256 different gray tones ranging from black to white.

**Palette Images** - These are images coded using one number per pixel, where the number specifies which color in a palette of up to 256 different colors should be displayed for that pixel. The colors in the palette can be True Color RGB colors. Palette images save space at the cost of a reduced total number of colors available for use in the image. The image shown about uses only 16 colors.
**RGB Images** - These images use three numbers for each pixel, allowing possible use of millions of colors within the image at the cost of requiring three times as much space as grayscale or palette images. They are often called **True Color** RGB images in Microsoft applications.

**RGBa Images** - These images are RGB images with a fourth number added for each pixel that specifies the transparency of that pixel in the range 0 to 255. When seen in an image window, grayscale, palette and RGB images will be shown on a background of solid color (white by default). RGBa images are shown on a background of alternating white and light gray checkerboard pattern so that differences in transparency are more visible. (Use the Layers pane with images to click ON a background color layer or to show a border around an image.)

RGBa images are used when combining multiple images in maps for elaborate graphics composition or creation of special visual effects in maps. For example, the RGBa image illustrated above is shown in a layer above a grid of lines that become visible to an increasing degree as transparency increases towards the bottom of the image.
Compressed Images - Compressed images use sophisticated wavelet compression technology to not only compress the amount of data an image requires but also to reconstitute the image dynamically on demand. At any given zoom level the desired view of the image is reconstituted from the compressed data store. Compressed images can be viewed, but not edited or otherwise manipulated. Compressed images are used to display very large images that would require too much time for display and possibly too much room for storage if they were not compressed.

Compressed images have many of the display characteristics of RGBa images. The Layers pane will show Red, Blue and Green channels, and the View - Display Options command will allow choice of what image channels (in the case of multi-spectral compressed images) will be used for Red, Green, Blue and alpha channels.

Manipulating Images

Not all operations will work with all types of images. For example, compressed images may be viewed but cannot be edited, as can the other image types. For many operations the non-compressed types of images will seem equivalent. We can select a rectangular region of pixels in an image using Select Box, for example, without it mattering what type of image is involved. Some operations will only work for certain types of images. For example, the Hue / Saturation command only works with RGB or RGBa images and so this command will be disabled whenever the focus is on a grayscale image.

We can always convert a grayscale or palette image to RGB in order to use a particular command and then convert it back. To convert an image from one type to another, use the Image - Convert To dialog.

Other Types of Images

In addition Manifold can import data from multispectral raster data images that contain many channels. When importing from formats that support many channels Manifold will import each channel into one of the above image types (most normally, as a grayscale image). Operations on multispectral raster data sets can then proceed by choosing those images/channels to use. For example, three of the imported images can be combined into a single RGB image to create a "false color" image that uses three images/channels as R, G and B channels in a single image.

Saving Drawings, Maps, Surfaces and Labels as Images

Manifold can create images from other components. See the Tools - Make Image topic.

Tech Tip: Image Sizes

RGB and RGBa images require more space for storage than do grayscale or palette images. Each pixel of an RGB or RGBa image requires four bytes for actual color information and one byte to store information about selection, saved selections and invisible pixel status. At five bytes per pixel a 16000 x 16000 RGBa image requires 1.25 gigabytes of memory. Such a large image, when used for display only, should be converted into a compressed image for much faster speed.
At times when we would like to edit an image we cannot use compressed images and must convert such images back into RGB or RGBA or other image types. In such cases the compressed image will expand dramatically in size as it is decompressed and will require massively more processor time for computation. Working with very large, non-compressed images for anything other than display requires exceptionally fast computers and gigabytes of RAM.
Compressed Images

Compressed images are a special type of image that can be displayed but not edited or otherwise manipulated. In exchange for a limit on functionality, compressed images deliver very fast display capability even when the images involved are very large.

Manifold supports use of compressed images using industry-standard ECW format, the same as used with ER Mapper, or using industry-standard JPEG2000 format. The technology in both ECW and JPEG2000 allows astonishingly fast loading and display of large images (especially with ECW) but this speed is achieved by trading off the benefits achieved against significant limitations. Compressed images may be kept within the project, linked from an external ECW or JPEG2000 file, or linked from an external ECWP server.

The limitations of compressed images are:

- **Display only** - Compressed images may be viewed but not manipulated. They are read-only.
- **No selection** - Compressed images cannot be altered and their pixels may not be selected.
- **Limited on-the-fly re-projection** - A compressed image may be viewed only within a map whose coordinate system of which is more or less similar to that of the image. If the re-projection between the coordinate system of a compressed image and the coordinate system of a map containing the image is curvilinear, the compressed image layer will not be displayed in the map.
- **Reduced information content** - The compression process eliminates the original pixel information in the image. Although compressed images when reconstituted for display may appear visually identical to an original uncompressed image, the reconstituted pixels are a synthetic approximation of the originals.
- **No transparent pixels** - ECW and JPEG2000 compression do not support four channel (RGBa) data so there is no channel available to save transparent pixel information. Note that when working with other types of images and “deleting” pixels the pixels are not really deleted - they are simply made transparent. The only way to delete pixels in an image is to crop the image, in which case the cropped pixels are genuinely deleted. If images containing transparent pixels are converted to a compressed image the transparent pixels will be restored as black regions.

Compressed images nonetheless provide significant benefits:

- **Fast display** - The reconstitution process provides for very rapid display of an image view at any desired zoom or pan.
- **Fast loads and saves** - Projects containing compressed images load and save much faster than projects using uncompressed images.
- **Linked images** - Compressed images may be left in their original .ecw files or in their JPEG2000 files instead of being imported into the Manifold .map project file.
- **Reduced disk space** - Compressed images require much less room than uncompressed images. Using linked images to utilize a single image file in many different projects will also save much disk space as compared to duplicating that image within many projects as an imported image.
- **Streaming links** - Compressed images in ECW format may be linked into a Manifold project from an ECWP server URL, loading from a data stream served by an ER Mapper Image Web Server.
- **Dynamic channel combinations** - The **Image - Display Options** command allows selection of which channels from a multi-channel image will be used for R, G, B and alpha channels.

Compressed images are a good choice for images displayed for their visual merit only, such as when images are used to form a background layer for a map, or when a background image layer will be traced to create a new vector map.

Any image type within Manifold may be converted into a compressed image, and any compressed image may be converted into other image types using the **Image - Convert to** dialog.

**To create a compressed image:**

1. Open the image that is to be converted to a compressed image.
2. Choose **Image - Convert to**
3. In the **Convert To** dialog, choose **Compressed** as the **Target** format. Choose the desired **Ratio** of compression. Larger **Ratio** numbers will result in greater compression at the cost of lower image quality.
4. If desired, check **Save result as new component** to save the result as a new image component instead of converting the opened image. Press **OK**.

The **Ratio** value specifies how large the compressed image is relative to the original image. A ratio of 10 will create a compressed image that is one-tenth the size of the original image.

**To import a compressed image:**

1. Choose **File - Import - Image**.
2. In the **Open** dialog choose **ECW / JPEG2000 Files** in the **Files of type** box.
3. Browse over to the desired .ecw or JPEG2000 file desired and open it.

Importing any .ecw or JPEG2000 file will automatically create a compressed image.

**To link a compressed image from an ECW or JPEG2000 file:**

1. Choose **File - Link - Image**.
2. In the **Open** dialog choose **ECW / JPEG2000 Files** in the **Files of type** box.
3. Browse over to the .ecw file or JPEG2000 file desired and open it.

Linking any .ecw file or JPEG2000 file will automatically create a compressed image referring to a linked file. Working with the image will fetch image data on the fly.

**To link a compressed image from an ECWP server:**

1. Choose **File - Link - Image**.
2. In the **Open** dialog choose **ECWP Image Servers ()** in the **Files of type** box.
3. In the resulting **Link ECWP Data** dialog, provide the URL for an ECWP image server in the **Server** box. The **Server** box remembers most recently used ECWP servers, including those used in previous Manifold sessions.
4. If desired, press the **Test** button to verify the connection. Press **OK**.

Linking to an ECWP image server will automatically create a compressed image referring to that server. Working with the image will fetch image data on the fly.

**To export a compressed image:**

1. Choose **File - Export - Image**.
2. In the **Export** dialog choose **ECW / JPEG2000 Files** in the **Files of type** box.
3. Enter a name for the file in the **File name** box, using .ecw extension if an ECW file is desired and a .j2k extension if JPEG2000 is desired and press **Save**.

Compressed images can only be exported into .ecw files if the benefits of the compression technology are to be retained. Exporting into any other image format will lose the ability to do dynamic compression. Although some file formats, such as .jpg, do use compression they do not allow dynamic, multi-resolution compression as does .ecw format.

**Limitations on Re-Projection**

Except for limited exceptions of interest only to experts, compressed images, linked images and image libraries cannot in general be re-projected.

For example, opening an ECW compressed image and attempting to re-project it to a different projection or dragging and dropping either an ECW compressed image or an image linked from some image server into a map that uses a different projection will fail. In such cases, Manifold will pop open a dialog telling us of the projection incompatibility.
If we would like to re-project such images, we should first convert them to an unlinked local image (in the case of linked images) or to an uncompressed image type (in the case of compressed images) or to a regular local image (in the case of an image library). We can then re-project the image as desired.

Note by the way that attempting to re-project such images on the fly by dropping them into a map that uses a different projection usually indicates a conceptual error on the part of the user: usually, large images of the sort that are used as compressed images, linked images or image libraries are likely to be the largest, or among the largest, layers in any such map. It is therefore would be wisest to use their native projection as the projection for the map, so that when the map is displayed it is other, smaller layers that must be re-projected on the fly to display the map and not the large image layer.

To do so, create the map using the image layer first. This will assure that the map uses the image's projection. Next, drag and drop the other layers into the map. For maximum speed, re-project the other layers to match the projection used by the map. This is easily accomplished by (in the map window) right-clicking on the layer's tab and choosing Project to Map from the context menu.

**About Compressed Images**

Any grayscale, palette, RGB or RGBa image is a *static* image in that it consists of a fixed number of pixels where each pixel consists of an unchanging channel value or values. Every time the image is opened the values will be exactly the same.

Compressed images are *dynamic* images that are created from static images by a compression algorithm that reads the fixed pattern of pixels and encodes the apparent visual content of those pixels as seen by humans into a reduced amount of data. Whenever we wish to view the dynamic image, the data representing it is fetched and used by a special algorithm to reconstitute an image with the same approximate visual appearance as the original static image.

The compression and dynamic reconstitution process allows very large images to be saved in a much smaller amount of disk space and allows very fast viewing. The reconstitution algorithm fetches only that part of the compressed data that is necessary to reconstitute an acceptable visual effect at whatever zoom level (resolution) we wish to view the image. When creating a compressed image, Manifold allows us to choose what level of compression we want. Higher levels of compression will result in images that have less visual fidelity to the original.

Consider the RGB image seen at high zoom level above. We have zoomed in so that individual pixels are visible. The scene illustrated is the Northern part of Baja California in Mexico and the Sea of Cortez.
After conversion to a compressed image, the scene at the same zoom level appears above. Note that individual pixels are no longer discernable because the compression technology used synthesizes a scene using full screen resolution to utilize however many pixels are available in the computer monitor's display.

Although the scene looks very realistic (considering the high zoom into what was originally a low-resolution image), it is very important for scientific purposes to understand that the information content in the compressed image is less than that of the original. The compressed image only looks good visually because a clever decompression-on-the-fly algorithm was used to synthesize a visually appealing image from a smaller number of bytes.

The compressed image may appear to be the same but the data content of compressed images is not fixed as with non-compressed images. Non-compressed images have fixed, constant values for their pixel channels while compressed images have variable results depending upon the scale at which they are displayed and the variation caused by the compression/decompression process. If the content of images contains some specific data, such as representations of heights or specific measurements by instruments at a given location, compressed images will not preserve that data exactly. At best, they will provide an interpolation that approximates the original data.

For this reason, compressed images should not be used to store image data if that data will subsequently be subjected to analyses in which the original value of each pixel must be preserved. For example, some satellite sensors may measure reflectance and save the specific reflectance values in the R, G and B channels of an image, which will then later be analyzed to determine the material constituents of the view (such as snow, ice, sand, water, etc.) based upon reflectance of each pixel. Such an image should not be stored as a compressed image because the compression and decompression process will alter the stored values from the original measurements made by the satellite sensor.

Compressed images are best suited for visual display. The compression / decompression process is a very reasonable compromise considering the perceptual interpolation done by the human visual system. In fact, the results of the process often will give compressed images a "better" appearance to the human eye than the original uncompressed image.

Many tasks in GIS involve the use of images purely for display. Using images as backgrounds in maps with drawing layers overhead is a part of very many tasks ranging from the display of various maps to use of tracing to create new drawings. Compressed images are ideal for such purposes.

**Importing and Linking Images**

Compressed images may be either imported into a Manifold project or they may be left outside the project and linked into it. Compressed images may be linked into a Manifold project either from an .ecw file, a JPEG2000 file or from an ECWP image server.

Compressed images that are linked into a project will be shown in the project pane using a linked image icon.

To link a compressed image into a Manifold project from a file:

1. Choose File - Link - Image
2. In the Files of type box choose ECW / JPEG2000 Files.
3. Browse over to the .ecw file or JPEG2000 file to be linked and open it (either by double-clicking on it or by clicking on it and choosing Open).

Linking a compressed image from an ECWP image server is similar.

To link a compressed image into a Manifold project from an ECWP server:

1. Choose File - Link - Image
2. In the Files of type box choose ECWP Image Servers (
3. In the Link ECWP Data dialog that pops open, specify the URL to a server.
4. To test connectivity to the server without commanding a link, press the Test button. If a connection can be correctly established, a Connection successful message box will appear. Press OK to close the message box.
5. In the Link ECWP Data dialog, press the OK button.
6. A linked image icon will appear for the data from the image server.

Maintaining compressed images in external .ecw files provides several advantages:

- **Fast project loading** - Projects containing linked compressed images will open very rapidly because they will be relatively small in size since the .map project file does not contain any storage space for the linked images.
- **Fast image loading** - Compressed images loaded from disk files will load just as fast as if they were stored inside the project.
- **Reduced disk space** - If several projects use the same compressed image only one copy of the image need be kept on disk.

Linking compressed images into a project has these disadvantages:

- **Multiple files** - If parts of a project are stored outside the .map project file one can no longer send a single .map file to a colleague and be sure that all data is included. All .ecw files used in the project must also be sent. In addition, we must be careful not to delete or move .ecw files that are used in projects.
- **Network delays** - If image files are linked over a network or when linking image files from ECWP servers through a network image display speed may be dramatically reduced due to delays caused by relatively slow network speeds compared to processor - disk speeds in a local system. This will not be a factor on gigabyte local area networks but may be a significant factor if image files are linked through Internet connections.

If a linked image cannot be found (perhaps because the project file has been moved), when the compressed image is opened an empty image window will result. To reconnect the image, right click on the linked image in the project pane and choose Relink, browsing over to the new location of the image.

**Preserving Paths to Linked Images**

Linked images are saved within Manifold projects using relative pathnames. Moving a .map file that contains a linked image will preserve the link to the image provided that the relative path from the .map file to the linked image file has not changed.

For example, suppose we have a .map file located in C:\projects\Carson\mymap.map that contains a linked image located in the file C:\projects\Carson\images\airport.ecw. If we move the .map file to D:\backups\January\mymap.map it will still preserve the link to the image if the image file is moved to D:\backups\January\images\airport.ecw.

**Unlinking a Linked Image**

Compressed images that are linked into a project may be converted into an imported image at any time.

To convert a linked image into an image within the project:
1. Right click on the linked compressed image in the project pane.
2. In the context menu choose **Unlink**.

Unlinking a compressed image linked from a file will import that image into the project as a compressed image stored within the project.

Unlinking a compressed image linked from an ECWP image server will import that image into the project as an RGB image (since necessary wavelet data cannot be fetched through ECWP protocol to construct a local compressed image). Be careful when unlinking an ECWP server image since the resulting RGB image can be a very large image. Once the ECWP server image is unlinked into a local image it can be converted into a compressed image to save space and improve performance.

**Compressed Images and MrSID Format**

If a suitable decoder has been installed, Manifold has the ability to import MrSID format images. See the **Import Image - SID, MrSID** topic for details.

Since MrSID has largely been replaced in modern usage by open formats such as ECW and JPEG2000, Manifold will import MrSID images but it will not export images to MrSID nor utilize MrSID as a native format for linking images as compressed images as is possible with ECW and JPEG2000.

The assumption is that if you are working with Manifold and must deal with an image in MrSID format, your first objective will be to immediately convert the image into a compressed image and to save it out as an **ECW** or **JPEG2000** format image. Once the image has been converted into and saved as a compressed image, loading it and viewing it will be instantaneous and it no longer will be imprisoned in MrSID format.

Because many images are trapped in MrSID format and most GIS users would prefer to use a more open format, some software developers who have licenses to work with both MrSID and ECW or JPEG2000 have created scripts or utilities that can automatically traverse a hard disk and find and convert all MrSID files into ECW files. That is the most efficient way of freeing images trapped in MrSID format since the lengthy process of converting a MrSID image to a more modern format can be accomplished at night or over the weekend. Check the **manifold.net** website's **Free Stuff** page for examples of such scripts.

Intermediate Levels and Pyramids

Manifold is often used to display very large images using technologies such as Compressed images or Image libraries or Linked images served from image servers or linked images from Oracle Spatial that make it feasible to display truly immense images on a desktop computer.

Most such technologies for displaying very large images will include the use of intermediate level images or pyramids to allow much faster display of images, including zooming in or out and panning the image. These two terms mean the same thing, but some software packages will refer to this idea as pyramids while others will use the term intermediate level images or simply intermediate levels. It's the same idea, which may be explained as follows.

Consider a very large image that is shown above in greatly reduced form. The image shows one meter resolution TerraServer photos that have been combined into a single large image that covers the region in the Montara Mountain example surface. See the Combine a Surface and a Drawing in a Map example topic for an example that uses the Montara Mountain sample data.

This image was created by opening the Montara Mountain surface and then linking an image from TerraServer. The drawing was then downloaded at highest resolution using the Image - Download command.

The image shows a region of the San Francisco peninsula ranging from the San Francisco International Airport in the upper right down to the harbor at Half Moon Bay at the lower left. It is over 700 megabytes in size.
If we zoom all the way into this image in the vicinity of the San Francisco airport so that each image pixel occupies one pixel on the computer monitor (so-called Native resolution) we can see that the image is extraordinarily detailed. The image is so detailed that thousands of individual homes and tens of thousands of individual automobiles can be discerned if we zoom all the way into the image.

Computer monitors usually display images using resolutions of about 72 pixels per inch. Even though that results in millions of pixels available in a large monitor, this example image is so large at 11119 x 13929 pixels, that at 72 pixels per inch it would require a computer monitor over 12 feet wide (about four meters) and over 16 feet tall (over five meters) to display the entire image at full resolution on a computer screen.

Obviously, therefore, we will never see this entire image at full resolution on our computer monitor. We will only see parts of the image at full resolution when we zoom in to specific locations. If we zoom far enough out so that the entire image fits, we won't really be looking at the image's pixels, but instead we will be looking at an approximation or interpolation of the image that averages out millions of pixels per square inch to show us an approximate visual representation of what the real image might look like when viewed at greatly reduced scale.

For example, the image above is roughly 1/100th of the size in width and height of the image seen at full resolution. In rough approximation, instead of being 154 inches wide it is only approximately 1.5 inches wide. Therefore, each pixel in the above image represents all of the pixels in a 100 x 100 region of the full resolution image. Each pixel represents over 100 x 100, that is, 10,000 pixels in the full sized image. At 72 pixels per inch,
each square inch of the above greatly reduced view was created by calculating an interpolation of almost 52 million pixels of the full image. Just one square inch of reduced view requires a lot of calculations.

To calculate what the full image would look like at the above greatly reduced view requires computations on hundreds of millions of pixels. That can take a lot of time even on a very fast desktop machine so it is no surprise that truly huge images might appear to be slow whenever we zoom in or out or pan them. Each such step can require a lot of computational power and processor time to compute the necessary view by interpolating millions or hundreds of millions of pixels.

The trick to speeding up that process is make those calculations in advance and to store the results. If we zoom out from the full image so that the entire thing fits on the screen as in the example above the resulting view requires only a few tens of thousands of pixels. It is insignificantly small compared to the hundreds of megabytes of the full sized image. We may as well make the computation just once (perhaps when we store or export the image) and then save the result for use whenever anyone ever wants to see a zoomed out view of the image.

If someone wants to see a zoomed out view, instead of repeating the massive calculation we can simply fetch the pre-built view and display it. Since computer monitors show relatively small numbers of pixels (the number of pixels on even large, high resolution computer monitors is but a tiny fraction of the size of really big images), we can fetch pre-built images to fill up a computer monitor virtually instantaneously. That's a lot faster than computing such zoomed out views on the fly.

The whole idea of intermediate image levels, therefore, is when a very large image is first created or stored our software will automatically compute views of that image at various zoom levels and will store those views along with the image. Programs that display the image can then use those pre-computed, stored views whenever anyone wants to zoom in or out to see different parts of the image at different zoom levels.

In the case of our full resolution example, as seen above, our software might also compute views at regular intervals such as zoomed out at twice the scale, four times the scale and so on.
The image above shows the same region at lower resolution (1/4th the zoom) so that only 1/16th as many pixels are used to cover the same region. A series of images at this intermediate zoom level covering the entire image could be stored with the full sized image.

Zooming even further out requires only 1/64th as many pixels to cover the same region. Another way of saying the same thing is that when zoomed out like this we can use the same number of pixels to show a region 64 times larger.

Obviously, if we compute intermediate levels of zoom and save extra images that takes time. If we compute and store very many intermediate levels of zoom that will also increase the storage size required for images because in addition to the image itself there will be additional space required to store the intermediate level images that are created.

Different technologies have different ways of figuring out what is a reasonable number of views and how to implement storing those intermediate views, but the basic idea is the same: compute some reasonable number of intermediate views and save them so that later on display of the image at different zoom levels will be very fast.

It turns out that with most such technologies it is not a great burden to take the time to compute intermediate levels in advance. That's because such computation usually is done when an image is being stored or exported.
in some process that already will take a significant amount of time. Delays in such cases are not as unpleasant as delays when we zoom in with our mouse and are waiting expectantly for something to happen right away with the image.

In addition, such delays when creating or exporting the image are one-time delays: after the intermediate levels are created once they never again have to be created. We might have a slightly slower, one-time creation process but then every time we view the image our will go much faster.

The need for extra storage space also is not usually a burden, since most people would happily see an image increase in storage space by, say, 50% if thereafter display was virtually instantaneous instead of taking minutes for each change in zoom.

Why are intermediate level images also called pyramids?

If we imagine a sequence of such images stacked up we see that the reduced intermediate levels form a conceptual pyramid of sorts in that "higher" images are smaller than "lower." In addition, when designing such software the data structures used for storage often are diagrammed using hierarchical diagrams that look like pyramids, hence the name.

The bottom line is that whenever we have the choice of using intermediate levels or pyramids, we should always choose that option. It’s a very fast and convenient technology that is well worth the small increase in one-time processing time when creating such images as well as worth being any increase in disk space consumed. Remember, disk space is virtually free while time spent at a keyboard tapping your fingers waiting for a zoom to happen is priceless!

**Image Libraries**
Linked Images

Linked images are images that are stored outside of a Manifold project file and which are dynamically fetched into the project as necessary when the linked image is opened or otherwise used. Note that linked images cannot normally be re-projected (see comments below).

Images may be linked from a variety of external sources, including:

- **Image libraries** - Folders on disk that contain image tiles consisting of images in graphics formats supported by Manifold. For example, a large linked image may be linked in from an image library folder that contains dozens of smaller images in .tif format (the image tiles) that mosaic together to form the larger image. Image libraries are good for smaller collections of images. Larger collections of images or image tiles should be stored within a spatial DBMS (see below) for performance.
- **Compressed images** - Images stored on disk in ECW or JPEG2000 format.
- **ECWP image servers** - Servers providing compressed image data streams using ECW format.
- **Google servers** - Google servers providing images rendering maps or satellite images.
- **Manifold IMS Web Sites** - Manifold IMS can be configured, in addition to standard IMS usage or to OGC WMS image serving, to serve images as an image server.
- **OGC WMS servers** - Servers providing data streams of image data using OGC WMS format.
- **Oracle servers** - Oracle DBMS servers providing Oracle Spatial or Locator facilities within standard Oracle databases to store images.
- **Spatial DBMS servers** - Almost any databases managed by Manifold as spatial DBMS can store images and surfaces in a high performance way.
- **TerraServer** - Servers providing image data in TerraServer format.
- **Tables and Queries** - Linked images may be created dynamically from tables or queries.

Linked images are shown in the project pane using an icon that includes a yellow "database" cylinder to show they are created from some other source. Linked images are normally read-only.

Opening a linked image brings the data for the image in from the source. When the image window is first opened, it will appear with a gray, partially transparent background that will fill in as the image is brought into Manifold. Most linked images are linked to sources that send the image in as tiles, that is, as rectangular pieces that form a seamless mosaic of the complete image. As we zoom in or out of the image, or as we pan in different directions, Manifold will fetch tiles from the image source to create the appropriate view.

As the tiles are fetched from the source, they will fill in more and more of the image window. Manifold tries to fetch tiles that are closest to the center of the visible area of the image and then will fetch tiles that are nearer to the edge of the visible area, in the expectation that we are usually most interested in seeing the center of the image and would like to begin viewing that while the rest of the image fills in.

The speed with which image tiles appear depends on the technology used by the image source as well as by the connection to the image source. For example, a linked image created from an ECW file stored on local disk will be breathtakingly fast even if the image is many gigabytes in size. Likewise, an image linked from a local Oracle server will be amazingly fast. However, an image using a slower technology, such as an image library assembled from .bmp files could be much slower to come into view.

Images linked from remote servers accessed by Internet connections, such as TerraServer or OGC WMS servers cannot be any faster than the Internet connection to that server or the speed of the server. Some OGC WMS servers, for example, are appallingly slow to begin with and are further overloaded with too many users. It can take seemingly forever to get images from such servers.

Manifold will try to help us out in such situations by caching any fetched tiles if the Cache data between sessions option is turned ON (the default) in the image linking dialog. In that case, if we ever return to a view already fetched, such as, for example, by panning to the right and then panning back to the left, Manifold will not need to fetch the necessary tiles a second time: they will be saved in cache and will instantly display.

Another important command used to get around slow image servers is the Image - Download command, which we can use to instruct Manifold to get all tiles for a desired view in background while we continue working on other things.

Linked Images from Tables or Queries
The tables and queries used to create linked images may be inside the Manifold project or they may be in external databases.

Linked images may also be created in a two step process, where the virtual table for an existing image is used in a query to manipulate that image or to fetch part of the image based upon desired criteria. A linked image can then be created from that query. This technique is often used within Manifold projects that will be used in an IMS website.

Linked images may also be created from tables or queries stored in external databases. For example, we could use a query to select all columns for all pixels in an image's virtual table and then export that query as a table into an .mdb file or to some other database storage.

When an image is linked from a table or query, each record in the table or query produces a pixel. The coordinates of the pixel are taken from the X and Y columns (cast to integer) specified in the Link dialog. The color of the pixel is taken from either the Color column or the channel columns.

**Editing Linked Images**

Although a linked image that appears in the project pane is normally read-only, in the case of linked images created from tables or queries it is often possible to edit that linked image by editing the data source from which it is created. For example, suppose we have a linked image created from a query that uses the virtual table of another image. We could change that linked image by editing either the original image or by editing the query.

**Linked Images and IMS**

Linked images are therefore perfect for a wide class of Manifold Internet Map Server applications where images must be dynamically updated based on changing information stored in database management systems. For example, an image providing a background to a map may be taken from an ECWP streaming server that provides a satellite image showing the weather in the region as it exists at the time, or an image showing a weather chart may be fetched from an OGC WMS server that synthesizes an image from a vector representation of weather data.

**Linked Image Tiles are Fetched on Demand**

One especially useful characteristic of images linked from image servers is that the tiles that comprise an particular view are fetched on demand only when that particular scene is viewed. When a user zooms or pans into a particular view (or jumps directly there as a result of a Goto or other navigation command) Manifold contacts the image server and fetches image tiles of the required resolution that are automatically formed into a seamless mosaic for the visual display that fills the image window at the desired zoom at the location specified. If the user zooms further into the image then higher resolution tiles will be fetched to the limit of resolution provided by the image server. Zooming yet further into the image inflates the single, full resolution tile on view to create an ever more pixilated display.

By default, the image tiles used to build requested views of a linked image will be cached on disk by Manifold. If a particular view of a linked image is revisited, such as by using the Back navigation toolbar button, Manifold will redisplay the desired view by fetching necessary tiles from the disk cache rather than from the image server. Such redisplayed views will normally be much faster than previously unseen views since disk access is a much faster process than streaming data through even a fast network.

If portions of a very large linked image, such as a linked image of the entire United States, are never viewed then the image tiles for those portions will never be fetched. This characteristic together with caching allows us to use linked images to great effect in certain applications, such as IMS applications.

Suppose our IMS application is a web site that shows the location of schools in Ohio. We would like to have an image layer in our web site that, when zoomed in, shows aerial photography from an image server so that photographic details of each school, such as the location and nature of athletic fields and other facilities, can be seen. Perhaps the intent of the site is to assist the operation of a state-wide soccer league so that league planners, coaches and parents can get a visual preview of different facilities before scheduling or attending soccer matches.

If the image server we would like to use provides state-wide data, we could create this application by simply creating a linked image for all of Ohio to use as a layer in our web site's map. The initial view when we create our
application would consist of a relatively small number of very low-resolution tiles that form a mosaic to show the entire state.

As visitors to our site navigate to various individual schools (say, by giving the school's street address and going directly to each school, by picking names from drop down lists of counties and then school names or by some other suitably efficient navigation method), they will get portions of the overall Ohio linked image served to them at whatever resolution is required for the zooming and panning they do about each school. Image tiles for each view will be cached on disk.

The schools of greatest interest to visitors will naturally be viewed first and so the image tiles for those schools will be the first to be saved in cache. As a result, views for those schools will be fast and require no connection overhead to the image server, exactly the result we would like in a well-architected web site.

After a while as a result of many views of many schools by many visitors, the server machine will have many image tiles stored in cache on its hard disk. A visit to virtually any school in the system used for soccer games will utilize cached image tiles and will not require download from the image server. The cached image tiles on disk will represent a fraction of image tiles that are available for all of Ohio, clustered as they will be in a patchwork of tiles at the location of each school. But no image tiles will be wasted on high resolution views of vast stretches of farmland or other regions not viewed by visitors to the web site. Since a visit to almost any school will used cached tiles, the web site will be very fast as it will rarely need to fetch new tiles from the image server.

If we wanted to assure even greater efficiency we could apply a zoom range to the linked image layer so that it only appears when visitors to the web site are zoomed far into the map. If they are zoomed far into the map we can safely reckon they are looking at a close-up view of a particular school site and so the linked image layer should be displayed. In that case, should users choose to navigate to a particular school by successively panning and zooming further into the web site map (which presumably shows major streets and towns as an aid to navigation) instead of by jumping directly to a school using whatever clever navigation user interface we have provided, then no image will be displayed as background during the process of finding a particular school. No image will be displayed until the user zooms into a particular school and thus no image tiles will be cached during the process of finding a particular school.

That would be more efficient because we would avoid any delay while low resolution images of parts of Ohio are fetched in order to provide a background visual for such pan and zoom navigation to a particular school, and no space on disk would be consumed for any cached image tiles used in such navigation. It is true that if we did not use zoom ranges over time the server would accumulate in cache all of the low resolution image tiles for Ohio and many of the medium resolution tiles used in such navigation, so this method of navigation would become faster and faster as more tiles would become available from disk cache. It is also true that disk space is nearly free so that most webmasters for such a useful application wouldn’t worry about using a few tens of gigabytes of additional disk space to allow showing a background image all of the time.

However, it does take time to build up a fast cache and a perceptual delay when panning is something that for psychological user interface reasons especially should be avoided. Most people have used Internet so much that they expect when they jump to a new location they may have to wait a few moments to get the display they want, but when they pan through an apparently seamless view of a map or an image they expect fewer delays. A further point is that for large regions the number of tiles saved for various intermediate views could get very large as users take various random paths of panning and successively zooming to find a particular location. Finally, although everyone enjoys a view from space, the visual clutter of a background image is usually not the fastest and most comprehensible way of helping visitors orient themselves. Simple, clear maps, the simpler the better, are usually the best way, with detailed images reserved for close-up views once a location of interest has been found.

Therefore, although we might get away with not using zoom ranges on a linked image of Ohio used in a web site, it is unlikely we would not use zoom ranges if the web site showed the entire United States. Even for a smaller region such as Ohio most webmasters would use zoom ranges to suppress the background image until zoomed far enough into the map to view an individual school.

**Note:** On demand retrieval of tiles as discussed above applies to images linked from Manifold Image Servers, images linked from OGC WMS servers and images linked from TerraServer.

**Relink and Unlink**

If a connection is lost between a linked image and its originating data, the **Image - Relink** command allows us to restore the connection. If we would like to convert a linked image into a regular image, the **Image - Unlink** command will sever all connections to the originating source and will convert it into a regular image.
Converting a Linked Image to a Local Image

An image linked from a remote server can be converted to a native (local) image within the project using the Image - Convert To command.

Limitations on Re-Projection

Except for limited exceptions of interest only to experts, compressed images, linked images and image libraries cannot in general be re-projected. They can only be re-projected into a projection that is affinely equivalent (change of scale and location only) to the projection in which the image exists. As a practical matter, this means that for most purposes such images cannot be re-projected or used in maps that use a projection different from the image.

For example, opening an ECW compressed image and attempting to re-project it to a different projection or dragging and dropping either an ECW compressed image or an image linked from some image server into a map that uses a different projection will fail. In such cases, Manifold will pop open a dialog telling us of the projection incompatibility.

If we would like to re-project such images, we should first convert them to an unlinked local image (in the case of linked images) or to an uncompressed image type (in the case of compressed images) or to a regular local image (in the case of an image library). We can then re-project the image as desired.

Linked Images and Map Projections

If we need to use a linked image in a map, the map should be created from the image so that the map uses the same projection as the image. If we try to include a linked image as a layer within a map that uses a projection different from the linked image, the image will not appear in the map because it cannot be re-projected into the projection used by the map. Manifold will warn us if we attempt to drop a linked image into a map with an incompatible projection.

One way around this projection limitation is to unlink the linked image so that it is converted into a local image. We can then re-project as we please, although of course in this case the dynamic linkage between the image and the source will no longer apply. It will be a static, local image stored in the project just like any ordinary image.

Note by the way that attempting to re-project such images on the fly by dropping them into a map that uses a different projection usually indicates a poor performance choice on the part of the user: usually, large images of the sort that are used as compressed images, linked images or image libraries are likely to be the largest, or among the largest, layers in any such map. It is therefore would be wisest to use their native projection as the projection for the map, so that when the map is displayed it is other, smaller layers that must be re-projected on the fly to display the map and not the large image layer.

To do so, create the map using the image layer first. This will assure that the map uses the image's projection. Next, drag and drop the other layers into the map. For maximum speed, re-project the other layers to match the projection used by the map. This is easily accomplished by (in the map window) right-clicking on the layer's tab and choosing Project to Map from the context menu.

If we attempt to create a map using several linked images at once that use different projections, then at least some of those images will have projections incompatible with that chosen for the map. Manifold will display a warning message if we attempt to do this.

Properties

The View - Properties dialog for components shows the data source of a linked component (such as an image library or other linked image) and other relevant information.

The Link / Share dialog accessed from the [...] browse button for linked or shared components accessed from the View - Properties dialog will provide a summary of the link or share properties. This will show the status of a shared component and whether or not changes in a linked component will propagate back to the data source.

For Enterprise Edition Users
Sharing a linked image to an Enterprise server places the linking information into the Enterprise server and not the actual image data. Importing or linking such a shared linked image to a local project will re-establish the connection to the relevant file or server. See the Enterprise Edition topic for information on Enterprise Edition.

**Tech Tip: Using Linked Images in Print Layouts**

It's not a good idea to use in layouts images that are linked from external servers (such as from ECWP servers, OGC WMS servers or TerraServer servers) because such images are downloaded as necessary to fill a particular view at a given zoom level and pan.

If such images are used in print layouts, it could well be that the tiles necessary to show the image at whatever resolution ends up being necessary for printing at a given printer resolution will not have been downloaded at the time the print job runs. Since it can take a long time to fetch such tiles, the system will use whatever is available for the print job, resulting in odd effects such as images that are blank or partially blank.

A further problem is that the image might change on the server between the time a print layout is created and when it is actually printed.

The way to avoid any unexpected effects is to first download the image to a regular image at the desired resolution and then use the regular image in the print layout.

**Tech Tip: Permissions and Linked Images in IMS Applications**

When using linked images in an IMS web application it is important that the web application has read and write permissions in the cache folder, or otherwise it will not be able to use the tiles cached for the linked image.

Image Libraries

An image library component is a type of linked image component that shows what appears to be a single image that is created by automatically forming a mosaic from one or more images saved in image files within a folder on disk. The individual images that comprise the image library are called image tiles. The image library component takes its name from the name of the folder that contains the image tiles that comprise the image library. Image tile files may be in BMP, ECW, GIF, JP2 (JPEG 2000), JPG, PNG, TGA or TIFF formats.

- If the image tile files are in ECW, JPEG 2000 or GeoTIFF formats that contain projection information within the file then the coordinate system information within each image file will automatically be used to georegister the image and form the image library mosaic.
- If the image tile files are accompanied by like-named files containing projection information in XML, PRJ, GSR or world files then the coordinate system information from those accompanying files will automatically be used to georegister the images and form the image library mosaic.
- If the image tile files are not accompanied by like-named files containing projection information, then the image library mosaic can still be created if the image tile files are named to indicate their position in the mosaic.

We can link an image library into a project by choosing File - Link - Image and then choosing Image Library Files in the Files of type box and then navigating into the folder in which the image library images are located and choosing one of the images. This launches the Link Image Library dialog.

Link Image Library Dialog Controls

- **Arrange images using filenames** If checked (the default), derive the location of image tiles from the name of each image file and place images accordingly. Choosing this option ignores coordinate system data in any accompanying coordinate system files or in the image files themselves.
- **Mask** A template using \[X\], \[Y\] and optionally \[L\] nomenclature to show how the names of image files should be used to place each image tile into position.
- **Automatically save intermediate levels** If checked (the default), will automatically generate tiles for intermediate image levels and will store them into the folder together with the other image files.
- **Reverse Y** Reverse the order in which \(Y\) values are interpreted.
- **Margins** The number of pixels to clip from left, right, top and bottom margins. Used when image tiles overlap and some part is to be deleted.
- **Georegister images using accompanying files** If checked, derive the location of image tiles from accompanying coordinate system files or from the files themselves for supported formats.
- **Mask** The template used for a filename when the above option is checked. Normally just an asterisk and the extension for that type of image file, such as .jpg, .tif or other supported image format.
- **Ignore datum differences** Enabled when the coordinate system for each image is to be defined by an accompanying file. If more than one datum is in use the system will arbitrarily choose one such datum from those used and will then treat all datums as if only that arbitrarily selected datum was the controlling datum.
- **Scan subfolders** If checked (the default), scan folders recursively below this folder to find more image files. If not checked, will only use image files from this folder.

Creating Image Libraries using Georeferenced Image Tiles

It's very easy to create an image library component if the image tile files we would like to use are either:
- In GeoTIFF, JPEG 2000 or ECW format and containing georeferencing information (although unusual, it is possible some ECW or JPEG 2000 files might have been created without embedded georeferencing information), or
- Are accompanied by accessory files giving projection information in XML, PRJ or GSR files or are accompanied by world files that give shifts and scales. If accompanying XML files are used they must be the .xml files written by Manifold System to specify the projection / georegistration information for an image.

If image library image tile files fall into one of the above categories it doesn't matter what file names are used or what the size of each image file may be.

To link an image library into a Manifold project using image tiles with accessory projection files.

2. In the Files of type box choose Image Library Files.
3. Browse into the folder containing the image tile files. All image tile files to be used must be in that same folder.
4. Double-click any one of the image files.
5. In the resulting Link Image Library dialog, check the Georegister images using accompanying files option.
6. In the Mask box, provide a mask that matches the file type to be used, for example, *.tif if using .tif files and *.jpg if using .jpg files.
7. Press OK.

A new linked image library component will appear in the Manifold project, taking its name from the name of the folder that contains the image tile files. Opening the image library component will show a gray background that will begin populating with images as the individual image tiles are loaded.

Example

Consider a series of nine images saved in ordinary .tif files (that is, not GeoTIFF files but plain, ordinary tif files as might be processed by PhotoShop and saved without georeferencing tags) in a folder called Bay image. These images may be arranged in a mosaic to form an overall view of the San Francisco Bay area.
Each image is georegistered and was saved (using Manifold) so that it has an accompanying .xml file giving relevant coordinate system information. Each image when imported therefore will be automatically georegistered. The images are all different sizes.

We can create an image library component from these images by choosing File - Link - Image, choosing Image Library Files in the Files of type box and then browsing into the Bay image folder and double-clicking one of the .tif image names. In the resulting dialog, we check the Load coordinate systems... option and in the Mask box we use *.tif as the mask. Press OK.

When we open the resulting Bay image image library component Manifold will import all of the image tiles and use the accompanying .xml coordinate system file for each to know where each file should be positioned to make a combined mosaic that appears to be a single image.

In this example, each image tile neatly abuts the adjacent image with no overlaps or gaps. If any image tiles overlapped, the resulting image library would average the pixel colors in the region of overlap to create the pixels in that region for the image library composite. If there were gaps or no image tile in a particular region, the image library would have transparent pixels in that region.

Image libraries made up from image tile files that are accompanied by XML, PRJ or GRS files that provide exact coordinate system information for each image tile are very easy to work with because the placement of each image is completely automated by Manifold. There's really no need for any significant thought on the part of the user because the files themselves contain all information necessary to mosaic them together. The files can be named using whatever names they have and they can be different sized as well. Easy!

It's also easy to work with GeoTIFF, ECW, or JPEG 2000 files that contain georegistration information inside the files. In that case projection information comes from the files themselves.

We can also create image libraries from image files that are accompanied by world files. World files are a highly imperfect way of storing partial projection information, but they are better than nothing. See the discussion of world files in the Importing Images topic.

Specifying Image Locations using Image File Names

Creating an image library requires more effort when image tile files do not use a geographically aware format like GeoTIFF or ECW or when they do not have accompanying XML, PRJ or GRS files to enable automated mosaics. It is still possible to automatically mosaic such image tiles into an image library component, but we will have to organize the images by naming the files in a regular way so that Manifold can tell from the name of the image where to put each image tile.

Giving images names where the filename indicates where each image is located is nothing new; that's a common technique often used when saving images in various applications so that later on it is easy to tell from file names on disk the geographic area covered by a particular image.

To link an image library into a Manifold project using image tiles without accessory projection files.
2. In the Files of type box choose Image Library Files.
3. Browse into the folder containing the image tile files. All image tile files to be used must be in that same folder. All images must be the same size in terms of their height and width in pixels.
4. Double-click any one of the image files.
5. In the resulting Link Image Library dialog, check the Arrange images using filenames option.
6. In the Mask box, provide a mask that describes the style of file name used to specify the position of the image.
7. If parts of each image should be masked off (for example, to remove some unwanted common border or region of overlap) use the Margins settings to specify the region on each side to be removed.
8. Press OK.

With the above technique we must understand how the naming convention being used should be specified in the Mask box. Manifold provides flexible options so that different forms of file names may be accommodated.

**Example**

Consider a set of images similar to those used in the example above, which may be arranged to form a mosaic of the San Francisco Bay area. Each image is saved in an ordinary .tif file without any projection information.

![Example Image](image.png)

However, in this case, each of the individual images forming the mosaic are exactly the same size in terms of numbers of pixels in width and breadth.
Images on the edge of the mosaic contain regions of black pixels in areas not represented in the original photograph. The images are saved in files that do not have accompanying coordinate system information. Upon import into Manifold, they will not be georegistered.

A collection of images like those above may be used in Manifold to form an image library if they are named in an orderly fashion so that Manifold knows from the file names for each image tile where that image tile is to be placed within the image library mosaic.

We can use a naming scheme that contains within the filename an indication of which X,Y position each particular image tile occupies within the image library mosaic. The conventional way to designate X and Y locations is to begin in the lower left hand corner and to number to the right for X values and upwards for Y values.
If we do this for the mosaic as seen above, we can provide an X,Y coordinate for each image tile. For example, the 3,2 tile is the one located in the third X position in the second Y position, that is, on the rightmost part of the middle row.

We can give each image tile file a name that incorporates the X,Y location of the tile in its name. For example, the image tile that is supposed to go into the 3,2 position will be named `Bay0302.tif`.

Why the use of leading zeroes as well as the name `Bay` within each file name? That's not required but it does help to keep things organized and easily legible. We could have just as easily named the 3,2 tile `32.tif` or
Manifold’s Mask specification used in the image library dialog allows variations like those, as we will see below.

We will give each tile a name using the above scheme. If we were to open the individual images in a package like Photoshop we’d see that they are just a group of unregistered images that happen to have been given names that indicate where they should be placed if a mosaic of the entire Bay area is to be constructed.

If we create an image library component using the above images, we would use a Mask value of

\[
\text{Bay}[X:2][Y:2].tif
\]

to indicate the names of the image tile files. The \([X:n]\) and \([Y:n]\) escape sequences tell Manifold what part of the file name has to do with X and Y coordinates. The \([X:2]\) specification tells Manifold that two characters in that position in the file name specify the X position of the tile in the mosaic and the \([Y:2]\) specification tells Manifold that two characters in that position specify the Y position.

The above mask matches file name specifications ranging from Bay0101.tif to Bay9999.tif. It would not match Bay123ab.tif. Other masks and examples include:

<table>
<thead>
<tr>
<th>Example</th>
<th>Mask</th>
</tr>
</thead>
<tbody>
<tr>
<td>32.tif</td>
<td>[X:1][Y:1].tif</td>
</tr>
<tr>
<td>003002.tif</td>
<td>[X:3][Y:3].tif</td>
</tr>
<tr>
<td>thisoneisthe32tile.tif</td>
<td>thisoneisthe[X:1][Y:1]tile.tif</td>
</tr>
<tr>
<td>img_x3y2.tif</td>
<td>img_x[X]y[Y].tif</td>
</tr>
</tbody>
</table>
When the above mask is used to create an image library component, the individual image tiles will be placed into a mosaic based upon their file names to create an overall image of the Bay area.

**Reverse Y Option**

While it is virtually universal practice to number the X axis with increasing values to the right, not everyone numbers their Y locations counting up from the bottom left corner. Some people and systems prefer to begin at the top left corner and count down.
We can use this arrangement if we like, as seen above, and create different file names. In this case, the Bay0101.tif image is the upper left corner image and not the lower left corner image. If we prefer to name our image tile files in this manner we can still use the same Mask specification. We simply check the Reverse Y option in the Link Image Library dialog to tell Manifold we are numbering Y values from the top down instead of the conventional bottom up.

**Exporting Image Libraries**

An image library may be exported to a file using the File - Export - Image command. The image library will be exported as a single image using the specified image format.

**Unlinking Image Libraries**

An image library may be transformed into an ordinary image by right clicking the image library in the project pane and choosing Unlink.

**Converting Image Libraries**

Another way to convert an image library into an ordinary image is to open the image library in a window and then choosing Image - Convert. Converting an image library creates a local image in the project of the desired type, being equivalent to first unlinking it and then converting the new local image into an image of the desired type.

**Limitations on Re-Projection**

Except for limited exceptions of interest only to experts, compressed images, linked images and image libraries cannot in general be re-projected.

For example, opening an ECW compressed image and attempting to re-project it to a different projection or dragging and dropping either an ECW compressed image or an image linked from some image server into a map that uses a different projection will fail. In such cases, Manifold will pop open a dialog telling us of the projection incompatibility.

If we would like to re-project such images, we should first convert them to an unlinked local image (in the case of linked images) or to an uncompressed image type (in the case of compressed images) or to a regular local image (in the case of an image library). We can then re-project the image as desired.

Note by the way that attempting to re-project such images on the fly by dropping them into a map that uses a different projection usually indicates a conceptual error on the part of the user: usually, large images of the sort that are used as compressed images, linked images or image libraries are likely to be the largest, or among the largest, layers in any such map. It is therefore would be wisest to use their native projection as the projection for the map, so that when the map is displayed it is other, smaller layers that must be re-projected on the fly to display the map and not the large image layer.

To do so, create the map using the image layer first. This will assure that the map uses the image's projection. Next, drag and drop the other layers into the map. For maximum speed, re-project the other layers to match the projection used by the map. This is easily accomplished by (in the map window) right-clicking on the layer's tab and choosing Project to Map from the context menu.

**Index Drawings**

When an image library is open the Image - Create Index Drawing command is enabled. This command allows us to automatically create a drawing that contains areas showing the extent of each individual image file that makes up that image library together with desired information about each image file, such as the name of the file, the path to that file's location and the type of file.

Index drawings are used in a variety of applications. For example, we might not wish to display all of the images in an image library but need to fetch an image that is part of the library. An IMS application, for example, might show a variety of vector layers and use an index drawing to show where imagery is available in a particular region. The application could be programmed so that a user who wants to see that imagery can double-click onto an index drawing area to pop open the corresponding image in a new window or to make it visible in a map window.
See the Image - Create Index Drawing topic for an example that creates an index drawing for the image library seen in this topic and then uses that index drawing within a Manifold IMS web page.

**Intermediate Levels**

If we provide intermediate image levels manually using the [L] specification and user-supplied intermediate level files we can improve interactive performance. See the Intermediate Levels and Pyramids topic for an explanation of intermediate level images, with illustrations.

If we do not manually provide intermediate level files (it's rare that they are available) it is a good idea to keep the **Automatically save intermediate levels** option checked so that Manifold will create intermediate level images for us. Even if we manually provide intermediate level images it is not a bad idea to have Manifold supplement them with automatically created intermediate level images. Here's why:

Most image libraries make up an image mosaic that is far larger than can fit into a computer monitor screen at one to one scale (one pixel in the image appearing in one pixel in the monitor). When we zoom far out enough to see the entire image, we don't see every pixel in the screen: instead, we see an interpolation or averaged out view where each pixel in the zoomed out image represents potentially hundreds of pixels at full resolution.

Computing such averaged out views takes time. The process can be speeded up a lot if intermediate level images, also known as pyramids, are computed in advance for intermediate zoom levels. Saving such intermediate zoom level images doesn't take much space but if they are available when we zoom in or out Manifold can simply utilize a pre-computed view for faster zooms and panning. This is much faster than re-computing an interpolated view on demand.

Most technologies for fast viewing of very large images, such as ECW, incorporate some scheme for pre-computing intermediate views in advance and then fetching them as needed to support faster zooming and panning. The **Automatically save intermediate levels** option allows us to utilize intermediate image levels even when working with image libraries that do not have intermediate levels. When the option is turned on, Manifold will automatically create intermediate level images and save them into the folder being used with the rest of the image library tiles.

**Note:** to use this option, our user login must have write permissions to the folder being used for image library tiles. If our login does not have write permission, Manifold won't be able to write intermediate level image files into that folder.

If the option is turned off, the image library will try to keep autogenerated intermediate image tiles in RAM cache. If the amount of available RAM decreases below an internally-computed safety level, the intermediate image tiles in RAM will be discarded and then regenerated again on demand.

**[L] Level Specification**

The [L] specification allows us to manually specify intermediate level image files to be used in the image library if we have intermediate level files available.

It is often the case that a particular region has images of greater and lesser resolution that cover it. For example, a region might be covered by sixteen images at high resolution and also be covered by four images at lower resolution and by one image at very low resolution. The different sets of images covering the same region represent **intermediate levels** of resolution.

Manifold can exploit the different levels of images to select the best level to match a given zoom into an image library. When zoomed far into an image library the higher resolution level images will be used. When zoomed out, so that very detailed pixels could not be seen anyway, Manifold can use a lower resolution image level for faster display.

The [L] specification in an image filename mask allows us to tell Manifold which images should be used at which level of zoom.

To specify the level to which different image files belong, we use the [L] specification within an image mask. Level number always uses **zero based** counting as in 0, 1, 2, 3... with level 0 being the highest resolution images covering the smallest regions and higher level numbers referring to lower resolution images that cover a larger...
The [L] specification is used together with the [X] and [Y] specifications to describe the organization implied by filenames.

<table>
<thead>
<tr>
<th>Example</th>
<th>Mask</th>
<th>Comment</th>
</tr>
</thead>
<tbody>
<tr>
<td>132.tif</td>
<td>[L:1][X:1][Y:1].tif</td>
<td>An image tile that belongs to level 1 where levels are specified using one digit.</td>
</tr>
<tr>
<td>01003002.tif</td>
<td>[L:2][X:3][Y:3].tif</td>
<td>An image tile that belongs to level 1 where levels are specified using two digits.</td>
</tr>
<tr>
<td>level3position32.tif</td>
<td>level[L]position[X:1][Y:1].tif</td>
<td>An image tile that belongs to level 3 where levels are specified using one digit.</td>
</tr>
</tbody>
</table>

It is easy to get confused as to what intermediate level image relates to which higher-resolution (smaller) images it covers. We can help keep things straight by using an orderly naming scheme which in the case of image libraries that employ intermediate levels should use zero based numbering.

When numbering X and Y, most people begin with 1 as illustrated above so that the first, corner tile is in the 1,1 position. However, if we like we can number beginning with zero in the series 0, 1, 2, 3... so that the first tile is in the 0,0 position. That means names such as Bay0000.tif for the first corner tile instead of Bay0101.tif are perfectly acceptable to Manifold.

Using zero for the first thing when counting is a bit atypical, though, as most people count their fingers (or anything else) using “one,” “two,” “three” and so on and do not count their fingers using “zero” for the first finger. Although our everyday experience of counting things such as our fingers argues against starting with “zero” for the first item, there is a very good reason why some programming languages and numbering schemes do so: that is to preserve the ability to do modulo arithmetic. In the case of image libraries if we number from zero we make it easier to retain a common naming scheme if intermediate levels are used.

The reason is that intermediate level images will be arranged by their names which, to facilitate a modulo arithmetically related connection to lower level images are always zero based. That is a mask of level[L]position[X:1][Y:1].tif will mean that a name of level2position00.tif is the corner second level image.

Notes

If we have Enterprise Edition installed, image libraries may be shared on an Enterprise server. Note that the image tiles are not actually stored on the Enterprise server: instead, the image tiles remain in the folder where they are located.

If image tile files are accompanied by more than one different type of accessory projection file, then any XML files will be read first and other projection files ignored, next any PRJ files will be read, then any GSR files and finally any world files will be read. If image tile files are not accompanied by any projection files, or if the accompanying files are not in the correct format, the system will use coordinate system data embedded within the image files themselves if the image files are GeoTIFF, ECW or JPEG 2000 files.

Image libraries have many uses. They are especially handy when converting large numbers of legacy image files into a modern format such as ECW: assemble an image library from the many small legacy image files, unlink the image library to create a single image and then export the image as an ECW.

Manifold will use more than one thread to render image libraries if more than one processor or processor core is available on the computer system. Therefore, image libraries will render faster on multiprocessor or on multi-core processor systems. For example, using a dual-core processor will allow image libraries to render faster.

Tech Tip for Experts: Level Nomenclature Illustrated

If you never plan on manually using intermediate levels, you can safely skip this part of the topic. Use the Automatically save intermediate levels option and Manifold will create intermediate levels for you automatically.
and take care of all naming details. This discussion is intended for experts who will be manually working with intermediate levels.

Even for experts, the naming scheme used for levels can be confusing. It’s best to use some illustrations to sort things out.

Consider an image library created from 25 image tiles. For this simple example, each image is 100 x 100 pixels in size and contains a solid green color. The illustration above shows the image tiles forming an image library with borders showing the edges of each tile.

We’ve now added labels that show the name used for each tile. The tiles were arranged into an image library using the **Arrange images using filenames** option. The **mask** used was

\[ L[L]_{[X:1][Y:1]}.tif \]

...with zero-based numbering so that a filename such as **L0_20.tif** means the file is the third X position over from the origin in the lower left, and is in the first Y row. The number 0 after the **L** in the filename means this tile belongs to the zero level, that is the first and highest resolution set of images.
To keep things simple, we will change the labels in the above illustration to simple X:Y representation so we can see more directly how the X and Y numbering scheme works. So far, so good.

Now let's show another layer of images that represent an intermediate level of images.

Shown in blue we see four images, also using the same mask of

L[L]_{[X:1]}_{[Y:1]}.tif

...as a template for their file names. There are only four blue tiles, not quite enough to cover all of the green tiles. This set of illustrations deliberately does not use enough blue tiles to cover all of the green ones so that the illustrations can show both some uncovered as well as covered lower level tiles. Note that all of the blue image tile names begin with an L1 to indicate they are on the next level up from the zero level.

A nuance: it is easy to mistakenly think that a single intermediate level image must be 200 x 200 pixels in size if it covers four more detailed images which are 100 x 100 pixels in size. That's not true. The intermediate level image is also only 100 x 100 pixels in size, but when it is displayed it is automatically scaled (making its pixels "larger" or "smaller") so that it covers the same geographic region as four more detailed images. It covers four times as much ground using the same number of pixels, hence it is less detailed because one pixel in the
intermediate level image cannot convey the same level of detail that four pixels in the more detailed level show. That doesn't coarsen the visual display because the intermediate level image is only used when the image is zoomed far out enough that the greater number of pixels in the more detailed images would in any event go to waste.

Let us now look at the numbering of these blue intermediate level images together with the numbering of the green images.

To make that easier to see, we will change the labels used on the blue images to $X:Y$ labels as well, and we will move the labels on the blue image tiles from the center of the tile down to the lower left corner of the tile.

The above image shows the green tiles with their name numbering scheme indicated in $X:Y$ form as labels in the center of the tile. The blue tiles also have their name numbering indicated in $X:Y$ form in the lower left corner of the tile. There are two things we can see from this comparison:

- First, both the blue tiles and the green tiles use the same mask, which provides a pattern for how each tile should be named based on its position in the image library. The same pattern applies to both the green and the blue tiles. In both cases, the leftmost lowest tile (at the origin) uses 0:0 for its naming. The three tiles adjacent to the leftmost lowest tile in both cases are named 0:1, 1:0, and 0:0.

- Second, we can see why, as a result of modulo arithmetic (that is, integer arithmetic discarding any remainder), it makes sense to use zero based numbering when levels are involved. If we use zero based numbering we can easily calculate for each lower level tile what numbering name should apply to any higher level tile that covers it.

In our above example, each blue tile is twice ($2$ times) the size in $X$ and $Y$ of each green tile. Consider the green tile at the 3:2 position. What should the numbering name be of the blue tile that covers it?

To get the $X$ part of the name we divide 3 by 2 and get 1 (three divided by two to get an integer without any remainder or decimal fraction is one). So the name will be 1:something. To get the $Y$ part of the name we divide 2 by 2 and also get 1. So the name should be 1:1 and, indeed, 1:1 is the name of the blue tile covering the 3:2 green tile.

If we repeat the above arithmetic for every green tile we can see that it works in all cases to accurately predict the name of the blue tile that covers that green tile. If we extrapolate how any additional blue tiles would be named going to the right and upwards we see that the rule continues to work.

This rule may seem to be almost idiotically simple, but it not only can simplify programming that works with image libraries, it can also help save us from simple mistakes. It is such a strong and useful rule that level names always use zero based numbering.
We must keep that in mind to avoid conceptual errors. Let’s consider an example of a possible conceptual error.

Suppose we have only four green tiles, and we have named them using one based numbering, that is starting the lower left tile at 1:1. The above illustration shows those four image tiles along with an empty matrix of where other tiles would be placed by name if they existed (and, in the case of green tiles, if we were to use zero based numbering).

Now, suppose we have created a single, new intermediate level image (shown in blue) that covers a region four times larger than a single green tile. If we name this image 1:1, see where it appears in the positioning matrix: it is not aligned to the lower left of the four green tiles but instead is aligned to the 2:2 green tile.
This is exactly what one would expect from the modulo arithmetic of the matter since $1$ divided by $2$ is zero using integer arithmetic. The $1:1$ green tile is covered by what would be the $0:0$ blue tile as can be seen from the illustration above.

So what would an actual image library consisting of many high resolution green images and four lower resolution blue images actually look like?

If we recall the situation shown above, we see that the four lower resolution tiles do not fully cover all of the green tiles.
If we open the image library and zoom far enough into the image library all we will see will be the green tiles. When we are zoomed far into the image Manifold will use only the highest resolution tiles.

As we zoom farther out, at some zoom level Manifold will begin using the blue image tiles since their lower resolution is a better match to the zoom level. In regions where there are no intermediate levels Manifold will have to interpolate on the fly from the higher resolution, green images.

Let's consider a photographic example using images of San Francisco Bay. We will use images that are all 200 x 200 pixels in size. Because they are identically the same size we can use the *Arrange images using filenames* option and manually specify an intermediate level image to use.
The overall image library will use nine images. Four of those images are seen above. These four images will occupy the lower left hand region of the image library.

We will also use one intermediate level image, seen above, which is also 200 x 200 pixels in size.
The intermediate image will cover the four higher resolution images in the lower left corner using the naming scheme shown above.

We will use the same mask as before so that the intermediate level image is called L1_00.tif and the nine higher resolution images have names such as L0_00.tif, L0_01.tif, L0_10.tif, L0_11.tif and so on up to L0_22.tif

When we open the image library window it looks like the illustration above, which has had an index drawing for the image overlaid on the image in a map window.

The index drawing has been formatted with transparent area background so the image can be seen. The area borders of the index drawing have been thematically formatted according to the value of the Tile Level field and labels have been automatically created using the X and Y columns from the index drawing. [The astute reader will immediately see that the illustrations for this topic have all been created in Manifold by using appropriately formatted index drawings.]

In the above illustration the intermediate level drawing does not cover all of the higher resolution tiles. It only covers the region within the red border. The regions outside of the red border are being interpolated by Manifold directly from the higher resolution images to create a seamless image mosaic regardless of which part comes from a higher resolution, lower level image and which part comes from a lower resolution, intermediate level image.

In fact, Manifold does such a good job at this that without the red border seen above it would be very difficult to tell by eye where the intermediate level image ends and where the higher resolution, non-overlapped images begin. Even if we carefully zoom in and out to be sure that we are seeing both the intermediate image and the high resolution images (just on the edge of the zoom value that would stop using the intermediate image), it is difficult to tell where one ends and the others begin.
It's easiest to see if we have a magnifying glass and can take a closer look at the actual pixels being displayed on the computer monitor. Seen above is a magnified view of a captured screen shot that shows the border between the intermediate image (lower part of the illustration) and the higher resolution images (upper part of the illustration). Note that the pixels in the lower image are "fatter" because they have to be inflated to cover four times the region each pixel in the higher resolution image can cover.

The above illustration shows one of two artificial effects at play in the illustrations in this documentation that are not typically found in image libraries in the real world:

- Usually when intermediate images are used they have been automatically calculated so that they cover any higher level, more detailed images. There is never an opportunity in such cases to see both an intermediate image and a higher resolution image together to make a comparison so we never see a difference in pixel size as seen in the image above. In such cases Manifold seamlessly switches between using different levels as appropriate for the zoom level displayed.

- To keep the example illustrations small enough to fit conveniently into this documentation, the intermediate image used above is only twice the X and Y extent of the higher resolution images. That makes the resolution difference relatively small so that the eye doesn't notice it as a great change even when the two resolutions are seen together. A more normal case would be to make a jump to four times the size so that each intermediate image covers sixteen higher resolution tiles.

**Tech Tip on Performance**

Image libraries are designed to work with large sets of small files, the kind that one gets when browsing an online mapping site such as MapQuest or Virtual Earth. Image libraries can be used with small sets of large files but performance will be significantly worse.

If we have ten large image files, it is better to use them directly without joining them into an image library. This can be done by showing the images together in a map with each image a different layer.

Alternately, if a single image is desired import the images into Manifold, uncompress them if they are in a compressed format, use Copy and Paste to create a single large image and then save the result as a single ECW or JP2 file. This process is tedious and very slow for large images but once the single large image has been created and saved as a ECW or JP2 file thereafter it will import and display with great speed.

The fastest way to store images is to use a spatial DBMS. Manifold can save images that are even tens of gigabytes into a spatial DBMS and then pan/zoom the image almost instantly.

Images and Channels

Images are often referred to as RGB images that use **channels**. Channels are a very simple idea that is easy to use.

**RGB Explained**

Much of how images are stored and manipulated in computers derives from the television technology that was first used to create computer graphics displays.

If we took a look at our computer monitor’s display with a magnifying lens we would see that it consists of a very large number of triplets of red, green and blue dots. Depending on the monitor manufacturer they may be round dots or small squares or other shapes but there always will be triplets of red, green and blue elements. In most monitors the dots are quite large and easy to see even with a weak lens.

Images on the computer display are formed when the monitor precisely varies the brightness of the red, green and blue elements in each triplet. Because the dots are close together the human eye will fuse the three red, green and blue dots of varying brightness into a single dot that appears to be the color combination of the three levels of red, green and blue color. For those of us who missed art class in school, all colors perceived by humans can be formed by the right brightness combination of red, green and blue color. Amazing, but true!

From here on in we’ll refer to the Red, Green and Blue elements of images as "R", "G" and "B".

Images on computers are usually nothing more than a series of number triplets where each triplet of three numbers is intended to control a single triplet of R, G and B dots on the monitor. Each triplet of numbers is a single pixel. A number triplet such as 67, 228, 180 means to turn the R element up to 67 brightness, the G element to 228 brightness and the B element to 180 brightness. The result will be seen by humans as a pretty shade of green-blue color. The RGB numbers are called **color values**.

Image files are arranged so that there is a series of pixels in rows that correspond to the rows of tiny triplet dots on the monitor. When an image is displayed on the monitor so that each pixel triplet in the image file controls one color triplet on the monitor we say that the image is "natural size" or "100% zoom".

In most modern software packages we take for granted the ability to zoom in or zoom out of an image to see it smaller or larger than natural size. If we zoom in, our graphics software will take the RGB values in a pixel that were originally intended to control just one color triplet and will use that same value across and down as many triplets as is necessary to make the image bigger on the monitor. If we zoom out so that the image is much smaller than intended, then there will be more RGB values than there are color triplets to control. In that case our graphics software will average out the RGB pixel values to figure out what average value should be used to drive the color triplet for that spot in the image. Manifold System performs these functions automatically.

**Channels**
How many numbers are used to specify the color of each pixel is the number of **channels** each pixel has. In RGB as described above, an image has three numbers for each pixel that directly correspond to the three R, G and B elements in the computer display. Such RGB images have three channels.

When we consider that an image that is 1000 pixels wide by 1000 pixels high contains a million pixels overall, if we have three numbers for each pixel (one number each to control the R, G and B dots) that can add up to very many bytes of data. If each number is just one byte, then a one million-pixel image will take three megabytes of space. Not surprisingly, there have been many clever software schemes invented to reduce the amount of space required for an image.

A quick and dirty scheme is to use just one number for all three RGB dots. If the brightness of all three dots is at the same level, we perceive no color but just different shades of gray. Using one number per pixel in a million-pixel image reduces the size to only one megabyte, but at the price of seeing the image in shades of gray as a **monochrome** ("black and white") or **grayscale** image.

How many numbers we have per pixel is the number of channels that image has. A monochrome image that has one number per pixel has one channel. A more typical image that has three (R, G, B) numbers per pixel has three channels. Such images are called **RGB** images. Although images with three channels are most common because of the universal use of RGB formats in color displays, there is no reason why an image could not contain more numbers per pixel for a greater number of channels than three.

For example, images used in sophisticated graphics editing use four channels: three channels for RGB plus an extra **alpha** or "a" channel. The alpha number says how transparent that particular pixel is supposed to be when it is combined in layers with other images. Such images are called **RGBa** images. Images coded with four, RGBa, channels can have regions of the image that are semi-transparent, so items in lower layers can be seen to a greater or lesser degree. Ordinary RGB images can have invisible pixels but this is a simple ON/OFF effect for each pixel. RGBa images can have a different percent transparency for each individual pixel in the image. This is called **pixel transparency**.

Another type of one-channel image uses a single number per pixel to specify which color in a palette of 256 colors is to be used for that pixel. See the Palettes topic for an explanation of what palettes are and how they are used. For the purposes of channels, it is important to note that images that use palette images are one channel images. This one channel is then expanded into three numbers per pixel via the palette.

Images collected by satellite sensors can contain hundreds of channels per pixel, with each channel being a number that represents some special quality collected by that sensor. Channels might code the height of that pixel, the temperature as seen from space or the reflectance as seen in various spectral bands invisible to human eyes. Since computer monitors only have three, RGB elements for each pixel, showing such multi-channel images requires software that maps the many channels into only three for display purposes. Such multi-channel images are often displayed using "false color" techniques that map one or more channel values into a specific range of RGB values.

There are two ways of working with multi-channel images such as multi-spectral satellite raster data images. First, such images may be stored as **.ecw** images and imported into Manifold as multi-channel compressed images. Channels from the compressed image may then be assigned to R, G, B and Alpha channels using the View - Display Options dialog. An alternate technique is to import multi-spectral images from non-.ecw formats into Manifold as multiple grayscale images where each image represents one channel. The grayscale images may then be combined three at a time to create false color RGB images or analyzed with scripts that can work with multiple images (in this case representing multiple channels) at once.

**Channel Controls**
When working with photographic images it is often very convenient to manipulate just one channel at a time. For example, if a photograph was taken outdoors without a blue sky filter the overall image may appear too blue. In that case, it would be very convenient just to see the blue channel and to turn down the "blue" intensity overall to get a more natural-looking image.

When used with images, the Layers pane (pop open from the View - Panes menu) will automatically display all the channels in whatever image has been opened. Click the checkboxes to turn channels off and on. Any editing effects will be applied to only those channels that are checked on and when painting into the image only those channels which are enabled will get painted.

The layers pane will show one channel for grayscale and palette images, three channels for RGB images and four channels for RGBA images. The layers pane also provides checkboxes to draw a background as well as a border around the image. See the Layers pane topic for more information on the border and background checkboxes.

Using all three channels shows the image in natural color.

Using no channels results in no visible image.
Checking just the Red channel shows the image using only the red dots on our monitor.

Checking Green only uses only the green dots. Note that the region of blue sky has darker red and green tones because it is predominately blue in appearance. The white clouds are bright in all three channels because simultaneous brightness in R, G, and B results in white.
Checking Blue uses only the blue dots. If we have a photograph shot outdoor with a sky filter correction it may end up too blue. To provide a more natural appearance, we might reduce the brightness of all blue tones to make the photograph less blue.

Using two channels together results in "combined" colors as used in the printing industry. For example, Blue and Red together are Magenta.

Blue and Green together are Cyan.
Green and Red together are Yellow (surprisingly!). Keep in mind when mixing RGB channels we are mixing light, not paint. Mixing green and red paint together results in mud, but mixing red and green light together results in yellow.

Commands use Visible Channels

All Manifold image commands work only on those channels that are enabled. For example, changing Brightness in an image with the Red and Green channels unchecked and only the Blue channel visible will affect the brightness of the Blue color value numbers only.

To make an image more or less yellow, check the Green and Red channels ON and the Blue channel OFF and increase or decrease brightness.

Likewise, painting into an image paints color values only into those channels that are checked ON. See the Painting within Channels topic for details.

Saving Channels as Separate Images

At any time we can save the separate channels of an RGB or RGBa image as different grayscale images. To do so, we use the Edit - Save Mask/Channel command with the channel to be saved specified in the dialog's Save box.

See the Masks topic for a discussion on how Edit - Save Mask/Channel can be used to separate an image into different images for each channel.

Colors as Hue, Saturation and Brightness

Describing colors using hue, saturation and brightness (also at times referred to as hue, saturation and lightness, or HSL) is a convenient way to organize differences in colors as perceived by humans. Even though color images on computer monitors are made up of varying amounts of Red, Green and Blue phosphor dots, it is at times more conceptually appropriate to discuss colors as made up of hue, saturation and brightness than as varying triplets of RGB numbers. This is because human perception sees colors in these ways and not as triplets of numbers.

If we imagine the three primary colors red, green and blue placed equally apart on a color wheel, all the other colors of the spectrum can be created by mixes between any two of the primary colors. For example, the printer's colors known as Magenta, Yellow, and Cyan are mid-way between Red and Blue, Red and Green and Blue and Green respectively.

This diagram is called the color wheel, and any particular spot on the wheel from 0 to 360 degrees is referred to as a hue, which specifies the specific tone of color. "Hue" differs slightly from "color" because a color can have saturation or brightness as well as a hue.

Saturation is the intensity of a hue from gray tone (no saturation) to pure, vivid color (high saturation).

Brightness is the relative lightness or darkness of a particular color, from black (no brightness) to white (full brightness). Brightness is also called Lightness in some contexts, in particular in SQL queries. See the Raster Extensions topic.

The illustration above shows the difference between saturation and brightness. We first pick a blue hue from the color wheel (stretched out into a line to make a prettier illustration). We can then reduce the saturation so that the blue hue becomes more and more blue gray. With zero saturation it is gray. We pick a less saturated blue tone and then turn the brightness up and down on that tone.
Note that increasing the brightness is not the same as decreasing saturation. Decreasing saturation turns the colors into gray shades. Increasing brightness turns a blue into a lighter sky blue but without making it gray.

Taking an almost totally desaturated blue, so desaturated it is almost perfectly gray, and increasing the brightness will result in what appear to be lighter shades of gray. However, if there is any "blue" at all in the gray by increasing saturation we can achieve a bright blue again.

This is why increasing saturation to a great degree in ordinary photographs will at times bring out unexpected, bright, vivid, posterized color effects. What has happened in such cases is that some "gray" pixels were not truly neutral grays but rather were desaturated hues. Increasing saturation to 100% saturation brings out the hidden hues.

**Numeric Definitions**

Hue, saturation and lightness (brightness) are computed from raw R, G and B channel values scaled into a range of 0 to 255 according to the following formulae:

- \( H \) (hue) = 0, if \( R = G = B \), otherwise a value between 0 and 255, with the range of 0 to 255 being split into three strips for G to B, B to R and R to G gradients.

- \( L \) (lightness) = \((M + m) / 2\), where \( M \) is \( \max(R, G, B) \) and \( m \) is \( \min(R, G, B) \).

- \( S \) (saturation) = 0, if \( R = G = B \), otherwise \( 255 \times (M - m) / (M + m) \), if \( L < 128 \), otherwise \( 255 \times (M - m) / (511 - (M + m)) \).

**Luma**, for historical reasons referred to as **intensity** is computed according to the following formula:

- \( I \) (luma) = \( 0.3 \times R + 0.59 \times G + 0.11 \times B \).
Invisible Pixels

Any image except a compressed image in Manifold can have invisible pixels, which do not appear in the image. They are simply placeholders for empty regions of the image. When images containing invisible pixels are stacked above one another in a map, items in layers below the invisible pixels will be visible.

Invisible pixels are a simple, low-overhead way of creating transparent regions within images. They are available within any Manifold image type. Using invisible pixels does not increase the storage size required for the image. The only disadvantage of the invisible/visible pixel facility is that pixels are either completely opaque or they are completely invisible.

If partial transparency is required, two other transparency methods may be used with images:

- **Layer Transparency** allows changing an entire image layer's opacity on a percent basis. This works with any image layer in a map. All the pixels in the layer will have the same percent opacity applied. This is a good effect for creating "see through" images for purposes such as aligning images to each other within maps or for creating faint images overlaid on maps to provide guidance. Layer transparency works with any image layer in Manifold and does not add to the storage size of the project.

- **RGBa Pixel Transparency** allows setting a different percent transparency for each individual pixel. This allows sophisticated gradients in transparency for the creating of drop shadows, composite images and feathering images. Pixel transparency is normally applied using editing tools such as partial erasers to partially erase various regions or by using gradients as masks for the alpha channel. Pixel transparency is available only within RGBa images, which are larger by one channel than they would be as RGB images.

Selections and other operations can occur with regions of invisible pixels; however, unless we paint color into them using some method such as the paint bucket they will not participate in image operations. For example, adjusting hue, saturation or lightness has no effect on invisible pixels. Painting color into an invisible pixel makes it a regular pixel again.

**To Create a Region of Invisible pixels**

1. Select the desired region.
2. Choose **Edit - Delete** from the menu or press the **Delete** key on the keyboard: The pixels will disappear from the image.

To restore invisible pixels into ordinary pixels, paint the region with any image drawing tool.

**Example**

Suppose we view the above two images in a map, with the bronze image above the schloss image. ["Schloss" is German for "castle" or "chateau". The image shows the famous Schloss Neuschwannstein in Bavaria.]

838
We wouldn't be able to see those parts of the castle image covered by the bronze image. We can look at the bronze image in an image window as well as in the map window.

The image window background has been turned off so we can see which parts of the bronze image become invisible. Manifold uses a checkerboard pattern to show regions where there is neither background nor any visible pixels. This makes it easy to see regions that are less opaque.
To create invisible pixels in the sky region, we simply select the pixels in the sky region and then *Delete* them.

If desired, we could have selected them in the map window and deleted them there.
When we delete the pixels they disappear. They will immediately disappear in the map window as well.

This makes that region of the bronze image completely invisible and allows more of the castle image to become visible.
Any operations applied to the image will not involve the invisible pixels. It is as if those regions of the image are not even there. For example, we can increase the saturation of the bronze image.

We can do this either in the image window or the map window without affecting the schloss image. Any operations we apply will affect only the visible pixels.

It's often the case that we would like to render invisible all pixels except those selected.
Suppose we've selected the region of pixels in South America and we would now like to make all other pixels invisible. We use **Edit - Select Inverse** to invert the selection.

Now we can use **Edit - Delete** to delete the selected pixels and make them invisible. The image is shown with the **Border** turned on in the Layers pane so we can see the size of the image.

**RGBA Pixel Transparency**

We can use RGBA pixel transparency in images that have transparent pixels. If the bronze image is an RGBA image, we can vary the transparency of each pixel independently.
For example, if we load the above grayscale gradient as a Mask for the alpha channel in the bronze image we are telling Manifold to vary the transparency guided by the grayscale value of the gradient.

Since the grayscale value increases from black to white this will increase transparency in a continuous gradient from zero transparency at the top of the image to full transparency at the bottom of the bronze image.
It's easy to create complex images mixing many layers of other images with suitable use of invisible pixels, RGBA pixel transparency and transparent layers. We can layer images of different sizes and move about the different layers to achieve the effect desired. For example, if we wanted to add pigeons flying about the statue we could cut pigeon images out of a picture with pigeons and then paste them into layers above the bronze layer, with one pigeon per layer if desired. We could then move the pigeons about by moving their layer, warp the pigeons with perspective effects to make them appear as seen from different angles and perhaps reduce a few in size and desaturate and lighten them to make it seem they are in the distant background.

Just for fun, let's Colorize the schloss image into a light sepia tone to allow the colors of the saturated bronze image to better stand out. We have also taken the liberty of selecting and then deleting the remnant pixels for the upper part of the clouds in the bronze image. The improvement in the composite effect can be seen by comparison with the illustrations below, where the screen shots were made before trimming the clouds and thus a fine outline of cloud layer can be seen in front of the castle.

**Invisible Pixels vs. RGBA Pixel Transparency**

RGBA pixel transparency is a different mechanism than invisible pixels. Key differences include:

- Invisible pixels are an "all or nothing" effect: either the pixel is fully visible or it is invisible. Alpha transparency allows a different transparency setting for each individual pixel.
• Deleting a pixel to make it an invisible pixel is a permanent deletion. The pixel with its original color values cannot be retrieved. Alpha transparency, in contrast, can be changed at any time to restore the original appearance of pixels.

• Using invisible pixels does not add to the size of the image. Alpha transparency works only with RGBA images and requires a fourth channel for each pixel whether transparency is used or not.

• Invisible pixels do not take any longer to process than regular pixels. RGBA images take longer to display because transparency for each individual pixel must be reckoned.

**Use with Projections and Drawings**

Invisible pixels work fine when combined in maps with drawing layers or with projections.

![Image of world map with sea areas removed](image)

A frequent use is to remove sea areas from photographic images so that graticule lines or other drawing elements in layers below the image can be seen.

Using **Select Touch** we selected the pixels in sea regions and then deleted them to create the above image in Mollweide projection. See the Invisible Pixels and Selection topic for information on selecting invisible pixels and on using the Invisible Pixels selection in the **Selections** pane.

**Cutting, Copying and Pasting and Invisible Pixels**

Some commands will automatically create regions of invisible pixels.

**Cut**

Cutting a selection out of an image leaves a region of invisible pixels.

**Copy / Paste**

Copying a selection takes only the selected pixels. When pasting from the clipboard into a new image layer, the "empty"
region in the rectangular image will consist of invisible pixels.

**Painting over Invisible Pixels**

We can create "real" pixels in regions of invisible pixels by simply painting into those regions using any painting or drawing tool that works with images.

Suppose we delete the sky pixels in our sample *bronze* image to create a region of invisible pixels.

We can see the preview of this in the Selections pane using the Invisible Pixels saved selection.
We can paint onto the region of invisible pixels however we like. In the illustration above we've added dots and other figures in green and gold.

Once we paint onto a region those pixels are no longer invisible. The Invisible Pixels saved selection, for example, no longer includes them.

**Invisible Pixels in Masks**

Any invisible pixels in masks will not participate in whatever the mask is asked to do. If the mask is loaded as a selection, regions of invisible pixels will not be selected. If the mask is loaded as a channel, any parts of the mask containing invisible pixels will not alter the target image.

**Saving Invisible Pixels as a Separate Image or Mask**

At any time we can save the region of invisible pixels as an image within an image. Such images are called masks and may be used at any time in the future for subsequent selection or channel operations. To save the region of invisible pixels as a mask, we use the Edit - Save Mask/Channel command with the Invisible pixels system saved selection specified in the dialog's Save box.

At any time we can use Edit - Load Mask/Channel to load a mask that specifies a region of invisible pixels. For example, we may have previously saved some selection as a mask and now we would like to use that selection to create a region of invisible pixels in the shape of that selection. We can use Edit - Load Mask/Channel with Load set to Invisible pixels and the region of invisible pixels will be set by the mask being loaded. Note that any previously invisible pixels will remain invisible since making a pixel invisible is always a "one-way" operation that deletes the pixel.

See the Masks topic for a discussion on how Edit - Save Mask/Channel can be used to save different regions for use as selections. It's easy and fun.
See the Invisible Pixels and Selection topic for information on selecting invisible pixels and on using the Invisible Pixels selection in the **Selections** pane.

**Invisible Pixels are not Deleted**

Note that when "deleting" pixels the pixels are not really deleted - they are simply made transparent. The only way to delete pixels in an image is to crop the image, in which case the cropped pixels are genuinely deleted.

Consider the example **SanFran** image on the Manifold CD that shows a LandSat image of the San Francisco Bay area. Note that it has regions of black pixels because the LandSat image is tilted. The black pixels are necessary because all images are rectangular (made up of a rectangular array of X times Y pixels).
We can select the black pixels and delete them.

However, deleting the pixels simply makes them invisible. The image still has the same original extent as it did before. The "deleted" pixels are still there as invisible pixels.

We can see that by turning on the Selections pane for this image and previewing the built-in [Invisible Pixels] selection in blue preview color. Because images must be rectangular there is no way to cut off triangular portions of them.
If we want to reduce the size of the image so that it contains no invisible pixels we must make a rectangular selection and then crop the image to that selection.

This will genuinely delete the cropped pixels, albeit at the cost of cropping the image down to a rectangular region that covers only visible pixels.

- About the Sample Images provides notes on the *schloss* and *bronze* sample images.
Invisible Pixels and Selection

By default, selection methods do not select regions of invisible pixels. The one exception is **Touch Selection**, which will select invisible pixels when they are touched.

Suppose we delete part of our standard *bronze* image to create an image with invisible pictures. We've also drawn a blue bar across parts of the image to divide it into upper and lower halves. We have turned on the **Border** in the Layers pane so we can see the actual size of the image.

If we click near the lower right corner with **Touch Select**, all the invisible pixels contiguous to the spot touched will be selected. Note that the contiguous selection "flows" only through the actual extent of the image. Therefore, it did not select "around" the blue band or the lower leg of the monument.
If we **SHIFT-click** with **Touch Select** we can select all of the invisible pixels in the image no matter where they are located.

**Other Selection Commands**

All other selection commands will ignore invisible pixels by default.

**Use the SHIFT key to Select Invisible Pixels**

**Select Touch** will select contiguous invisible pixels when the mouse is clicked on a region of invisible pixels. All other mouse selection commands, such as **Select Box**, will select only visible pixels within the mouse selection region. To select invisible pixels as well, hold down the **SHIFT** key while making the mouse selection.

A **SHIFT - Select Touch** command will select all invisible pixels in the image, whether contiguous or not.

A **Select Circle** selection does not select the invisible pixels. It only selects visible pixels within the selection circle.
Using **SHIFT - Select Circle** selects both invisible and visible pixels within the selection circle.

**Invisible Pixels Saved Selection**

Precisely because invisible pixels are not seen there are times when we might like some help in seeing them.

Invisible pixels are very frequently used when composing sophisticated images (that is, maps) that consist of stacks of many constituent image components. When working with many different image components that contain transparent regions we might forget which parts are transparent and which regions are simply white pixels in images or “white space” in drawings seen through the layer stack.

When working in an image window we can see which regions are invisible pixels by working with the background color turned off to allow the checkerboard pattern to show through. However, in the case of RGBA images it is possible to set RGBA pixel transparency to full transparency to make the pixels entirely disappear. The effect is the same, but these are not invisible pixels. They are visible pixels with their alpha values set to full transparency for each individual pixel and so the checkerboard pattern will be seen through such pixels as well.

In addition, we often would like to use the region of invisible pixels in selection combinations with selections made in other parts of the image. To support this usage and to make it easy to unambiguously see the region of invisible pixels Manifold devotes one of the seven saved selections in images to a system-provided saved selection that always shows the region of invisible pixels. This saved selection will appear in the Selections pane if any invisible pixels occur in the image.

Suppose we have an image that may contain invisible pixels.
To see the region of invisible pixels, simply click on this saved selection to highlight it and press in the **Preview** button in the Selections pane toolbar.

Any invisible pixels in the image will appear in blue preview color.

**Example**

This example shows use both of the invisible pixels saved selection as well as the use of the SHIFT key to select invisible pixels in addition to visible pixels.

We will use the `globe.bmp` sample image with contrast increased (to make touch selection easy in water areas) and relief added for a pretty appearance.
Using **SHIFT - Touch Select** we touch regions with water to select them throughout the image.

Choose **Edit - Delete** and the pixels disappear. (We have the white **background** color turned on in the Layers pane so the background appears white).

However, the invisible pixels are still there as placeholders for the region they occupy. We can click on a region of invisible pixels with **Touch Select** and they will be selected. They are simply invisible. Once selected we can pour color into them with the paint bucket to make them visible again.
Selections made over invisible pixels do not normally select them. Here we have made a Select Circle selection that ignores the invisible pixels.

To select invisible pixels, we hold the SHIFT key down while making the selection. For example, a SHIFT - Select Circle command will select the invisible pixels within the circle as well as the visible pixels.

It’s often the case that we would like to see the region of invisible pixels or use it with selection combinations. Clicking the invisible pixels saved selection in the View - Selections pane will show it to us in blue preview color if the Preview button is pushed in.
We can use the invisible pixels selection like any other saved selection. For example, we can use **Subtract from Selection** to subtract the region of selected pixels from the circle selection.

If we push out the **Preview** button to remove preview color we can see that we have just made a circular selection within Africa that is "clipped" at the coastline. This is a somewhat contrived example since we could have done the same thing just by selecting the circle without holding down the SHIFT key as we did in an earlier step. However, there will be many times when it will be convenient to use the invisible pixels saved selection in **Replace, Add, Subtract, Invert** or **Intersect** commands together with the existing selection.
RGBa Pixel Transparency

RGBa images can have a different transparency level for each individual pixel in the image. This is achieved by adding an alpha channel to the three basic R, G and B channels. The effect is also known as alpha transparency. Compressed images can also utilize alpha transparency by choosing an image channel to be used as the alpha channel via the View - Display Options dialog.

The appearance of each pixel in RGBa images is defined by four numbers: the three R, G and B numbers that specify the color and an alpha channel number that specifies the transparency of that particular pixel in a range from 0 (fully opaque) to 255 (completely transparent). The ability to work with RGBa images is one of the key capabilities that distinguishes a professional-class image editor like Adobe Photoshop or Manifold System from consumer-grade graphics editors.

If you have not yet done so, please read the Images and Channels topic before proceeding with this topic.

To use RGBa Pixel Transparency:

1. Convert the image to RGBa using Image - Convert to
2a. Paint any gray color into the alpha channel of the image using any paint tool; or
2b. Load a grayscale mask for the alpha channel using Edit - Load Mask/Channel

RGBa pixel transparency works only with RGBa images. If the image is converted to any other type (RGB, grayscale or palette) the partial transparency effects will be lost.

Alpha transparency does not change the R, G, and B channels that define the color value of the pixel. When we appear to “erase” pixels using alpha transparency the pixels and their original color values are still there. They are simply transparent because their alpha channel values have been set to high amounts. If we change our minds about any transparency effects applied we can restore the original appearance of the pixels by converting the image to an RGB image.

See the Painting within Channels topic for examples of painting gray color into the alpha channel to control alpha transparency.

Example

Suppose we have an image of Europe using mostly blue colors.
We can make a copy of the blue Europe image and use Hue / Saturation to change the color range to red.

Using the partial eraser we can erase most of the image leaving only the central portion with a gradual transition from fully opaque pixels to fully transparent pixels.

If this image is layered in a map above the blue Europe image we get the effect seen above.

We can also use masks, such as the grayscale gradient above, to control alpha transparency.

When the mask above is loaded into the alpha channel of the red Europe image it causes zero transparency in black regions of the mask and complete transparency in white areas of the mask. The regions of the mask that transition from black to white cause a gradient of partial transparency in the red Europe image.
Seen in the map above the blue image the result is a gradual color transition from Northwest to Southeast.

There is no limit to the artistic and presentation effects made possible by alpha transparency. We can adjust the region of transparency using a wide variety of Manifold editing tools.

The illustrations above show the red Europe image as a separate image to make clear what is going on. Many times we will edit alpha transparency free-hand in maps using editing tools such as the partial eraser to see the effect in a many-layered map in real time.

We can create many special effects by making copies of an image and then adjusting the different copies in different ways (such as by Hue / Saturation or other commands), partially erasing pixels in the variations and then recombining them.

**Uses for Alpha Transparency**

- Creation of complex images using many layers.
- Graphics art effects. See the Invisible Pixels topic for an example.
- Drop shadows, halos and "stand outs". See the Gaussian Blur topic for an example.
- "Feathered" transitions from one image to another.
- Color range effects as shown above.
- Transitions between different effects, such as blur to non-blurred images.
- Fine feathering of images to eliminate anti-aliased pixels at the edges of "cut outs."
- To give the appearance that text or other images are painted onto a surface.
- To merge tiles of different images into one image without obvious borders.
To paste patches into images to hide defects or unwanted imagery without an obvious border line.

**Example**

Manifold System has such powerful image manipulation capabilities that it may also be used to create complex images by combining multiple images in layers as is done with professional quality graphics image editors such as Adobe PhotoShop.

The marketing promotion "splash" screen used with Manifold System Release 5.00 was created using over 40 layers of other images. Alpha pixel transparency and invisible pixels were used throughout the various layers so lower layers could combine to form the image. Looking at seventeen of the various layers we can see how the image was created:

The bottom three layers were screen shots from a Terrain window using different settings for sky and surfaces. The uppermost of these is the grid.

The next two layers are the floating city and its shadow, which are in separate layers so that the transparency and relative position of the shadow may be easily controlled. Once the shadow was in the right position relative to the city, the Move Together box for both was clicked for these two layers so that moving the city automatically moved the shadow as well. See the Gaussian Blur topic for details on creating drop shadows.

The next twelve layers consist of text or logotype images together with various drop shadows. By checking and unchecking the Move Together boxes as we click on any of the layers, we can move various layers together to compose the image as desired.
The actual production "map" for the splash screen included over 40 layers. The extra layers contained variations of the logotype, different visual elements such as different sky cloud patterns and other variations. By checking the layers ON and OFF and moving the various layers about it was easy to try out many different variations to end up with exactly the effect desired.

Each image in the layer stack was heavily manipulated using various effects, resized, partially erased or made transparent to "feather" its features visually into features from other layers, and so on. For example, the city originated in a scanned photograph snapped from the bell tower in St. Mark's square in Venice. It was cut out of the photograph and then different parts of the image had hue, contrast and color balance adjusted in different ways. To bring out detail in the trees the green areas were re-built from several layers using different settings for brightness, contrast, saturation, colorization and color balance.

See the Composing Complex Images in Layers topic for an additional example of how to compose complex images using Manifold.

**Saving the Alpha Channel as a Separate Image**

At any time we can save the separate channels of an RGB or RGBA image as different grayscale images. To do so, we use the Edit - Save Mask/Channel command with the channel to be saved specified in the dialog's Save box. For example, we can save the gradations of an alpha channel as a grayscale image by choosing Channel: alpha in the dialog's Save box. This is a very useful way of saving different transparency patterns. We can try out different amounts of alpha transparency as we like and always return to one pattern that we like the best.

See the Masks topic and the Separating Images by Channels topic for information on how Edit - Save Mask/Channel can be used to separate an image into different images for each channel.

**Invisible Pixels vs. RGBA Pixel Transparency**

Alpha transparency is a different mechanism than invisible pixels. Key differences include:

- Invisible pixels are an "all or nothing" effect: either the pixel is fully visible or it is invisible. Alpha transparency allows a different transparency setting for each individual pixel.
- Deleting a pixel to make it an invisible pixel is a permanent deletion. The pixel with its original color values cannot be retrieved. Alpha transparency, in contrast, can be changed at any time to restore the original appearance of pixels.
- Using invisible pixels does not add to the size of the image. Alpha transparency works only with RGBA images and requires a fourth channel for each pixel whether transparency is used or not.
- Invisible pixels do not take any longer to process than regular pixels. RGBA images take longer to display because transparency for each individual pixel must be reckoned.

**Performance Considerations**

Working with RGBA images is slightly slower than working with regular RGB images because of two factors:

- RGBA images are larger than RGB images.
- Adjusting transparency for each individual RGBA pixel takes longer than simply displaying an RGB pixel.

Most graphics art editing of images is done with images that are tens or hundreds of times smaller than images can be in GIS applications. For that reason using RGBA and alpha transparency is not normally a performance issue with graphics arts image editing in applications such as Adobe Photoshop.

Because GIS images such as raster data images can be well over a hundred megabytes we need to consider in a GIS environment whether it is worth it or not to convert images to RGBA and to use alpha transparency. Operations with such large images on desktop machines should consider every performance issue.

**Nomenclature**
Transparency and opacity are two terms that mean the same concept viewed from different directions. When something is completely opaque it is not at all transparent. When something is perfectly transparent it may be said to have zero percent opacity.

Which word is used depends on the discussion. When imagining layers stacked up above each other like transparent sheets it is conceptually clearer to use the word transparency. When discussing a specific percentage of light transmission to be applied via a slider bar in a dialog most applications use the word opacity.

The convention in the graphics arts editing software industry is to adjust layer transparency with controls that set a number from 0% to 100% opacity, so that an image with 100% will be fully opaque and not allow any view of an image underneath it. Manifold follows this convention. This convention persists in the graphics arts industry even though the technical implementation of transparency effects is done using an alpha channel within RGBA images where the higher the value of the alpha channel (from 0 to 255) the higher the transparency.

One therefore encounters the slight conceptual dissonance of increasing opacity with higher numbers (up to 100%) in dialogs and other user interfaces while the internal data sets use numbers (alpha channel values) in which opacity decreases with higher numbers. Since we rarely set alpha values by hand this is not so bad. Alpha values are normally set using various tools, such as erasers, or masks. In the case of masks, the darker the mask region the lower the alpha value is and thus the higher the opacity. From a casual conceptual view this is very acceptable because it leads to an effect where black regions of masks cause full opacity and white regions of masks cause full transparency. Since we are used to thinking of “white space” as being transparent this works well as a natural mnemonic for the effects of masks.

Palettes

Palette images save image space by reducing the number of colors used in the image to 256 colors and then using one number per pixel (one channel) to specify the color for each pixel. Each color number corresponds to a color in a palette of 256 colors. Each color in the palette is a True Color RGB color out of a possible range of millions of colors.

Manifold uses the terms “palette images” and “palettes” because those are the terms used in Microsoft standard applications such as Microsoft Photo Editor and Microsoft Office. Non-Microsoft graphics packages and legacy GIS applications may use different terms. For example, palette images are known as Indexed Color mode images in Adobe PhotoShop and palettes are called color tables or color maps in some applications.

Palette images have become less important for graphics editing in modern times because the cost of disk drive space has plummeted. In an era when cheap disk drives deliver tens of gigabytes it is no longer as important as it used to be to reduce the space consumed by images. Preserving high visual quality is usually much more important with most images than saving space.

The exceptions are massive raster data images that originate in various technical programs, which may be tens or even hundreds of megabytes in size. Reducing the size of such images by converting them to palette images is often a wise trade-off between quality and size.

Another reason for use of palette images is that many images are published in formats that use palettes. Manifold supports fine control over palette images and the palettes they use to allow maximum exploitation of such images.

Another reason to use palette images is to reduce the size of images that will be published on Internet. Even with fast connections, Internet is so slow that it is very important to reduce the size of images used on web sites. Reducing the number of colors in an image allows web graphics formats such as .gif and .jpg the best possibilities of compressing the image to a small size.

Finally, an important raster data usage of palettes is to force pixels into a pre-defined set of color values. Such values can represent various classification schemes for the physical regions represented by the pixels or other data values.

About Palette Images

RGB images use three numbers per pixel to specify the colors in an image. Using three numbers per pixel allows about 16 million color combinations in most installations but it requires a lot of storage space for each image. As mentioned in the Images and Channels topic there have been many methods invented for reducing the size of RGB images.

One method noted uses one number per pixel by averaging brightness for all three pixels to provide a single, grayscale number for each pixel. This is very compact for storage, but it loses all non-grayscale colors in the image. Another popular method for reducing the size of RGB images is to use a palette. This method will preserve good color appearance in many cases while dramatically reducing the size of the image.

The palette method depends on the observation that most RGB images use only a small number of the 16 million possible colors available for use. There are two reasons why this is so. The first reason is that most images have far fewer than 16 million pixels in them. A 1024 x 768 image, for example, has less than a million pixels. Even if each pixel were a different color such an image would require much less than 16 million different colors to draw.

The second reason is that most colors used in computer images are so similar to each other that they are indistinguishable to the human eye. An example:
If we zoom far into our example bronze image near the head and chin of the monument we can see that the blue sky is composed of many blue pixels that are slightly different shades of blue. However, most of the blue shades are so similar to each other that it is very difficult to tell them apart. We could easily replace the hundreds of different, but virtually identical, shades of blue with two or three “blues” without significantly changing the appearance of the image.

That's exactly what the palette method does: to convert an RGB image into a palette image the system analyzes all RGB colors in the image and groups them into similar shades. The palette method then takes all the very similar colors in a group and replaces them with one color that is a close match to all of the colors in that group. For many images, it is possible to choose only 256 colors that are so reasonably close to the various similar colors out of all 16 million possible colors that the image appears the same as the original.

To see this in action, consider the above two images. Both images are zoomed in views of the bronze sample image showing the head and chin of the bronze monument. The image at left uses three RGB numbers per pixel so that each pixel can be any one of 16 million possible colors. Note how the blue sky is composed of many similar shades of blue, most of which are indistinguishable from each other.

The image on the right uses only 32 colors throughout the entire image. Each of these 32 colors is an RGB color chosen from the overall range of 16 million colors to be the best match possible to the group of similar colors it replaces. Only two shades of blue, for example, appear in the blue sky. We use 32 colors in this example because using 256 colors as is normally done with palette images results in such a close match to the original image that it is hard to tell the difference. Using 32 colors makes differences more apparent for the sake of an example.

The palette method saves the reduced number of colors in a palette (also known as a color table or color map) which is to be used for that image. Each color in the palette is listed as a three-number RGB color. The 32-color palette for the sample bronze image converted to 32 colors (part of which is shown above), for example, is:

Using only the above 32 colors results in an image that is remarkably close to the original.
The image on the left is the original, while the image on the right is the 32-color image.

**How Palettes Work**

Palette images in Manifold use 256 colors per image. This makes it possible to save images using only one byte per pixel, since each byte can represent 256 colors (bytes range in value from 0 to 255 for 256 positions in all). The first step in converting an RGB image is reducing it to 256 colors as described above. This requires picking out a palette that is a "best match" to the many colors in the RGB image and then assigning a color from the palette to each pixel in the image. Each pixel then is represented with one number that specifies which color in the palette is to be used for that pixel. All this is done automatically in one step by the Image - Convert To dialog when it converts an RGB image to a palette image.

*For programmers:* Palette images have one byte per pixel where the byte is an index into the palette. The palette is just a look-up table that says what RGB value is to be used for that pixel. That is why Adobe PhotoShop refers to such images as "Indexed Color" images.

Let's take a look at how the example 32-color bronze image might be saved as a palette image.

The pixels in the region enclosed in red in the illustration would be coded as one number per pixel:

<table>
<thead>
<tr>
<th>6</th>
<th>8</th>
<th>15</th>
<th>16</th>
<th>16</th>
<th>16</th>
</tr>
</thead>
<tbody>
<tr>
<td>7</td>
<td>9</td>
<td>15</td>
<td>16</td>
<td>16</td>
<td>16</td>
</tr>
<tr>
<td>6</td>
<td>8</td>
<td>15</td>
<td>16</td>
<td>16</td>
<td>16</td>
</tr>
<tr>
<td>3</td>
<td>7</td>
<td>15</td>
<td>16</td>
<td>16</td>
<td>16</td>
</tr>
</tbody>
</table>

The number for each pixel says which color in the palette to use for that number. To figure out what color the number 16 in red shown above is supposed to be, we look at the palette used for this image:
All the colors used in this image are listed in the palette.

The look-up process is simple: the number 16 takes us to the sixteenth color in the palette, which is a shade of blue specified by the RGB triplet of numbers 91, 143, 207. These three numbers will be used to control the RGB pixel elements in the computer monitor for that specific pixel.

Note that the pixel to the right of the one shown in red has the value 18, which is a lighter shade of blue, the eighteenth color in the palette, two slots over from 16.

A Useful Analogy

If the above sounds confusing, perhaps a Liberal Arts analogy will help. Many people during their childhood have had exposure to "paint by numbers" kits. These kits provide white drawing boards that are covered with faint lines denoting regions that are to be filled with paint. Each region has a number in it. The numbers correspond to a collection of paint colors that are provided with the kit. Each color has a number. The child's task is to paint each region with the color paint corresponding to the number in that region. For example, all number 5 regions should be colored using paint from the number 5 container, which might be red. If done carefully the result will be a reasonable picture.

In classical artistic circles, the word "palette" means the board with colors on it that a painter holds in his or her hand. The painter chooses colors from the palette to load onto a brush that applies those colors to the canvas. Some painters in art history had a preference for using a particular selection of colors on their palettes and so the word "palette" in art history has also come to mean a particular collection of colors favored by a painter. One can speak of the distinctive palette of Cézanne, for example, or one might compare the sepia palette used by Van Gogh in his early work with the vivid palette he employed late in life in Arles.

In a paint-by-numbers kit the palette is the numbered set of paint colors. Palette images in computers are like the drawing boards in a paint-by-numbers kit where the number at each spot says which dab of paint to apply at that spot. It's obviously a lot more economical to code each spot with a single number than to write out "Ocher Brown" at one spot and "Goldenrod Yellow" at another.

The analogy is even more useful if we recall another childhood incident we may have experienced or heard about. Suppose in the coloring-in of our paint-by-numbers kit we get confused and think that the number 5 means to paint in a blue color and not the red color. The result will be that throughout the entire image we have switched the palette color for red with blue. In Manifold, such changes in palette colors are something that may be deliberately done with palette images in order to achieve desired color effects.

Images and their Palettes
Each image that is a palette image will have an associated palette that it uses. The project pane will show each palette underneath the image it serves.

Note that a logical outcome of the palette method for images is that for photographic or visual rendering the palette used with each particular image is specific to that image. The particular set of 256 colors that does the best job of approximating colors in one RGB image will not be the same as the 256 colors used to best approximate a different image.

For example, the sample *bronze* image is mostly greens and blues so the 32-color palette for this image shown above has many different shades of green and blue.

The sample image of *tokyo* airport, on the other hand, would use an entirely different palette that has many shades of near-black color when reduced to 32 colors.

**Changing Palettes**

Most graphics editors either do not show palettes that are used by palette images or they bury access to the palette deep within specialized menus. They do this because it is rare that one changes the palette in a photographic image that is only intended to provide a good visual appearance to the human eye. Images in a GIS environment are often used for other purposes besides providing a natural, photographic view of a scene. We will want to change palettes sometimes for such other purposes. Manifold System therefore provides the palettes used with images as separate components immediately at hand in the project pane.

We may wish to change palettes to achieve sophisticated image effects with visual images or to better represent data that is shown as a raster data image using a palette. Raster data images, for instance, are often created from multi-channel satellite images using “false” color to show data in the satellite scans. The colors used in a palette for such images might be arbitrary choices intended to show data in some range. For example, a palette image might show temperatures at particular locations using a palette where the colors range from blue to green to yellow to orange to red to show an increasing temperature range.

When working with such images in a GIS environment Manifold makes it easy to pop open the palette used in a palette window if changes to the palette colors are desired. For example, one might wish to change the colors in the temperature range palette so that the very coldest colors are all blues and the very hottest values are all reds with nothing but one shade of gray in between. To do this we would select all the colors between red and blue in the palette and change them to gray. All pixels in the image that were colored using those palette colors would instantly switch to gray. It's just like changing the paint containers in a paint-by-numbers kit.
Double click on a palette component to open it in a palette window. Make any changes by clicking into the color wells for individual colors and changing the colors. All standard Manifold selection methods will work when selecting colors in the palette window. See the Editing Palettes topic for an example.

Any changes made to a palette will immediately be applied to the image that uses that palette.

**Palette Sizes and Image Sizes**

Using a palette involves adding about 1000 bytes to the image size to save the palette lookup table (256 palette positions having three numbers each adds up to 768 bytes). For images that are thousands or millions of bytes in RGB form that is a big economy because investing 1000 bytes into a palette cuts the image size down by two-thirds at least. Some image formats using palettes can compress the image size even further if the image is exported into those formats.

Manifold palettes are always 256 color palettes. Images may be adjusted so they use fewer than 256 colors out of the palette. The main reason for using fewer than 256 colors is to simplify data management when using palettes with false color raster data images. It’s easier to assign different colors if there are only 8 colors, say, in our range of temperatures for a raster data image than if we need to assign 256 colors for different temperatures.

Although there is no savings in image space used within the Manifold project if an image uses fewer than 256 colors, using fewer colors may result in space savings if the image is exported to certain formats. Some graphics formats, such as GIF, will automatically compress the image to a smaller size if the number of color changes is fewer. Keeping the size of the image as small as possible is important when creating images for use on web sites, where every byte of the image must be flung down a potentially very slow Internet connection.

Using as few colors as possible will give the web image format used the best chance of compressing the picture when it is exported for use as a web image. Another way of keeping images as small as possible for web use is to use a standard palette, such as the standard web browser palette.

**Standard Palettes**

The use of palette images is so widespread that operating systems and web browsers are set up to exploit their use.

Although using a palette always provides big savings in space with large images, when images are very small the thousand bytes required for the palette becomes a significant percentage of the total size of the image. For example, one thousand extra bytes are a lot of bytes if the image itself is only a 32 x 32 icon (1024 bytes). In an operating system where numerous small images may occur it would be very inefficient if each small image had to carry its own palette around with it. To avoid this inefficiency Microsoft Windows includes a standard palette that is built into the operating system. Images that use the standard palette don't have to include a copy of their palette. They simply use the operating system palette.

Many web pages include numerous small images used as buttons or other graphical elements. If each used a unique palette, the size of such images could effectively double. To economize on download bandwidth all Internet web browsers include the same, standard palette for use by web pages. Using the standard web palette for small images destined for a web site will often reduce their size. Unfortunately, since the first web browsers were designed by people who were oblivious to the interests of the general computing public a different palette is used in web browsers than that made standard by Windows.

Both the web palette and the Windows palette incorporate a selection of colors that will work reasonably well for most images. Neither will work quite as well as a palette adapted specifically to a particular image but both will often work well enough for operating system or web use. Manifold's Image - Convert To dialog for creating palette images provides a list box that allows choice of a standard palette if one is desired. If a standard palette is selected the image will automatically be converted using only those colors that are in the palette selected. Standard palettes include both Windows and web palettes. For those with a sense of humor there is even an option to use the Mac system palette.

**Importing / Exporting Palette Images**

Some graphics image formats use palettes and some do not. When importing an image from a format that uses palettes Manifold will automatically import and create a palette component for the image.
When exporting to a format that uses palettes Manifold will combine the image and palette components in the correct way for storage within that format. The palette used with each image is embedded within the image file for all standard graphics formats that use palettes.

Creating a Palette Image

Palette images and their palettes are created automatically when importing from a graphics format that uses palettes. Palette images may also be created by converting from grayscale, RGB or RGBA images.

Use the Image - Convert To dialog to convert an image into a palette image. A choice of conversion methods and standard palettes will appear in the Palettes list box.

When to Use and Not to Use Palettes

It is important to understand that converting an RGB image into a palette is a permanent change in the data of the image. An image that formerly could have consisted of as many different colors as there are pixels in the image (up to a total of about 16 million different colors) will be simplified into using only 256 colors.

Reducing an image to only 256 colors will often result in negligible change in visual appearance. However, certain finely detailed images will lose vividness and may get a granular appearance in regions of smooth color gradient changes. If images must retain as much visual quality as possible it is best not to convert them to palette images. Images destined for enlargement or professional printing should never be converted.

Not all image commands will work in palette images. For example, Hue / Saturation depends on having three RGB channels for fine control of shades and will not work in one channel images such as palette images.

When creating complex images using RGBA transparency and other sophisticated effects all editing should be done using RGB or RGBA images. Only after the final image is ready should one consider converting it to a palette image and then only if it is destined for publication on the web. In an era of very inexpensive disk drives that deliver many tens of gigabytes of storage it is more important to keep visual quality high in photographic images than it is to save disk space.

Many raster data images in the mapping world originated as raster data sets in circumstances where each pixel's data had some scientific importance. Despite their technical origin such raster images often end up being used in a purely visual way where the specific data attached to each pixel is no longer important. Such images in their original raster data form can be enormous, with sizes in the hundreds of megabytes. It's a good idea to convert such images to palette images to save space and to increase system performance.

However, if the multi-channel data for each pixel continues to be important for some analytic purpose they should not be converted since doing so will destroy the data.

Notes

The above examples are written as if the "original" images use 16 million colors and the palette images are 32 colors. In fact, all images that appear in this Help file have been reduced to at most 256 colors due to limitations of the Windows Help system. Using 256 colors to represent the "16 million-color" images nonetheless results in such a good effect that we still had to use 32 color examples for palettes in order for the effects of conversion to be obvious.

The numbers in the palette example were made up by glancing at the image and estimating what the numbers should look like inside the image. They show the idea and relationships correctly but should not be taken as the exact numbers that will appear when the *bronze* image is converted into a 32-color palette image.
Images and Surfaces

Surfaces are data sets that may be visualized in 2D or 3D. They often provide terrain elevation data so that the heights of a given region may be seen in 3D. Although surfaces are imported from a variety of formats, once imported into a Manifold project they have many operations in common with images.

When a surface is opened in a surface window or appears as a layer in a map, the appearance of the surface is controlled by options in the View - Display Options dialog. By default, the surface appears as a grayscale image with color-coded by elevation.

Note that although surfaces appear in windows like images and share many commands that may also be applied to images, they are not images. The appearance of the data within the surface window is controlled by the display options, some of which (such as slope or aspect) may involve computation. In contrast, the appearance of images within an image window is "hard wired" by the color values of the pixels.

If desired, a surface may be converted into an image by copying the surface and pasting it as an image. In that case, the colors in the image pixels will be taken from the display options currently set for the surface. We might wish to convert a surface to an image to allow manipulation of the image for presentation purposes. Another way to make an image from a surface is to open the surface and then use the Tools - Make Image command.

We may also convert an image to a surface by copying the image and pasting it as a surface. The Paste as Surface dialog will appear when pasting that provides options for how the image data should be used to create a surface. Images that represent raster data such as elevations, temperatures and other factors are often very interesting to visualize as surfaces.

Linked Images from Image Servers

Linked Images from Manifold Image Servers

A recent development on the Internet is the emergence of a new class of image servers, which are web sites or web services that provide geographic images to users or programs seeking an image displaying a particular geographic region on Earth. Sites like TerraServer, Google Maps, Google Earth, Microsoft Virtual Earth, Yahoo! Maps and many more provide on-demand viewing of a variety of geographic images. Manifold can work with images from such servers if drivers are written that conform to a set of commonly-occurring interface standards expressed within the Manifold Image Server Interface API.

Depending upon the content provided by the server, such images can be:

- **Satellite or Aerial Imagery** - Photographic images that show a particular region as seen from above. Examples include TerraServer and Microsoft Virtual Earth.
- **Street Map Imagery** - Images that show a raster rendering of what would otherwise be presented as a vector drawing, as if someone made a screenshot of a drawing or vector map in a GIS system. The Microsoft Virtual Earth web service provides such images. Some image servers can present street map imagery with the "white space" made transparent. These displays are convenient to use as layers above satellite imagery layers so that street annotations can be seen over the satellite photos.
- **Other Images** - Images that show shaded-relief surfaces, renderings of CAD drawings (like a screen shot of a CAD drawing) and other content. Examples include images served by Manifold System web services.
Although the interfaces to such image servers vary in the details, in general they tend to have such similar capabilities that it is possible to use a more or less standardized dialog to link images from such servers. Manifold provides a standard Image Server Interface (ISI) that can be used to write an ISI driver for an image server so that it may be used from the standard Manifold image server dialog.

Image servers supported by an ISI driver are called Manifold Image Servers. ISI drivers can be either built into Manifold System or can be loaded as external add-ins. In either case, if an ISI driver exists within Manifold then access to the supported image server will appear to be a built-in Manifold capability whether or not the ISI driver was installed as an add-on or was built into Manifold itself.

By default, there are two Manifold Image Servers supported with ISI drivers:

- TerraServer - An ISI driver built into Manifold allows linking images from a variety of TerraServer themes.
- Manifold IMS Web Sites - A built-in ISI driver allows linking images from an IMS web site created using Manifold System if that web site was created with the IMS option to create an image server page. Note that using Manifold IMS to serve images in this way is a slightly different technology than the default IMS server and is in addition to Manifold's ability to function as an Internet Map Server or as an OGC WMS server.

In addition to the above two built-in ISI drivers, there are many other drivers created by third parties and distributed as open source projects, for example:

- Google Maps - An open-source ISI driver that allows using Google Maps as a Manifold Image Server to provide images of street maps. Must be installed.
- Google Earth - An open-source ISI driver that allows using Google Earth as a Manifold Image Server to provide satellite images and overhead aerial photographic images. Must be installed.
- Virtual Earth Street Map Image - An open-source ISI driver that may be downloaded from numerous sources on the web allows using Microsoft Virtual Earth as a Manifold Image Server to provide images of street maps. Must be installed.
- Virtual Earth Satellite Image - An open-source ISI driver that may be downloaded from numerous sources on the web allows using Microsoft Virtual Earth as a Manifold Image Server to provide satellite images and overhead aerial photographic images. Must be installed.
- Yahoo! Maps Street Map Image - An open-source ISI driver that may be downloaded from numerous sources on the web allows using Yahoo! Maps as a Manifold Image Server to provide images of street maps. Must be installed.
- NearMap - A super high quality image server providing satellite and street views, primarily in Australia.
- OpenStreetMaps image servers - Open source, open content street data presented by renderers such as CloudMade and others.

All of the above image servers must be installed. They are easy to download from the manifold.net image servers page (find it by drilling down through the Product Downloads page), except for the Google servers which are not distributed by manifold.net but which must be downloaded from other web sites.

Many image server providers will provide both satellite views and street map views. For example, the Microsoft Virtual Earth open source project provides access to both images of street maps and also of satellite imagery. manifold.net encourages all Manifold users to employ Microsoft Virtual Earth in preference to Google image servers. See the Linked Images from Google Servers topic for reasons why.

ISI drivers created by third parties are not supported by Manifold tech support. Such modules are often open source projects with full source code available so that communities of users can support each other and make whatever modifications are desired. Users often discuss such open source projects in the usual open source web sites or on Manifold user community forums.

Developers wishing to create ISI drivers for other image servers can study the open source code for existing image server modules (downloadable from the manifold.net web page) to learn how to create such drivers. Source code for such open source projects is available in the usual web sites serving the open source community. An ISI driver is, in effect an alternative browser that can connect to image server sites and provide a bridge for applications like Manifold to use the resulting imagery.
All Manifold Image Servers supported by ISI drivers will automatically fetch images to tile a particular region of interest as indicated either by the context of whatever component had the focus when the File - Link - Image dialog was launched or by manual specification of latitude and longitude extents, which can be a global extent if desired. Manifold Image Servers also normally allow a choice of resolutions and image levels to be downloaded if a linked image is to be converted into a static image within the project. The image linking dialog for all image servers using ISI drivers is virtually the same.

Very important: Before using an image server you must install the image server module for the image server you wish to use in your Manifold System installation. See the instructions below.

To create a linked image from a Manifold Image Server:

1. Image server modules will normally link worldwide coverage by default. If you want the image server to show only the region covered by a specific drawing or other component, open a drawing or other component showing the region to be covered by the image fetched from the server. Although we can specify the whole world or manually specify the latitude and longitude extents to be covered by the image, it is sometimes desired to let Manifold automatically restrict the view fetched to the extents of a given component. If you want to do that, open the component in a window and pan and zoom it to the region you want linked from the image server.
2. Choose File - Link - Image
3. In the Link dialog’s Files of type box choose Manifold Image Servers ()
4. In the resulting dialog, the Server box lists all Manifold Image Servers for which ISI drivers have been added to the system, plus the built-in setting for Manifold IMS Web Site. The built-in ISI-supported option of TerraServer will not appear in this dialog as it is accessed through its own Files of type choice. If you have installed any additional ISI drivers, such as those for Microsoft Virtual Earth, these will appear in the dialog. Choose the type of image server desired, for example, Virtual Earth Street Map Image.
5. Enter a URL to use for the connection (required for some servers, such as Manifold IMS web sites) or use the default URL provided (in the case of Virtual Earth or similar). To use a URL other than the default, click the Use custom server URL and enter the desired URL and then press the Refresh button. Some image servers, like those often provided for use with CloudMade allow you to change the formatting of the images based upon small changes in the URL, so you would click the Use custom server URL and enter the desired URL for those.
6. Specify the desired image Scale. Most people will use the default, which is usually the highest resolution available for that image server.
7. Choose the latitude and longitude extents to be covered by the image. To automatically get a worldwide image, press the Global button. If a component was open when File - Link - Image dialog was launched you can press the Window button to load the Longitude and Latitude range boxes with the correct latitude and longitude ranges to cover the opened component. If we would like to manually specify the latitude and longitude extents of the image we can do so.
8. Press the Refresh button next to the URL box. When the Refresh button is pressed, Manifold will establish a connection with the image server. This is normally quite fast, but may take tens of seconds or even longer. When the connection is established the OK button will be enabled. Press OK.
9. An image using a linked image icon will appear in the project. This image can now be opened and used like other images, except that images linked from image servers are read-only and cannot be re-projected.

When an image is linked from an image server, until the image is completely fetched, it will appear in an image window as a partially transparent gray rectangle covering the extents of the image. If the image is used as a layer in a map, it will appear in transparent color in those parts not yet fetched as tiles from the image server.

Images linked via the image server interface will use whatever coordinate system (projection) is returned by the image server module in use. If an invalid coordinate system is returned when linking an image Manifold will use the default coordinate system.

See the specific topics on liking images from the various ISI servers for details on using the linked image dialog with those servers.

Typical Link Image Server Dialog Controls

Manifold image servers will usually use a dialog with the following controls.
The server for the type of image desired. Different servers offer a variety of choices, such as different resolutions or color vs. grayscale images.

Use custom server URL
Specify the URL to use for the image server. If checked, enables specification of a custom URL in the Server box. This allows a change of URL if the image server moves from the default URL.

URL
URL to be used to connect to the image server. Enabled if the Use custom server URL box is checked.

Refresh - Establish connection to the image server.

Scale
Desired scale of the image. Some image servers provide a choice of different scales. Choosing 10m (ten meters) will result in a smaller image with fewer pixels than an image obtained by choosing 1m (one meter).

Longitude / Latitude
Longitude and Latitude extents of the image to be linked. Pre-loaded with values for worldwide coverage, like pressing the Global button by default.

Global
Press this button to automatically load the Longitude and Latitude boxes with values from minus to plus 180 degrees longitude and from minus to plus 85 degrees latitude. This provides worldwide coverage, with the most extreme Northern and Southern five degrees clipped to avoid problems with some third party image server modules which have problems very near the North or South pole.

Window
Press this button to automatically load the Longitude and Latitude boxes with values that cover the extents of whatever open component has the focus when the dialog is launched.

Cache data between sessions
Controls whether the cache folder used to cache image tiles retains its content between different sessions of Manifold or not. By default, the option is turned on. The cache folder is whatever location is set for Data Cache in the Tools - Options - File Locations dialog.

Proxy
Calls up the Tools - Options - Proxy server dialog that allows configuration of a proxy server connection, if a proxy server is used to connect to the Internet. Passwords supplied for proxy servers will be stored in encrypted form.

The Manifold Image Server Interface (ISI)

Manifold’s Image Server Interface (ISI) is an open standard published by manifold.net to make it easy for third party developers to create drivers that connect image servers to Manifold System. Image servers that can work with Manifold System using an ISI driver are called Manifold Image Servers and can be automatically accessed as if they were a built-in part of Manifold System using the File - Link - Image dialog.

See the Image Server Interface topic for a description of the interface. Programmers should also visit the manifold.net website for any supplemental documentation or example implementations, if any are made available in the future.

Third party developers creating image servers are strongly urged to craft an interface that, like those used by TerraServer, Microsoft and Yahoo!, is easy to support with an ISI driver. That will enable Manifold users to work with your image server from within Manifold System GIS projects. Using ISI provides maximum speed just as if your connection to the image server was built into Manifold’s own internal code.
To write a new ISI driver for your image server, see the open source projects for the ISI drivers for the existing image servers. These ISI drivers provide the open source community with a rich, practical example of how to write an ISI driver for a real-world image server. See the usual open source sites for access to the ISI drivers for Manifold image servers.

Creating ISI drivers for image services as an open source project also has the benefit that if these web sites change interfaces then the open source community can alter the ISI drivers without having to wait for some vendor, such as manifold.net, to issue a new release of software. This enables innovative companies like the image server providers to keep innovating while the open source community can continue working within open standards to support those innovations.

**Typical Image Server Driver Installation**

A typical image server driver installation package consists of a zip file that contains one or more .dll files. The file should be unzipped and the resultant .dll files should be copied into the Manifold System installation folder. When Manifold is launched it will detect the new .dll files and will add the supported to the image server dialog choices.

The default Manifold System installation folder is C:\Program Files\Manifold System. If you are operating a 64-bit Manifold installation in 64-bit Windows or a 32-bit Manifold installation in a 64-bit Windows system there will also be a second Manifold System installation folder at C:\Program Files (x86)\Manifold System. In that case, the .dll files for image server modules should be placed in both the C:\Program Files\Manifold System and also in the C:\Program Files (x86)\Manifold System installation folders.

After installation the .dll files will appear as seen in the above screenshot, showing how image server files for Google, Yahoo! and Microsoft Virtual Earth have been added to the default image server .dll files installed with Manifold.

**Projections and Linked Images from Image Servers**

Most image servers serve images using Mercator projection or a projection derived from Mercator. Images linked from image servers cannot be re-projected so if they appear as a layer in a map the map must use the same projection as the image. This is easy to guarantee by always creating a map component from the image linked from an image server.

Never create the map first and then drag and drop the image into the map. Instead, always right click on the image server image in the Project pane and then choose Create - Map in the context menu to create the map from the image server image. That will guarantee that the map is created using the same projection as the image server image. You can then drag and drop other components, like drawings, as layers into the map.

Although most image servers use Mercator projection, not all do, or some use a projection incompatible with Mercator. Image servers which use different projections cannot be used together as layers in a map, because if the map is created using the projection of one of the image servers the other image server image cannot be shown in that map. Therefore, although images linked from most image servers can appear together as layers in a map some might not be useable in that way.

Smaller images (limited by the Window button to smaller regions and thus smaller sizes) can be unlinked and then used as ordinary, local, unlinked images. Those may be re-projected into any projection desired. Very patient users can use this process to create remarkably large images if they have the free memory and disk space on their computers. For example, early research for the next generation of Manifold products used images 20 GB in size that were created in Release 8.00 by unlinking images originally linked from image servers.

Manifold provides a special datum for use by ISI driver writers, the **WGS84 Auto** datum. This is equivalent to the **WGS 84** datum used by Google and also used by Virtual Earth and Yahoo! Maps.

**Exporting Image Server Images**
An image linked from an image server may be exported to a file using the **File - Export - Image** command. The image linked from Virtual Earth will be exported as a single image using the specified image format.

If you have Enterprise Edition installed, an image linked from an image server can be shared to an Enterprise Server.

**Unlinking Image Server Images**

An image linked from an image server may be transformed into an ordinary image by right clicking the image linked from the image server in the project pane and choosing **Unlink**.

**Caution:** Images linked from an image server can be enormous and be far larger than can fit into either free disk available or memory on your computer. Think carefully about the size of image being unlinked, as it is very easy to carelessly ask for an image that is 0.3 meter in scale that covers such a large area that the resultant image requires terabytes of memory. Don't try this with a worldwide image linked from an image server. Instead, link an image using the **Window** button to constrain the image to a small, manageable extent and then convert, unlink or download it.

**Converting Image Server Images**

Another way to convert an image linked from an image server into an ordinary image is to open the image linked from the image server in a window and then choosing **Image - Convert**. Converting an image linked from an image server creates a local image in the project of the desired type, being equivalent to first unlinking it and then converting the new local image into an image of the desired type.

**Image Download**

The **Download** command appears when the focus is on a window for an image linked from an image server. The command allows automatic download of all tiles available for the image at any level of resolution available. Tiles will be assembled into a single image at each resolution level selected.

See the **Image - Download** topic for details.

**Notes**

Most users of image servers will work with global settings. Hard disk capacity is inexpensive so using the cache option (on by default) will build up a collection of local tiles for that image server that will be recycled by any project that uses those tiles. That leads to faster performance since tiles already fetched don't need to be re-fetched through Internet. Even if you have a fast Internet connection the image server you may be using is probably not as fast as access to your local hard disk.

Limiting extents using the **Window** button to only the extent of some previously opened component can be useful but it can also be frustrating if you want to pan the image server to a slightly larger view that wasn't part of the originally defined extent. No massive amount of detailed tiles will get fetched if you don't actually zoom in to a particular region, so there's no harm in working with **Global** extents. Because image servers use pyramided imagery only a very small amount of image pixels are involved in getting worldwide views when zoomed out.

Usually the main reason someone wants to work with a **Window** limitation is to have a view that's already zoomed in to a particular image server where navigation down to the desired small region from a global view would be tiresome. For example, suppose we have a drawing that shows a development of twenty houses in a small town and that is all we are interested in. We would normally zoom out the drawing a bit to provide some extra room on the margins and then link an image server using the **Window** button to restrict the image server linked image to only the view shown in the drawing. If we pop open the image server linked image right away we see that it is zoomed into the small region of the housing development. No need to zoom in from a global view.

We can then create a **map** component from the image server linked image and drag and drop the drawing as a layer into the map and see the two components together as layers in the map. Always create a map from the image server linked image to be sure that the projection of the map allows showing the image.

A project that uses an image linked from an image server may be saved within **.map** project file just like any other project. However, keep in mind if sending that **.map** file to someone else they also will need to have installed on
their machine the required image server module (if it is not one of the built-in image servers) to view the linked image. Loading a .map file with an image linked from a Manifold image server that is not installed on the system will report the problem and the name of the missing image server in the History pane.

**Cautions**

It is easy to think that we can avoid the effort of creating cool maps for all purposes by simply downloading them using an image server choice in the Server box. Although the use of image servers is indisputably convenient, the use of large raster images downloaded from the web is far from being a universal replacement for informed use of vector drawings.

Linking an image from an image server **does not** create a vector drawing, but instead links an image that shows a rasterized view of a nicely-formatted vector map. It can be a very bad idea to attempt to replace a vector drawing with an image of a vector drawing, as the image, if unlinked, may require hundreds of times as much storage space (or if not unlinked, bandwidth) as the equivalent vector map. Image servers may have licensing restrictions, and they may not be available when you want them.

For these reasons, no matter how convenient we find image servers for some purposes we should remember that image servers are not usually an efficient way of getting information into local storage for a GIS project. A better alternative can be to find a drawing that shows the same information (usually easy in the US) and then format it in a pretty way. The result will be a far smaller, more accurate data set that loads and displays much faster and which we entirely control.

On the other hand, using image servers to acquire satellite imagery and street map images for a particular region is often a very good idea, especially outside of the US where vector drawings may be extremely difficult to obtain. In many parts of the world the only way to get a good vector map is to trace it yourself from an image server image in Manifold.

Linked Images from Manifold IMS Web Sites

Manifold can link images into a project using imagery streamed from a Manifold Internet Map Server (IMS) web site operated as an image server. The images so obtained will be the same as would be displayed for the requested location and zoom in an IMS web site.

This topic assumes the reader is familiar with creating Manifold IMS web sites.

To create a Manifold IMS web site for use with image server clients:

1. Create a Manifold IMS page in the usual way using the File - Export - Web Page dialog. In that dialog, make sure to check the Include Manifold Image Server interface page box.
2. This will create an imageserver.asp page within the web site.

To create a linked image from a Manifold IMS web site:

1. Open a drawing or other component showing the region to be covered by the image fetched from the server. Although we can specify manually the latitude and longitude extents to be covered by the image, it is most convenient to let Manifold do so automatically based upon the extents of the opened component.
2. Choose File - Link - Image.
3. In the Link dialog's Files of type box choose Manifold Image Servers.
4. In the resulting dialog, the Server box lists all Manifold Image Servers for which ISI drivers have been added to the system, plus the built-in setting for Manifold IMS Web Site. The built-in ISI-supported option of TerraServer will not appear in this dialog as it is accessed through its own Files of type choice. If you have installed any additional ISI drivers, such as those for Google Maps or Google Earth, these will appear in the dialog. Choose Manifold IMS Web Site as the type of image server desired.
5. Enter the URL for the Manifold IMS web site's image server .asp page, for example, something such as http://www.mysite.com/imageServer.asp and press the Refresh button to connect to that URL. [The example URL given in this step is just a made-up example: use whatever is the actual URL for the site you wish to access.]
6. When the Refresh button is pressed, Manifold will establish a connection with the Manifold server. This is normally quite fast, but may take tens of seconds or even longer. When the connection is established the OK button will be enabled and the size of the image at the requested Scale and Longitude and Latitude range will be reported in the number of pixels. To get a larger or smaller image, change the Scale value and press the Refresh button again.
7. If desired, choose the latitude and longitude extents to be covered by the image. If a component was open when File - Link - Image dialog was launched the Longitude and Latitude range boxes will be pre-loaded with the correct latitude and longitude ranges to cover the opened component. If no component was open or if we would like to manually specify the latitude and longitude extents of the image we can do so. Press OK.
8. An image using a linked image icon will appear in the project. Highlighting the image in the project pane will report it as an Manifold image in the status bar. This image can now be opened and used like other images. Manifold IMS web site image server images are read-only and cannot be re-projected. Until the image is completely fetched, it will appear in an image window as a partially transparent gray rectangle covering the extents of the image. If the image is used as a layer in a map, it will appear in transparent color in those parts not yet fetched as tiles from the Manifold server.

Logotype

If the "Powered by manifold.net" logo is turned on in the IMS web site, then each image will be stamped with that logo. Enterprise Edition or higher Manifold edition must be used to turn off the logo.

Linked Images from TerraServer
**Linked Images from Google Servers**

Google provides web services that allow download of images showing maps like those in Google Maps and satellite images like those seen in Google Earth. Both images showing maps and images showing satellite images are often referred to as Google Maps data even though the satellite images are normally viewed within the Google Earth browser.

Manifold can link images from Google image servers if we have an Image Server Interface (ISI) driver to use the Google servers as Manifold Image Servers installed on our machine. See the Linked Images from Manifold Image Servers topic for information on the image server interface.

**Manifold.net** does not distribute image server modules for Google; however, many third parties do. A quick web crawl is usually all it takes to locate a Manifold image server module that conforms to the Manifold ISI standard and works with Google servers. For maximum irony, use Google to search the web to find image server modules for Google. If you want to be mean to Google, use Bing.

**Note**

**manifold.net** encourages all Manifold users to employ Yahoo!, Microsoft Virtual Earth, CloudMade, Yandex or NearMap in preference to Google image servers.

There are many important reasons why using Microsoft Virtual Earth ISI modules is a better idea than using Google Earth ISI modules:

- Manifold users who have experience with Google ISI connections have complained that Google has an undocumented "throttle" of some sorts that limits access to Google servers if people actively use the connection. Microsoft Virtual Earth has no such throttle and encourages use.
- Users with experience of Google ISI drivers complain that Google-sourced imagery sometimes is stamped with annoying "watermarks" that say "Google" over the image. Microsoft Virtual Earth does not disfigure the imagery it provides.
- Microsoft Virtual Earth imagery appears much smoother than Google imagery at large scales, without the annoying "mosaic" tile effects often seen in Google imagery at large scales.
- In some cases, Microsoft Virtual Earth imagery is more detailed at local scales than Google imagery.
- Microsoft provides an extraordinary range of developer-friendly programs to assist the use of Virtual Earth, either using Microsoft APIs or using open source connections unregulated by Microsoft.
- Google has attempted to impede developers providing open source connections to public Google web services. Microsoft has supported and encouraged such developers. Understanding and applying Google's restrictive legal positions for its API requires costly legal investigation, while Microsoft makes it very easy from a legal and business perspective to utilize Microsoft Virtual Earth.
- Numerous third party geographic browsers, like NASA World Wind, have connections to Virtual Earth while Google has tried to prevent competition from such browsers. Virtual Earth is therefore becoming the standard for geographic browsers.
- All Manifold development is aimed at Virtual Earth and Virtual Earth will be supported in future editions of Manifold directly by manifold.net. Google Earth is supported only by third party developers via open source projects that may or may not continue to be available with no development or technical support for such projects or modules by manifold.net. By georegistering your work to Virtual Earth you increase the likelihood that no adjustments will be required (in georegistration or otherwise) or that fewer adjustments will be required with future products from manifold.net.

For the above reasons, most experienced Manifold users working with ISI drivers have already switched to Microsoft Virtual Earth.

Other image servers popular with Manifold users include Yahoo! and newer entrants like CloudMade, which provide far greater control over display than Google. Yahoo! in particular is to be commended and supported for their very generous encouragement of the OpenStreetMaps project.

Linked Images from OGC WMS Servers

An OGC WMS server is one that can communicate using "Open" GIS Consortium Web Mapping Service (WMS) or similar communications specification. A WMS server produces an image of GIS data and streams the image to requesters. If the original data is vector data such as a drawing, the WMS server does not provide the drawing data, it only provides an image view of the data in some image form like a GIF or JPG.

Manifold is capable of linking images from WMS servers. Manifold will automatically negotiate with the WMS server to achieve a mutually understood level of the various WMS specifications that have been published. When operating as a WMS client Manifold will automatically correct several types of malformed URLs that may be returned by defective servers.

Manifold can also function as a WMS server as part of Manifold's Internet Map Server capabilities. See the Map Server Overview topic for additional information on running Manifold as a WMS Server.

WMS servers create an image at the desired size and then stream views of that image in tiles to the client depending upon the view position and the zoom desired. As we zoom farther into the image more tiles of greater detail are sent up to the limit of resolution implied by the specified size of the image. Note that the original choice of image size implies a limit of resolution per pixel implied by the extent of the original data divided by the number of pixels.

Manifold will cache image tiles streamed from an OGC WMS server so that panning and zooming in the image can be as fast as possible. For example, when zooming into an OGC WMS image Manifold will make use of less detailed image tiles that have already been fetched to quickly render the desired view as best as possible and then progressively update the display as more detailed tiles stream in.

Images linked from WMS servers are read-only images and cannot be re-projected. They can only participate in maps that use the same projection as the image, although they may be used in maps that have the same projection (coordinate system) except for the datum used. At any time, an image linked from a WMS server may be unlinked to create a local image that may be re-projected and otherwise altered as desired.

An image linked from an image server may be converted to a local image within the project either by using the Image - Unlink command or the Image - Download command. The Unlink command converts the existing linked image to a local image at whatever resolution is currently in use. The Download command may be used to automatically fetch all image tiles at any available resolution to create a local image at that resolution.

Images linked from a WMS server may also be exported to image files. In that case, the exported image will be the same as that which would be obtained by unlinking the WMS image.

Note that exporting or unlinking an image linked from a WMS server will only use the data already downloaded from the server and will not attempt to download any more data. It will also only use the data for the most detailed image level. It is usually a good idea to use Image - Download to check how much data has already been downloaded for the most detailed image level prior to exporting or unlinking the image.

If the connection is severed between a linked image in a project and the image server (such as, for example, if the project is moved to a different machine and a local URL must be changed to a global URL) the link to the image server may be re-established using the Image - Relink command.

Another way to create a local image from a linked image is to open the linked image and then to use the keyboard F6 command or the Tools - Make Image command. The Make Image dialog allows us to create a local image in several different ways from the linked image without unlinking the linked image. For example, we can use this command to create an image of the displayed window or of the entire linked image at a desired number of pixels or scale.

To create a linked image from an OGC WMS Server:

1. Choose File - Link - Image
2. In the Link dialog's Files of type box choose OGC WMS Servers
3. In the Link OGC WMS Data dialog enter a connection string for the Server and press the Refresh button in the dialog's toolbar.
4. When the Refresh button is pressed, Manifold will communicate with the WMS server to find out what layers are available. This can take a very long time, minutes at a time, in the case of slow WMS servers. When the catalog of layers (the "Capabilities" in WMS server jargon) has been fetched, it will be displayed in the Layers pane.
5. Specify the desired image **Size**, select the desired **Layers** and the desired **Style** for each layer and then press **OK**. Choosing more than one layer tells the WMS server to create an image that combines all selected layers into one image.

6. An image using a linked image icon will appear in the project pane using a name based on the name of the WMS server. Highlighting the image in the project pane will report it as an **OGC WMS** image in the status bar. This image can now be opened and used like other images. **OGC WMS** images are read-only. Until the image is completely fetched, it will appear in an image window as a partially transparent gray rectangle covering the extents of the image. If the image is used as a layer in a map, it will appear in transparent color in those parts not yet fetched as tiles from the WMS server.

**Link OGC WMS Data Dialog Controls**

- **Server**: URL to be used to connect to the WMS server. The **Server** combo remembers recently used WMS servers, including those used in earlier sessions of Manifold.

- **Size**: Desired size of the image. For maximum efficiency, use image sizes that are evenly dividable by the **Tile Size**.

- **Tile Size**: Size of tiles to use when fetching the image, ranging from **64 x 64** pixels to **1024 x 1024** pixels. Larger sizes take longer to download but use storage space more efficiently.

- **Refresh**: Update the **Layers** pane with layers available from the WMS server.

- **Select All**: Check all layers for retrieval.

- **Select None**: Uncheck all layers.

- **Select Inverse**: Uncheck all checked layers and check all unchecked layers. A fast way to retrieve all but one layer: click **Select None**, check the one layer not desired and then click **Select Inverse**.

- **Layers**: After the **Refresh** button is pressed, the **Layers** pane shows images available from the WMS server. The **Style** option chooses which optional style will be used.

- **Background color**: Controls the background color of the image. If the server can serve images in PNG, GIF or other format that retains invisible pixels, the option is turned off (but can be turned on). If the server cannot serve images in a format that retains invisible pixels, the option is turned on and cannot be turned off.

- **Cache data between sessions**: Controls whether the cache folder used to cache image tiles retains its content between different sessions of Manifold or not. By default, the option is turned on.

- **Link each layer as a separate image**: If unchecked (the default) all layers will be composed into a single image. If checked, all layers will be linked as separate images in the Manifold project. If the **Link OGC WMS Data** dialog is used to relink an existing image, the option is disabled (and turned off).

- **Proxy**: Calls up the Tools - Options - Proxy server dialog that allows configuration of a proxy server connection, if a proxy server is used to connect to the Internet. Passwords supplied for proxy servers will be stored in encrypted form.

Most WMS servers cannot provide a default image size, so the **Link OGC WMS Data** dialog provides a **Size** control to specify the desired size of the image. The larger the dimensions, the greater the resolution per pixel and thus the deeper we will be able to zoom into the image. The default dimensions are **4096 x 4096**, which is a good...
Images

A tradeoff between deepness of zoom and the amount of data which must be fetched from the server to display the entire image at high zoom.

Images are served by WMS servers as tiles. Tiles may range in size from $64 \times 64$ pixels to $1024 \times 1024$ pixels. The default setting of $256 \times 256$ is a good tradeoff between efficiency and flexibility.

Because images are fetched as tiles, the default dimensions for overall image size are slightly uneven ($4096$ instead of, say, $4000$) because the image is fetched in tiles that are $256 \times 256$. Dimensions of $4000 \times 4000$ would work, but would not be as efficient because the overall size dimensions are not evenly divisible by the tile size.

Layers displayed in the Layers pane are arranged according to their hierarchy on the server. Layers that contain no data and are used to group other layers (virtual layers) use gray checkboxes. Layers that contain real data (data layers) use black checkboxes. The total number of checked data layers is shown in the status readout below the layer tree.

User Names and Passwords

When connecting to some image servers, the URL given must include a user name and a password in the URL string. Manifold supports a common way of doing so using URLs in the form of:

```
http://user:password@host
```

For example, if our user name was johnbgood and our password was $3bart8tt2$ and the hostname for the image server was imagesupermarket.com, we could use a URL connection string of:

```
http://johnbgood:3bart8tt2@imagesupermarket.com
```

Note that the above style is just one popular way webmasters arrange to accept user login names and passwords as part of an image server URL. There are various other methods in use. If the image server we work with uses the above method we are in luck.

Layer Styles

Some WMS servers may offer to display a given layer using one or more optional styles within the synthesized image. If so, the Style cell for that layer will be a combo that allows choice.
For example, in the above illustration the Crosshairs layer has a variety of styles advertised by the server. We can change the style from the default red wire to blue wire if we like.

Not all layers will have a Style option. What styles are available for any given layer will be up to the WMS server providing the data, not Manifold.

**Fetching Image Tiles from a WMS Server**

Consider the following scenario: We link an image from a WMS server and a new linked image icon appears in the project pane. We open the image in a window zoomed to fit. Manifold will paint the area occupied by the image in semi-transparent gray and will start retrieving the image tiles required for the current view from the WMS server. As tiles are retrieved, Manifold will update the display.

Because image tile retrieval occurs in a background thread, we can continue doing other work as the image assembles from tiles retrieved from the WMS server. If the WMS server is fast and our Internet connection to the WMS server is fast, the image will assemble much faster than if the WMS server is slow or if our Internet connection is slow.

Suppose we zoom in to some region within the image, which we can do before all tiles have been fetched. Manifold will immediately begin retrieving tiles for the new view, which take priority over tiles in the old view. When Manifold retrieves all tiles in the new view, it will go back and continue retrieving any tiles in the old view that were not fetched when we zoomed in. Manifold does this so that the old view is ready for use just in case we decide to return to it later, say, by using View - Go Back. If we close the project file or delete the image the system will stop retrieving tiles from the server.

Tiles are retrieved one at a time, but tiles for several images can be retrieved simultaneously and more than one window containing an OGC WMS image can be open. The active window has elevated priority when rendering OGC WMS images in more than one open window. If we display an OGC WMS image in two windows (for example, in two maps), Manifold will first try to retrieve tiles for the active window, that is, the window that has the focus, and then for the window in the background.

Note that some WMS servers are run as advertising functions for the company providing the data shown in the images. WMS servers are often configured to mark each tile they send with a copyright text, a logo or some other
mark. If this is the case the mark will be repeated on each tile. Do not blame Manifold for this behavior as it is the WMS server that is disfiguring the tiles.

**Cache Files**

Manifold caches tile files retrieved from the WMS server so that panning or zooming to previously-viewed scenes does not require a re-fetch of previously retrieved tiles.

The **Cache data between sessions** option controls whether or not cached tile files will be retained in the cache folder between different sessions of Manifold. By default, the option is turned on.

The location of the cache folder is specified by the **Data Cache** item in **Tools - Options - File Locations**. The default value for the location is `%MyDocuments%`, so by default each user's files will be stored in the user's own cache folder. If we actually use the **My Documents** folder for other documents, we might not want to have many cache files appear in the same folder as various other working documents we use.

In that case, it is a good idea to create a folder within the **My Documents** folder, perhaps called **Cache** and then we can set the location for the data cache to `%MyDocuments%\Cache`. This will keep all of our WMS cached files in a separate folder so that we will not have to wade through long lists of cached files when working with other documents.

When multiple users are working it might make sense to modify the default **Data Cache** setting so the cache folder is on a shared resource available from all machines on the local network. For example, if there is a machine called **Storage** on our local network with a **Cache** folder on its **C**: drive, we might use a **Data Cache** setting of `\Storage\C\Cache` for all users. In that case, any tile files that are retrieved by one user will be available to all users so that tile files for a given view will never have to be fetched twice over the network.

Cache folders are organized as is as follows:

- Each combination of layers, styles and background color for a given URL is given a separate subfolder used to store PNG, GIF or other files containing individual image tiles.
- Names of tiles include the level and the XY coordinates of a tile.
- The overall dimensions of the image are in level 0. The dimensions in level 1 are half those of level 0, and so on.
- The subfolder containing the tiles also contains an XML file (currently named **RESOURCE.XML**) with the URL, layers, styles and background color used for the image.

**Caution:** Cache files persist forever and, in extreme cases, use up your free disk space unless they are manually deleted. See the recommended actions in the Managing Cache Files topic.

**WMS Version Negotiation**

Clicking **Refresh** the **Link OpenGIS WMS Data** dialog begins a negotiation with the WMS Server of the WMS protocol version to be used. Regrettably, the spastic approach used by OGC to design WMS has resulted in a plethora of irritatingly dissimilar WMS protocols that do pretty much the same thing. Manifold must negotiate with the WMS server to learn what protocol it uses. Manifold first tries to use the protocol version suggested by the WMS server. If the server refuses to suggest a WMS version or the version it suggests is not supported by Manifold, Manifold tries to use versions 1.3.0, 1.1.2, 1.1.1, 1.1.0 or 1.0.0. If the WMS server supports none of these versions, the connection fails. As the OGC bureaucracy dreams up yet more WMS variations, future versions and service packs of Manifold will add them to the roster of protocols to attempt.

The negotiation process initiated by clicking **Refresh** is done in a background thread to avoid locking the user interface.

Images linked from a WMS server will have their coordinate systems automatically adjusted by Manifold so the image has the same aspect in X and Y dimensions. This corrects images fetched from servers that do not conform to the WMS specification and thus distort the images they return (a surprisingly frequent problem).

**Projections and OGC WMS**
There is no standard way for an OGC WMS server to describe the coordinate systems (projections) it supports that covers all coordinate systems supported by Manifold. There are several semi-standard ways using schemas to describe the coordinate system used by a WMS server that cover various subsets of coordinate systems.

When used as an OGC WMS client, Manifold supports all schemas for describing coordinate systems that have been uncovered by manifold.net, no matter how many or how few OGC WMS servers that currently exist actually use them. Given the tendency of OGC to come up with new "standards" that are never used to any significant degree, it is always possible yet another schema may be introduced in the future that is not recognized by Manifold as an OGC WMS client; however, we feel confident that the current edition of Manifold when used as an OGC WMS client covers all such schemas either proposed or in actual use.

In contrast, when used as an OGC WMS server, Manifold only supports EPSG codes. EPSG is arguably both the richest and the most widely used schema within the OGC community. Manifold running as a WMS server only supports EPSG mostly to avoid confusing various non-Manifold WMS clients, some of which, unlike Manifold, cannot auto-adapt to a variety of coordinate system encoding schemas.

As rich as it is, the EPSG schema only supports a fraction of the coordinate systems that can be used in Manifold. If the coordinate system used by the component served by Manifold can not be expressed using the EPSG schema, that is, if it does not have an equivalent EPSG code, then the Manifold OGC WMS server reports the coordinate system as latitude / longitude and will re-project the data for that component on the fly into Latitude / Longitude. For large components that will have a terrible impact on performance.

Obviously, it is essential that any webmaster setting up a Manifold application as an OGC WMS server should check the projections used by the components being served and should make sure that they are coordinate systems that can be expressed using the EPSG schema.

The current list of coordinate systems which have EPSG codes may be obtained free of charge from the following link, clicking the link to the epsg-v69.zip or subsequently published file.:

http://www.epsg.org/CurrentDB.html

If all we are doing is using Manifold as an OGC WMS client we don't need to worry about the above because any schema used by the OGC WMS server we access as an image server will be recognized by Manifold.

**Most WMS Servers are Absurdly Slow**

In a perfect world, Internet connections to WMS servers will be very fast and images obtained from such servers will pop open with the click of a mouse. It may be possible to achieve such performance if the WMS server is an in-house machine serving private clients over a purely local network or over a private, high speed Intranet.

In the real world, WMS servers are often too slow to use for most practical purposes. There are two reasons for such incredible slowness: First, WMS servers tend to be very slow in their response to requests because, of course, like any popular site they are overloaded and the bureaucracies that run most of them tend to skimp on resources for public users. Second, it is almost a rule of nature that the Internet connection between our computer and the distant WMS server will be excruciatingly slow. Therefore, if we plan on using WMS servers we should get used to seeing semi-transparent gray images that get slowly assembled, tile by tile, into a final image.

Even if we have a fast link to Internet, such as a 6000/608 DSL connection, we must keep in mind that the rest of Internet and, in particular, the link to the WMS server can be very, very slow. With some slow servers it can take five minutes to fetch layers available once the Refresh button is pressed and then another five or ten minutes for an image to be populated. It only takes a few experiences with WMS servers to be very grateful that Manifold can download WMS image tiles in background while we continue on with other work.

Once the image has been fetched and browsed to whatever extents and zooms are needed then it will be saved in Manifold's cache. From then on, response will be fast as tiles are fetched from the local cache on our machine and not through an (incredibly slow) Internet connection.

**Notes**

A WMS server does not serve the original GIS data: it serves a snapshot of that data in the form of an image. To understand the difference, consider a map within a Manifold project that consists of a dozen layers, where each layer might be a drawing, surface or other component. At any time we can open the map and use the Tools - Make Image command to create an image from that map.
We can then open that image. However, the image we made from the map is not the map nor does it contain the vector data from that map. It's more like a screenshot. The image created and served by a WMS server is the same sort of image. It's just a "screenshot" at the resolution specified.

If the objective is to grab data that was originally in raster form, the use of WMS servers can be a very good idea and very useful. If the objective is to make authentic use of real data, then, unfortunately it is not such a good idea as raster images are very poor, at best partial replacements for bona fide vector data.

When used to serve images of vector data, the WMS server does not provide the original data to users in a form that is genuinely useful to GIS users. Instead, only a raster image representation of the original, true vector data is provided. Instead of getting access to the original data so the user can create his or her own maps, edit them, analyze them as they see fit and publish them as they would like, the user only gains access to that image view that the publisher deems appropriate to present.

When used in this way, WMS servers are therefore becoming popular with bureaucracies that would like to give the appearance of public access to data without actually providing any public access to the real data. This is a good example of how so-called "Open" GIS specifications are used in real life to assure "closed" systems and to enforce centralized control.

It is, of course, perfectly legitimate for private data owners not to want to publish the underlying data that is used to create WMS server images. We simply want to emphasize that publishing a WMS image is not the same as providing the underlying data, a distinction that many government WMS server sites fail to make.

There are many ways of using WMS servers. For example, Manifold itself can function as a WMS server. In theory, WMS servers can be a great way of creating background layers that can be varied, or to serve images or images of surfaces in a variety of applications. In the case of vector data, there's nothing wrong with using a WMS server to provide a handy source of images of that data (for people who do not have GIS capability). If desired, access to the underlying data can be assured by providing some means of easy download of the original vector data, such as an FTP or other link for downloads.

**OGC WMS Servers and ISI Drivers**

While most connections to image servers within Manifold (connections to TerraServer, Virtual Earth Maps, Virtual Earth Earth and Manifold Image Servers) are accomplished using Manifold Image Server Interface (ISI) drivers, the connection to OGC WMS servers does not use ISI drivers. OGC WMS servers are a standard unto their own and are sufficiently unlike other image servers (such as TerraServer or the Virtual Earth servers) that they cannot use ISI. Therefore, the internal Manifold connection to OGC WMS servers is specifically hard-wired for those servers.

**About ISI**

Manifold's Image Server Interface (ISI) is an open standard published by manifold.net to make it easy for third party developers to create drivers that connect image servers to Manifold System. Image servers that can work with Manifold System using an ISI driver are called Manifold Image Servers and can be automatically accessed as if they were a built-in part of Manifold System using the File - Link - Image dialog. See the Linked Images from Manifold Image Servers topic.

Linked Images from Oracle Servers

Manifold System Enterprise Edition and higher editions can link images into a project that are stored within Oracle Spatial databases or within standard Oracle databases using the GeoRaster facility. If you do not have at least Enterprise Edition installed, you will not be able to use the features described in this topic.

Oracle data sources using Oracle Spatial or that include GeoRaster capability (available in some other Oracle DBMS products) can store images as well as drawings. Manifold can import images or link images from an Oracle data source into the Manifold project. Manifold can import a variety of image types from Oracle data sources, including indexed (palette) images and images stored with channel interleaving.

Images are imported or linked from Oracle using the Database Console dialog.

To link an image from an Oracle server using the Database Console:

1. Launch the Database Console using Tools - Database Console.
2. Connect to the Oracle data source desired.
3. Browse the data source to locate the image desired.
4. Right click on the image and choose Link to link it or Import to import it.

The image will appear in the project pane as a linked image.

Oracle Data Source Dialog Controls

Server URL to be used to connect to the Oracle server.
User name User name, if required to login to the server.
Password Password, if required to login to the server.
Test Press to test the connection to the server.

Oracle Images and Projections

Oracle images are delivered by the Oracle server in a specified projection, which Manifold will maintain. As a practical matter they cannot be reprojected. To use such images in a map, create the map based upon the Oracle image so the map uses the same projection as the Oracle image. Alternatively, Unlink the image so it becomes a local image stored within the project. We can then do with it whatever we please.

Exporting Oracle Images

An image linked from Oracle may be exported to a file using the File - Export - Image command. The image linked from Oracle will be exported as a single image using the specified image format.

An image linked from Oracle can be shared to an Enterprise Server.

Unlinking Oracle Images

An image linked from Oracle may be transformed into an ordinary image by right clicking the image linked from Oracle in the project pane and choosing Unlink.

Converting Oracle Images

Another way to convert an image linked from Oracle into an ordinary image is to open the image linked from Oracle in a window and then choosing Image - Convert. Converting an image linked from Oracle creates a local image in the project of the desired type, being equivalent to first unlinking it and then converting the new local image into an image of the desired type.
**Linked Images and Channels**

Images linked from native Oracle data sources allow custom selection of which Oracle channels should be used for R, G and B channels via the **View - Display Options** dialog.

![Display Options Dialog](image)

By default the image will use **Channel 3** for **Red** color, **Channel 2** for **Green** color and **Channel 1** for **Blue** color. If we check the **Custom channels** box we can change these settings to whatever we like. We might wish to change channel assignments either to create a "false color" image or to adjust channels to their natural correspondence if an image was stored to Oracle using unusual channel / color assignments.

Linked Images from TerraServer

Manifold can automatically link images served by Microsoft's TerraServer image server. TerraServer is a free server operated by Microsoft Corporation that serves free aerial images and scanned USGS maps (DRGs) provided via a partnership with the U.S. Geologic Survey. At present, TerraServer provides images and raster maps for the United States, including Puerto Rico. See http://terraservice.net or http://www.terraserver-usa.com for details.

Important: The very cool Microsoft TerraServer should not be confused with the various non-Microsoft enterprises (such as terraserver.com) that have nothing to do Microsoft even though they have managed to obtain confusingly similar domain names.

TerraServer may be accessed either via an interactive web site visited by users, or as a web service to which applications like Manifold may connect to automatically fetch desired images.

- The Download and Mosaic TerraServer Images example topic shows how to work with images obtained using the interactive TerraServer website by hand and to manually assemble them into mosaics.
- This topic describes how to use the built-in Manifold capability of automatically downloading and combining images from TerraServer.

For most purposes, using the built-in Manifold ability to fetch and assemble TerraServer images is much more convenient than manually visiting the web site and then downloading and assembling images by hand.

Manifold can automatically access TerraServer to fetch desired images that cover a particular area of interest. When images are available for the area of interest, Manifold can automatically fetched the required TerraServer images and seamlessly mosaic them together into a single image.

If a component window is open and has the focus Manifold can automatically fetch and mosaic images from TerraServer to cover the region represented by that window (assuming, of course, the opened window is correctly georegistered and shows a region somewhere in the US). If a window is not open, we can still fetch images from TerraServer by specifying the desired latitude and longitude ranges of the region to be imaged.

To fetch an image from TerraServer, use the File - Link - Image command. In the Link Image dialog, choose TerraServer Server () in the Files of type box to launch the Link TerraServer Data dialog.

TerraServer images will be streamed from TerraServer as image "tiles" at the level of resolution required to construct the desired image. As we zoom into an image, Manifold will fetch more detailed tiles from TerraServer.

Manifold will cache image tiles streamed from an TerraServer server so that panning and zooming in the image can be as fast as possible. For example, when zooming into an TerraServer image Manifold will make use of less detailed image tiles that have already been fetched to quickly render the desired view as best as possible and then progressively update the display as more detailed tiles stream in.

Images linked from TerraServer are read-only images and cannot be re-projected. They can only participate in maps that use the same projection as the image, although they may be used in maps that have the same projection (coordinate system) except for the datum used. At any time, an image linked from TerraServer may be unlinked to create a local image that may be re-projected and otherwise altered as desired.
